The SDRAM controller contains a refresh function that periodically issues an AUTO-REFRESH command to both SDRAM banks. The period between the commands (in clock periods) is programmed in the refresh counter reload field in the MCFG3 register. Depending on SDRAM type, the required period is typically 7.8 or 15.6 μs (corresponding to 780 or 1560 clocks at 100 MHz). The generated refresh period is calculated as (reload value+1)/sysclk. The refresh function is enabled by setting bit 31 in MCFG2.

99.9.1 Self Refresh

The self refresh mode can be used to retain data in the SDRAM even when the rest of the system is powered down. When in the self refresh mode, the SDRAM retains data without external clocking and refresh are handled internally. The memory array that is refreshed during the self refresh operation is defined in the extended mode register. These settings can be changed by setting the PASR bits in the Power-Saving configuration register. The extended mode register is automatically updated when the PASR bits are changed. The supported "Partial Array Self Refresh" modes are: Full, Half, Quarter, Eighth, and Sixteenth array. "Partial Array Self Refresh" is only supported when mobile SDRAM functionality is enabled. To enable the self refresh mode, set the PMODE bits in the Power-Saving configuration register to "010" (Self Refresh). The controller will enter self refresh mode after every memory access (when the controller has been idle for 16 clock cycles), until the PMODE bits are cleared. When exiting this mode the controller introduce a delay defined by tXSR in the Power-Saving configuration register and a AUTO REFRESH command before any other memory access is allowed. The minimum duration of this mode is defined by tRAS. This mode is only available then the VHDL generic **mobile** >=1.

99.9.2 Power-Down

When entering the power-down mode all input and output buffers, excluding SDCKE, are deactivated. All data in the SDRAM is retained during this operation. To enable the power-down mode, set the PMODE bits in the Power-Saving configuration register to "001" (Power-Down). The controller will enter power-down mode after every memory access (when the controller has been idle for 16

clock cycles), until the PMODE bits is cleared. The REFRESH command will still be issued by the controller in this mode. When exiting this mode a delay of one clock cycles are added before issue any command to the memory. This mode is only available then the VHDL generic **mobile** >=1.

99.9.3 Deep Power-Down

The deep power-down operating mode is used to achieve maximum power reduction by eliminating the power of the memory array. Data will not be retained after the device enters deep power-down mode. To enable the deep power-down mode, set the PMODE bits in the Power-Saving configuration register to "101" (Deep Power-Down). To exit the deep power-down mode the PMODE bits in the Power-Saving configuration register must be cleared. The controller will respond with an AMBA ERROR response to an AMBA access, that will result in a memory access, during Deep Power-Down mode. This mode is only available then the VHDL generic **mobile** >=1 and mobile SDRAM functionality is enabled.

99.9.4 Temperature-Compensated Self Refresh

The settings for the temperature-compensation of the Self Refresh rate can be controlled by setting the TCSR bits in the Power-Saving configuration register. The extended mode register is automatically updated when the TCSR bits are changed. Note that some vendors implements a Internal Temperature-Compensated Self Refresh feature, which makes the memory to ignore the TCSR bits. This functionality is only available then the VHDL generic **mobile** >=1 and mobile SDRAM functionality is enabled.

99.9.5 Drive Strength

The drive strength of the output buffers can be controlled by setting the DS bits in the Power-Saving configuration register. The extended mode register is automatically updated when the DS bits are changed. The available options are: full, three-quarter, one-half, and one-quarter drive strengths. This functionality is only available then the VHDL generic **mobile** >=1 and mobile SDRAM functionality is enabled.

99.9.6 SDRAM commands

The controller can issue four SDRAM commands by writing to the SDRAM command field in MCFG2: PRE-CHARGE, AUTO-REFRESH, LOAD-MODE-REG (LMR) and LOAD-EXTMODE-REG (EMR). If the LMR command is issued, the CAS delay as programmed in MCFG2 will be used, remaining fields are fixed: page read burst, single location write, sequential burst. If the EMR command is issued, the DS, TCSR and PASR as programmed in Power-Saving configuration register will be used. To issue the EMR command, the EMR bit in the MCFG4 register has to be set. The command field will be cleared after a command has been executed. Note that when changing the value of the CAS delay, a LOAD-MODE-REGISTER command should be generated at the same time.

99.9.7 Read cycles

A read cycle is started by performing an ACTIVATE command to the desired bank and row, followed by a READ command after the programmed CAS delay. A read burst is performed if a burst access has been requested on the AHB bus. The read cycle is terminated with a PRE-CHARGE command, no banks are left open between two accesses.

99.9.8 Write cycles

Write cycles are performed similarly to read cycles, with the difference that WRITE commands are issued after activation. A write burst on the AHB bus will generate a burst of write commands without idle cycles in-between.

99.9.9 Address bus connection

The memory controller can be configured to either share the address and data buses with the SRAM, or to use separate address and data buses. When the buses are shared, the address bus of the SDRAMs should be connected to A[14:2], the bank address to A[16:15]. The MSB part of A[14:2] can be left unconnected if not used. When separate buses are used, the SDRAM address bus should be connected to SA[12:0] and the bank address to SA[14:13].

99.9.10 Data bus

SDRAM can be connected to the memory controller through the common or separate data bus. If the separate bus is used the width is configurable to 32 or 64 bits. 64-bit data bus allows the 64-bit SDRAM devices to be connected using the full data capacity of the devices. 64-bit SDRAM devices can be connected to 32-bit data bus if 64-bit data bus is not available but in this case only half the full data capacity will be used. There is a drive signal vector and separate data vector available for SDRAM. The drive vector has one drive signal for each data bit. These signals can be used to remove timing problems with the output delay when a separate SDRAM bus is used. SDRAM bus signals are described in section 99.14, for configuration options refer to section 99.16.2.

99.9.11 Clocking

The SDRAM clock typically requires special synchronisation at layout level. For Xilinx and Altera device, the GR Clock Generator can be configured to produce a properly synchronised SDRAM clock. For other FPGA targets, the GR Clock Generator can produce an inverted clock.

99.10 Using bus ready signaling

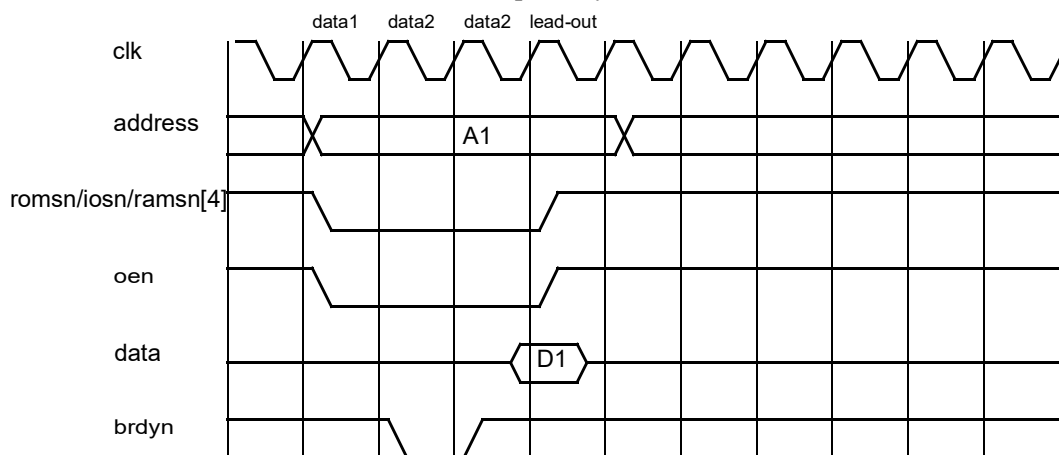
The MEMI.BRDYN signal can be used to stretch access cycles to the I/O area and the ram area decoded by MEMO.RAMSN[4]. The accesses will always have at least the pre-programmed number of waitstates as defined in memory configuration registers 1 & 2, but will be further stretched until MEMI.BRDYN is asserted. MEMI.BRDYN should be asserted in the cycle preceding the last one. The use of MEMI.BRDYN can be enabled separately for the I/O and RAM areas.


Figure 276. **READ cycle with one extra data2 cycle added with BRDYN (synchronous sampling). Lead-out cycle is only applicable for I/O accesses.**

+46 31 7758650 | frontgrade.com/gaisler
Figure 277. **Read cycle with one waitstate (configured) and one BRDYN generated waitstate (synchronous sampling).**

99.11 Access errors

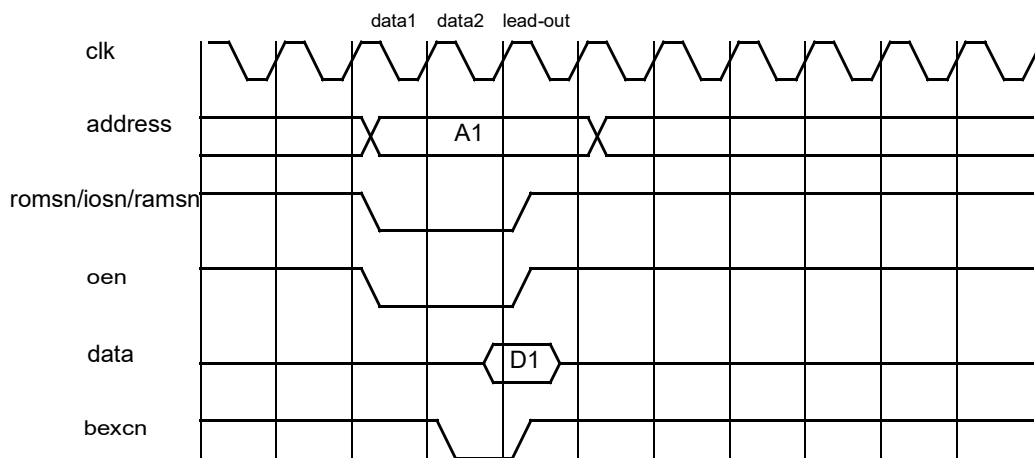
An access error can be signaled by asserting the MEMI.BEXCN signal, which is sampled together with the data. If the usage of MEMI.BEXCN is enabled in memory configuration register 1, an error response will be generated on the internal AMBA bus. MEMI.BEXCN can be enabled or disabled through memory configuration register 1, and is active for all areas (PROM, I/O an RAM).


Figure 278. **Read cycle with BEXCN.**

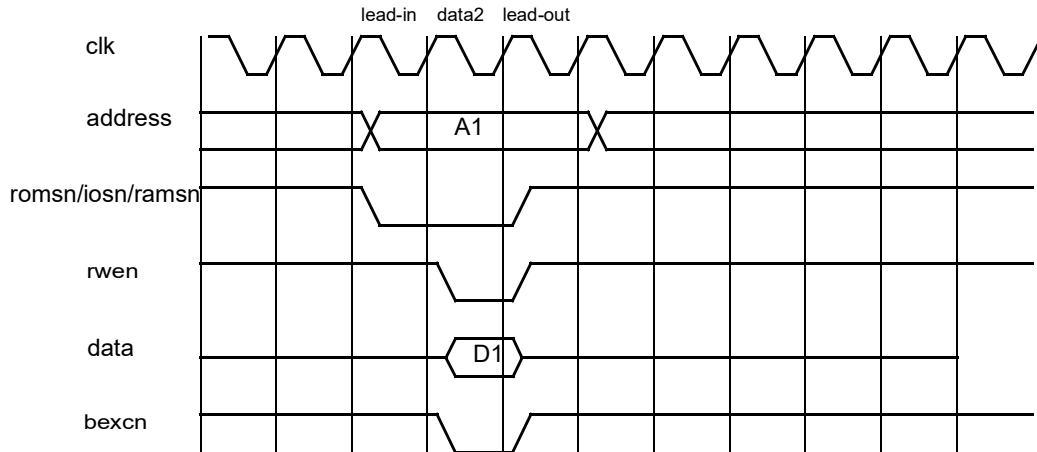
+46 31 7758650 | frontgrade.com/gaisler


Figure 279. **Write cycle with BEXCN. Chip-select (iosn) is not asserted in lead-in cycle for io-accesses.**

99.12 Attaching an external DRAM controller

To attach an external DRAM controller, MEMO.RAMSN[4] should be used since it allows the cycle time to vary through the use of MEMI.BRDYN. In this way, delays can be inserted as required for opening of banks and refresh.

99.13 Endianness

The core is designed for big-endian systems.

99.14 Registers

The memory controller is programmed through registers mapped into APB address space.

Table 2003. **Memory controller registers**

APB address offset	Register
0x0	MCFG1
0x4	MCFG2
0x8	MCFG3
0xC	MCFG4 (Power-Saving configuration register)

99.14.1 Memory configuration register 1 (MCFG1)

Memory configuration register 1 is used to program the timing of rom and local I/O accesses.

99.15 Vendor and device identifiers

The core has vendor identifier 0x04 (ESA) and device identifier 0x00F. For description of vendor and device identifier see GRLIB IP Library User's Manual.

99.16 Implementation

99.16.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers. See the documentation for the *syncrst* VHDL generic for information on asynchronous reset affecting external signals.

99.16.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

99.17 Configuration options

Table 2008 shows the configuration options of the core (VHDL generics).

Table 2008. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	1 - NAHBSLV-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
romaddr	ADDR field of the AHB BAR0 defining PROM address space. Default PROM area is 0x0 - 0x1FFFFFFF.	0 - 16#FFF#	16#000#
rommask	MASK field of the AHB BAR0 defining PROM address space.	0 - 16#FFF#	16#E00#
ioaddr	ADDR field of the AHB BAR1 defining I/O address space. Default I/O area is 0x20000000 - 0x2FFFFFFF.	0 - 16#FFF#	16#200#
iomask	MASK field of the AHB BAR1 defining I/O address space.	0 - 16#FFF#	16#E00#
ramaddr	ADDR field of the AHB BAR2 defining RAM address space. Default RAM area is 0x40000000-0x7FFFFFFF.	0 - 16#FFF#	16#400#
rammask	MASK field of the AHB BAR2 defining RAM address space.	0 -16#FFF#	16#C00#
paddr	ADDR field of the APB BAR configuration registers address space.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR configuration registers address space.	0 - 16#FFF#	16#FFF#
wprot	RAM write protection.	0 - 1	0
invclk	Inverted clock is used for the SDRAM.	0 - 1	0
fast	Enable fast SDRAM address decoding.	0 - 1	0
romasel	log2(PROM address space size) - 1. E.g. if size of the PROM area is 0x20000000 romasel is log2(2^29)-1 = 28.	0 - 31	28
sdrasel	log2(RAM address space size) - 1. E.g if size of the RAM address space is 0x40000000 sdrasel is log2(2^30)-1= 29.	0 - 31	29
srbanks	Number of SRAM banks.	0 - 5	4
ram8	Enable 8-bit PROM and SRAM access.	0 - 1	0
ram16	Enable 16-bit PROM and SRAM access.	0 - 1	0
sden	Enable SDRAM controller.	0 - 1	0
sepbus	SDRAM is located on separate bus.	0 - 1	1
sdbits	32 or 64 -bit SDRAM data bus.	32, 64	32
sdlsb	Can be used to shift address lines used for SDRAM. Leave at default value.	-	2
oepol	Select polarity of drive signals for data pads. 0 = active low, 1 = active high.	0 - 1	0
syncrst	When syncrst is set to 0 then the output registers of the core have asynchronous reset. When syncrst is set to 1 only synchronous reset is used within the core and the output signals are instead gated with the reset signal.	0 - 1	0
pageburst	Line burst read of length 8 when 0, page burst read when 1, programmable read burst type when 2.	0 - 2	0
scantest	Enable scan test support (connects test oen to output enables, handles asynchronous reset case).	0 - 1	0
mobile	Enable Mobile SDRAM support 0: Mobile SDRAM support disabled 1: Mobile SDRAM support enabled but not default 2: Mobile SDRAM support enabled by default 3: Mobile SDRAM support only (no regular SDR support)	0 - 3	0

ESA	MEMORYCTRL	Component	Memory controller component declaration

99.20 Instantiation

This example shows how the core can be instantiated.

The example design contains an AMBA bus with a number of AHB components connected to it including the memory controller. The external memory bus is defined on the example designs port map and connected to the memory controller. System clock and reset are generated by GR Clock Generator and Reset Generator.

Memory controller decodes default memory areas: PROM area is 0x0 - 0x1FFFFFFF, I/O-area is 0x20000000-0x3FFFFFFF and RAM area is 0x40000000 - 0x7FFFFFFF. SDRAM controller is enabled. SDRAM clock is synchronized with system clock by clock generator.

100   MEMSCRUB - AHB Memory Scrubber and Status Register

100.1   Overview

The memory scrubber monitors an AMBA AHB bus for accesses triggering an error response, and for correctable errors signaled from fault tolerant slaves on the bus. The core can be programmed to scrub a memory area by reading through the memory and writing back the contents using a locked read-write cycle whenever a correctable error is detected. It can also be programmed to initialize a memory area to known values.

The memory scrubber core is largely backwards compatible with the AHBSTAT core, and can replace it in many cases. Unlike AHBSTAT, the scrubber's registers are accessed through the AMBA AHB bus.
Figure 280. Memory scrubber block diagram

100.2   Operation

100.2.1 Errors

All AMBA AHB bus transactions are monitored and current HADDR, HWRITE, HMASTER and HSIZE values are stored internally. When an error response (HRESP = "01") is detected, an internal counter is increased. When the counter increments from "threshold" to "threshold+1" (where "threshold" is a user-programmable value), the status and address register contents are frozen and the New Error (NE) bit is set to one. At the same time an interrupt is generated, as described hereunder.

The default threshold is zero and enabled on reset so the first error on the bus will generate an interrupt.

Note that many of the fault tolerant units containing EDAC signal an uncorrectable error as an AMBA error response, so that it can be detected by the processor as described above.

100.2.2 Correctable errors

Not only error responses on the AHB bus can be detected. Many of the fault tolerant units containing EDAC have a correctable error signal which is asserted each time a correctable error is detected. When such an error is detected, the effect will be the same as for an AHB error response. The only difference is that the Correctable Error (CE) bit in the status register is set to one when a correctable error is detected. Correctable and uncorrectable errors use separate counters and threshold values.

GRIP

1721

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

When the CE bit is set, the interrupt routine can acquire the address containing the correctable error from the failing address register and correct it. When it is finished it resets the CE bit and the monitoring becomes active again. Interrupt handling is described in detail hereunder.

The correctable error signals from the fault tolerant units should be connected to the *scrubi.cerror* input signal vector of the AHB status register core, which is or-ed internally and if the resulting signal is asserted, it will have the same effect as an AHB error response.

100.2.3 Scrubbing

The memory scrubber can be commanded to scrub a certain memory area, by writing a start and end address to the scrubbers start/end registers, followed by writing "00" to the scrub mode field and '1' to the scrub enable bit in the scrubber control register.

After starting, the core will proceed to read the memory region in bursts. The burst size is fixed (set by the *burstlen* generic) and typically tuned to match the cache-line size or native block size of the slave. When a correctable error is detected, the scrubber performs a locked read-write cycle to correct the error, and then resumes the scrub operation.

If the correctable error is detected in the middle of a burst, the following read in the burst is completed before the read-write cycle begins. The core can handle the special case where that access also had a correctable error within the same locked scrub cycle.

If an uncorrectable error is detected, that location is left untouched.

Note that the status register functionality is running in parallel with the scrubber, so correctable and uncorrectable errors will be logged as usual. To prevent double logging, the core masks out the (expected) correctable error arising during the locked correction cycle.

To allow normal access to the bus, the core sleeps for a number of cycles between each burst. The number of cycles can be adjusted in the config register.

If the ID bit is set in the config register, the core will interrupt when the complete scrub is done.

100.2.4 Scrubber error counters

The core keeps track of the number of correctable errors detected during the current scrub run and the number of errors detected during processing of the current "count block". The size of the count block is a fixed power of two equal or larger than the burst length (set by the *countlen* generic).

The core can be set up to interrupt when the counters exceed given thresholds. When this happens, the NE bit, plus one of the SEC/SBC bits, is set in the status register. An interrupt will only be generated when a counter increments from "threshold" to "threshold+1". Additional increments when a counter is already larger than its threshold value will not generate interrupts.

100.2.5 External start and clear

If the ES bit is set in the config register, the scrub enable bit is set automatically when the start input signal goes high. This can be used to set up periodic scrubbing.

The external input signal clrerr can be used to clear the global error counters. If this is connected to a timer, it is possible to count errors that have occurred within a specific unit of time. This signal can be disabled through the EC bit in the config register.

100.2.6 Memory regeneration

The regeneration mode performs the same basic function as the scrub mode, but is optimised for the case where many (or all) locations have correctable errors.

In this mode, the whole memory area selected is scrubbed using locked read/write bursts.

GRIP
Apr 2024, Version 2024.1
1722
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

If an uncorrectable error is encountered during the read burst, that burst block is processed once again using the regular scrub routine, and the regeneration mode resumes on the following block. This avoids overwriting uncorrectable error locations.

100.2.7 Initialization

The scrubber can be used to write a pre-defined pattern to a block of memory. This is often necessary on EDAC memory before it can be used.

Before running the initialization, the pattern to be written to memory should be written into the scrubber initialization data register. The pattern has the same size as the burst length, so the corresponding number of writes to the initialization data register must be made.

100.2.8 Interrupts

The interrupt is generated on the line selected by the *hirq* VHDL generic. The interrupt is connected to the interrupt controller to inform the processor of the event.

After an interrupt is generated, either the NE bit or the DONE bit in the status register is set, to indicate which type of event caused the interrupt.

The normal procedure is that an interrupt routine handles the error with the aid of the information in the status registers. When it is finished it resets the NE bit and error counters in the AHB status register or the DONE bit in the scrubber status register, and the monitoring becomes active again. Error interrupts can be generated for both AMBA error responses and correctable errors as described above.

100.2.9 Mode switching

Switching between scrubbing and regeneration modes can be done on the fly during a scrub by modifying the MODE field in the scrubber configuration register. The mode change will take effect on the following scrub burst.

If the address range needs to be changed, then the core should be stopped before updating the registers. This is done by clearing the SCEN bit, and waiting for the ACTIVE bit in the status register to go low. An exception is when making the range larger (i.e. increasing the end address or decreasing the start address), as this can be done on the fly.

100.2.10 Dual range support

The scrubber can work over two non-overlapping memory ranges. This feature is enabled by writing the start/end addresses of the second range into the scrubber's second range start/end registers and setting the SERA bit in the configuration register. The two address ranges should not overlap.

100.5 Implementation

100.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

100.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

100.6 Configuration options

Table 2024 shows the configuration options of the core (VHDL generics).

Table 2024. Configuration options

Generic	Function	Allowed range	Default
hmindex	AHB master index	0 - NAHBMST-1	0
hsindex	AHB slave index	0 - NAHBSLV-1	0
ioaddr	AHB slave register area address	0 - 16#FFF#	0
iomask	AHB slave register area address mask	0 - 16#FFF#	16#FFF#

101   MMA - Memory Mapped AMBA bridge

101.1   Overview

The bridge acts as a slave on the memory bus and provides a master interface on the AMBA AHB bus. A read/write access issued towards the slave memory bus interface for the defined memory range is transferred to the AHB master interface and issued on the AMBA bus.

101.2   Operation

101.2.1 Read

Only 32-bit read accesses is allowed for the slave memory interface. When a read access is detected and decoded by the bridge, the bus ready signal is combinatorially deasserted. When corresponding AMBA access is done, the bus ready signal is asserted and the data is driven on the memory bus. When output enable / chip select signal is detected deasserted the data bus is tri-stated.

101.2.2 Write

Only 32-bit write accesses is allowed for the slave memory interface. When a write access is detected and decoded by the bridge, the bus ready signal is combinatorially deasserted. The bus ready signal is reasserted as soon as the write data is stored by the bridge. The bridge can store a write access when the last access has completed on the AMBA bus.

101.3   Default configuration

The default configuration is set by the defcfg signal. The configuration is arranged in the following order:

Table 2027.

101.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x07F. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

101.5 Implementation

101.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

GRIP
Apr 2024, Version 2024.1

1733

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

101.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

101.6   Configuration options

Table 2031 shows the configuration options of the core (VHDL generics).

Table 2031.Configuration options

Generic	Function	Allowed range	Default

```

102   MUL32 - Signed/unsigned 32x32 multiplier module

102.1   Overview

The multiplier module is highly configurable module implementing 32x32 bit multiplier. Multiplier takes two signed or unsigned numbers as input and produces 64-bit result. Multiplication latency and hardware complexity depend on multiplier configuration. Variety of configuration option makes it possible to configure the multiplier to meet wide range of requirements on complexity and performance.

For DSP applications the module can be configured to perform multiply & accumulate (MAC) operation. In this configuration 16x16 multiplication is performed and the 32-bit result is added to 40-bit value accumulator.

102.2   Operation

The multiplication is started when '1' is samples on MULI.START on positive clock edge. Operands are latched externally and provided on inputs MULI.OP1 and MULI.OP2 during the whole operation. The result appears on the outputs during the clock cycle following the clock cycle when MULO.READY is asserted if multiplier if 16x16, 32x8 or 32x16 configuration is used. For 32x32 configuration result appears on the output during the second clock cycle after the MULI.START was asserted.

Signal MULI.MAC shall be asserted to start multiply & accumulate (MAC) operation. This signal is latched on positive clock edge. Multiplication is performed between two 16-bit values on inputs MULI.OP1[15:0] and MULI.OP2[15:0]. The 32-bit result of the multiplication is added to the 40-bit accumulator value on signal MULI.ACC to form a 40-bit value on output MULO.RESULT[39:0]. The result of MAC operation appears during the second clock cycle after the MULI.MAC was asserted.

102.3   Implementation

102.3.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers if the GRLIB config package setting *grlib_async_reset_enable* is set.

102.3.2 Complexity

Table 2034 shows hardware complexity in ASIC gates and latency for different multiplier configurations.

Table 2034. Multiplier latencies and hardware complexity

Multiplier size (multype)	Pipelined (pipe)	Latency (clocks)	Approximate area (gates)
16x16	1	5	6 500
16x16	0	4	6 000
32x8	-	4	5 000
32x16	-	2	9 000
32x32	-	1	15 000

102.4 Configuration options

Table 2035 shows the configuration options of the core (VHDL generics).

*Table 2035.*Configuration options

Generic	Function	Allowed range	Default
tech	Multiplier technolofy selection. If set to 0 the multipliers will be inferred by the synthesis tool. Use this option if your synthesis tool i capable of inferring efficient multiplier implementation.	0 to NTECH-1	0
multype	Size of the multiplier that is actually implemented. All configuration produce 64-bit result with different latencies. 0 - 16x16 bit multiplier 1 - 32x8 bit multiplier 2 - 32x16 bit multiplier 3 - 32x32 bit multiplier	0 to 3	0
pipe	Used in 16x16 bit multiplier configuration. Adds a pipeline register stage to the multiplier. This option gives better timing but adds one clock cycle to latency.	0 to 1	0
mac	Enable multiply & accumulate operation. Use only with 16x16 multiplier option with no pipelining (*pipe* = 0)	0 to 1	0
arch	Multiplier structure 0: Inferred by synthesis tool 1: Generated using Module Generators from NTNU 2: Using technology specific netlists (techspec). Only supported for RTAX-D FPGAs. Other technologies will assert a simulation error. 3: Using Synopsys DesignWare (DW02_mult and DW_-mult_pipe)	0 to 3	0
scantest	Enable scan test support. Only required if GRLIB has been changed to use asynchronous reset.	0 - 1	0

103   MULTLIB - High-performance multipliers

103.1   Overview

The GRLIB.MULTLIB VHDL-library contains a collection of high-performance multipliers from the Arithmetic Module Generator at Norwegian University of Science and Technology. 32x32, 32x8, 32x16, 16x16 unsigned/signed multipliers are included. 16x16-bit multiplier can be configured to include a pipeline stage. This option improves timing but increases latency with one clock cycle.

103.2   Configuration options

Table 2038 shows the configuration options of the core (VHDL generics).

Table 2038. Configuration options

Generic	Function	Allowed range	Default
mulpipe	Include a pipeline stage (0 -pipelining disabled, 1 - pipelining enabled)	0 - 1	0

103.3   Signal descriptions

Table 2039 shows the interface signals of the core (VHDL ports).

Table 2039. Signal descriptions

Signal name	Type	Function	Active
CLK (16x16 multiplier only)	Input	Clock	-
HOLDN (16x16 multiplier only)	Input	Hold. When active, the pipeline register is not updates	Low
X[16:0] (16x16 mult) X[32:0] (32x8 mult) X[32:0] (32x16 mult) X[32:0] (32x32 mult)	Input	Operand 1. MBS bit is sign bit.	High
Y[16:0] (16x16 mult) Y[8:0] (32x8 mult) Y[16:0] (32x16 mult) Y[32:0] (32x32 mult)	Input	Operand 2. MSB bit is sign bit.	High
P[33:0] (16x16 mult) P[41:0] (32x8 mult) P[49:0] (32x16 mult) P[65:0] (32x32 mult)		Result. Two MSB bits are sign bits.	High

103.4   Library dependencies

103.5 Component declaration

The core has the following component declaration.

```
component mul_33_33
  port (
    x    : in  std_logic_vector(32 downto 0);
    y    : in  std_logic_vector(32 downto 0);
    p    : out std_logic_vector(65 downto 0)
  );
end component;
```

103.6 Implementation

103.6.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

103.7 Instantiation

This example shows how the core can be instantiated.

The core is configured to implement 16x16 pipelined multiplier with support for MAC operations.

```
library ieee;
use ieee.std_logic_1164.all;

library grlib;
use grlib.multlib.all;

.
.

signal op1, op2 : std_logic_vector(32 downto 0);
signal prod : std_logic_vector(65 downto 0);

104 NANDFCTRL - NAND Flash Memory Controller

104.1 Overview

The NAND Flash Memory Controller (NANDFCTRL) core provides a bridge between external NAND flash memory and the AMBA bus. The memory controller is an Open NAND Flash Interface (ONFI) 2.2 command compliant core (see exceptions below) and it can communicate with multiple parallel flash memory devices simultaneously, where each device in turn can consist of up to four individually addressable targets, one target addressed at a time. The core is configured through a set of AMBA APB registers, described in section 104.4, and data is written to / read from the flash memory by accessing internal buffers mapped over AMBA AHB.

This document mainly describes the NANDFCTRL core's functionality. For details about the actual flash memory interface, flash memory architecture and ONFI 2.2 command set please refer to the *Open NAND Flash Interface specification, revision 2.2*, hereafter called the ONFI 2.2 specification.
Note: One device might have more than one target, using one chip enable signal for each target.
This will reduce the number devices that can be placed horizontally in the figure.
All devices (and the internal targets) placed vertically in the figure belong to the same chip enable signal,
with individual write enable signals controlling each 8-bit/16-bit data lane.

Figure 281. Block diagram

104.2 Operation

104.2.1 System overview

A block diagram of the core can be seen in figure 281. Features and limitations of the core are listed below:

- All commands defined in the ONFI 2.2 standard are supported, except Synchronous Reset and Interleaved Read.

- The core does not implement support for the source synchronous data interface, only asynchronous data interface.

- The core does not place any other limitation on the device architecture other than those specified in the ONFI 2.2 standard. For example, the core does not need to know how many LUNs, blocks, or pages a connected flash memory device has. (See the ONFI 2.2 specification for information about LUNs, blocks, and pages.)

- Multiple parallel data lanes are supported, which gives the possibility to read / write several flash memory devices at the same time.

GRIP

- To support interleaving of flash memory accesses and AMBA accesses and give greater through-put, two buffers for reading / writing flash memory data are implemented.

- The data interface timing can either be fixed (set at implementation time) or programmable through AMBA APB registers. With fixed data interface timing support for ONFI timing modes 0 - 5 can be implemented and then switched between during run-time. Programmable timing interface allows for clock frequencies unknown at implementation time, as well as custom timing. It is highly recommended to use programmable timing as the additional delays (like I/O timings) might require custom timing options. Read section 104.5 (Timing Modes) for more information.

- The core does not implement any wear-leveling or bad block management.

- The core does not implement any direct access to flash memory devices from the AMBA AHB bus. Instead accesses are performed through two temporary buffers by initiating command and data transfers through control registers via the AMBA APB bus.

- The temporary buffers are mapped into AMBA AHB memory space. Note that the buffer addresses are not directly mapped to the flash memory, but are mapped specific addressing registers. This allows large amount of flash memory to be address, exceeding the 4 Gbyte address space of the AMBA bus.

104.2.2 Internal buffer structure

The number of buffers implemented in the core depends on whether or not the core is implemented with separate buffers for each parallel 8-bit/16-bit data lane or not. This is indicated by the *sepb* field in the *Capability register*. How many data lanes the core implements can be found by reading the *nlane* field of the *Capability register* and adding one. If separate buffers are used then for each data lane there are four different buffers implemented. Two buffers are used for data that are read from / written to any page area in the flash memory device (hereafter called *page buffer*), and the other two are used for data read from / written to any page's spare area (hereafter called *spare buffer*). The size of each page buffer (in bytes) is $2^{(pbits+1)}$, where pbits is the value of the *pbits* field in the *Capability register*. The size of each spare buffer (in bytes) is $2^{(sbits+1)}$, where sbits is the value of the *sbits* field in the *Capability register*. If separate buffers aren't used, then the core implements one set of the above mentioned four buffers and uses them for all data lanes.

One page buffer and one spare buffer for each data lane (or all lanes if separate buffers aren't used) are grouped together into what in this document is called *buffer 0*. The other set of page buffers and spare buffers are grouped into *buffer 1*. For example, if the core has support for eight data lanes with separate buffers, and the page buffers are 4096 bytes, and the spare buffers are 256 bytes, then buffer 0 and buffer 1 will each be 32768 + 2048 bytes large. Buffer 0 and buffer 1 are associated with their own set of control registers, described in section 104.4.

Note that support for buffer 1 is optional. Whether or not support for buffer 1 is implemented is indicated by the *b1en* bit in the *Capability register*.

All buffers are mapped into AMBA AHB address space, and the core supports two different mapping schemes, with their own designated AMBA AHB address space:

- For the first address map, called *Consecutive address map*, the first part of the assigned AHB memory area is mapped to the page buffer corresponding to the first 8-bit/16-bit data lane, followed by the page buffer corresponding to the second 8-bit/16-bit data lane etc. After all the page buffers the spare buffers follow in the same manner. See table 2041 for an example with 4096 bytes page buffer and 256 bytes spare buffer and table 2042 for an example with 2048 bytes page buffer and 128 bytes spare buffer.

- For the second address map, called *By page address map*, the first part of the assigned AHB memory area is mapped to the page buffer corresponding to the first 8-bit/16-bit data lane, followed by the spare buffer corresponding to the same data lane. After that follows the page buffer and spare buffer pairs for all other data lanes. Note that since the spare buffers normally are much

smaller than the page buffers there is normally a gap between the last address of a spare buffer and the first address of the next page buffer. The size of the gap is page buffer size - spare buffer size. See table 2043 for an example with 4096 bytes page buffer and 256 bytes spare buffer and see table 2044 for an example with 2048 bytes page buffer and 128 bytes spare buffer.

- See table 2045 for an example which illustrates both *Consecutive address map* and *page address map* for 8192 bytes page buffer and 2048 bytes spare buffer with two lanes, separate buffers and buffer 1 is not implemented.

Note that the page and spare buffer areas might be larger than the size of the page and spare memory implemented in the actual flash memory device. Thus, there might be gaps in the addressing schemes. If the EDAC is implemented (indicated by the *edac* bit in the *Capability register*) then the buffers have an additional AHB address map. Read and write accesses to the additional AHB address space will trigger EDAC operation. This additional address map is also shown in table 2041 and table 2042.

Table 2041. Buffer memory map, consecutive addressing. Example with 4096 B page size, 256 B spare size, separate buffers, both buffer 0 and buffer 1 implemented, and with EDAC.

104.2.3 Data interface timing

The ONFI timing parameters that the core explicitly handles are:

- tCCS - Change Column setup time
- tADL - ALE to data loading time
- tCS - CE setup time
- tRP - RE pulse width
- tREH - RE high hold time (starting from REV. 2)
- tRR - Ready to RE low (data only)
- tWP - WE pulse width
- tWB - WE high to SR[6] low
- tRHW - RE high to we WE low
- tWH - WE high hold time
- tWHR - WE high to RE low
- tWW - WP transition to WE low

All other timing requirements are either fulfilled through design, or are handled by the flash memory devices. See the ONFI specification for details about the different timing parameters.

The data interface timing can be either fixed (set at implementation time) or programmable to allow both system clock frequencies unknown at implementation time as well as custom timing parameters.

GRIP
Apr 2024, Version 2024.1

1747

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

When the timing is fixed all timing parameters are calculated on implementation time based on the specified system clock frequency. When programmable timing is used the timing parameters are programmed through AMBA APB registers, described in section 104.4. The registers power-up / reset values are set at implementation time.

Note that the timing parameter tCCS is always programmable, even if fixed timing is used for all other parameters. This is because the ONFI specification says that after initialization is complete, the value for tCCS specified in the flash memory's parameter page should be used.

104.2.4 Accessing the NAND flash memory devices

The steps that need to be taken to access (i.e. send an ONFI 2.2 command to) the flash memory devices are:

1. Make sure that the chosen buffer is not busy by checking the *run* and *bsy* bits in the *Buffer control / status* register. If both the *run* bit and *bsy* bits are set then the core is currently executing a command associated with that buffer, and the buffer can not be used. If only the *bsy* bit is set then the core is done executing a command but the corresponding data buffer and control bits are still write protected. Software then needs to clear the *bsy* bit by writing '1' to it.

2. If the command requires a row address to be sent, write it to the *Buffer row address register*. Otherwise this step can be skipped.

3. If the command requires a column address to be sent, write it to the *coladdr* field of the *Buffer column address register*. Bits 7:0 of the *coladdr* field also need to be written with the one byte address used for SET FEATURES, GET FEATURES, READ ID, READ UNIQUE ID, and READ PARAMETER PAGE commands. Otherwise this step can be skipped.

4. Write the command value to the *Buffer command register*, and possibly set the control bits *sel*, *cd*, or *sc2* if needed. See table 2053 in section 104.4 for a description of these bits.

5. If the command should include a data phase then set the size of the data by writing to the *size* field of the *Buffer column address register*. This step is not necessary for the SET FEATURES, GET FEATURES, READ STATUS, and READ STATUS ENHANCED commands since they always have a fixed size data phase.

6. If data should be written to the flash memory devices then write this data to the corresponding buffers. Note that the core uses the *coladdr* field in the *Buffer column address register* to index into the buffers, which means that data that should be written with an offset into a flash memory page (i.e. column address is not zero) need to be written with the same offset into the buffers. The exception is the commands mentioned in step 3. They always read from the beginning of the buffers. This step can be skipped if no data are to be written.

7. Select which data lanes and targets the command should be sent to, if an interrupt should be generated when the command is finished, and start execution by writing to the *lanesel*, *targsel*, *irqmsk*, and *exe* bits in the *Buffer control / status register*. See table 2054 in section 104.4 for a description of these bits.

Once command execution has been started software can monitor the *run* bit in the *Buffer control / status register* (or wait for an interrupt if the core was configured to generate one) to learn when the command is finished. If data was read from the flash memory then it can be found in the buffers. Note that the core uses the *coladdr* field in the *Buffer column address register* to index into the buffers, which means that data that was read from a flash memory page with an offset (i.e. column address is not zero) was written into the buffers with the same offset. The exception are the commands mentioned in step 3. They always place their data in the beginning of the buffers.

104.2.5 Endianness

The core supports both little-endian and big-endian systems. The endianess can be configured using the settings in the GRLIB configuration package (see GRLIB User's Manual). Maximum 32-bit wide

GRIP

+46 31 7758650 | frontgrade.com/gaisler

accesses are supported when configured as little-endian. Only 32-bit wide accesses are supported when configured as big-endian.

104.3 EDAC

104.3.1 EDAC operation

The optional NAND Flash Memory controller EDAC automatically encode and decode data being stored in the NAND Flash memory with an error correcting code. The *edac* bit in the *Capability* register shows if the EDAC is implemented or not. If implemented, the EDAC is enabled by setting the *edacen* bit in the *Core control* register. Optional AHB error responses can be generated upon an uncorrectable error by setting the *ahberren* bit in the same register. See section 104.4 for more information.

The checksum of the code is calculated and stored for each word that is written, via the AMBA interface, into the page data part of the buffer, and automatically stored in parallel in the spare data part of the buffer. For each word of data written, one byte is stored. Note that data must be written into the EDAC part of the AHB address space. Data written to the non EDAC part of the address space does not trigger EDAC operation. See section 104.2.2 for information about the buffer memory map. Halfword and byte writes are not supported when the EDAC is enabled.

Since the number of spare bytes normally is less than what is sufficient to protect the full page data, the page data size is limited by the programmable *lpaddr* field in the *Core control* register. The *lpaddr* field defines how much user data (i.e. page data) is to be used, with the remaining part of the page data and spare data being used for checksums. Note that the spare data buffer portion is therefore made bigger than the actual spare data in the NAND Flash memory. When the NAND Flash memory is written, the data will be fetched first from the page data buffer up to *lpaddr*, and then the rest will be fetched from the spare data buffer. Errors can be detected in the underlying buffer memory when reading them as part of the write operation to the NAND Flash memory.

The reverse applies to when data is fetched from the NAND Flash memory during read. When the buffer contents are read out, via the AMBA interface, each read page data word is automatically corrected using the corresponding spare buffer checksum byte. Two levels of errors can occur, errors stemming from the underlying buffer memory protection, or errors stemming from the EDAC protecting the NAND Flash memory contents. All error flags are described in the *Core status* register.

It is possible to write or read additional dummy words to the page data buffer past the LPADDR address. This can be used to handle any surplus spare data bytes.

The memory contents are protected by means of a Bose Chaudhuri Hocquenghem (BCH) type of code. It is a Quad Error Correction/Quad Error Detection (QEC/QED) code.

The data symbols are 4-bit wide, represented as GF(2^4). The has the capability to detect and correct a single symbol error anywhere in the codeword.

104.3.2 Code

The code has the following definition:

- there are 4 bits per symbol; most significant has index 3 (to the left), least significant has index 0
- there are 17 symbols per codeword, of which 2 symbols represent the checksum;
- the code is systematic;
- the code can correct one symbol error per codeword;
- the field polynomial is

$$f(x) = x^4 + x + 1$$

- all multiplications are performed as Galois Field multiplications over the above field polynomial

GRIP
Apr 2024, Version 2024.1

1749

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- all additions/subtractions are performed as Galois Field additions (i.e. bitwise exclusive-or)

Note that only 8 of the 17 symbols are used for data, 2 symbols are used for the checksum, and the reset are not used, the code is thus shortened by 7 symbols.

104.3.3 Encoding

- a codeword is defined as 17 symbols:

  $[c_0, c_1, c_2, c_3, c_4, c_5, c_6, c_7, c_8, c_9, c_{10}, c_{11}, c_{12}, c_{13}, c_{14}, c_{15}, c_{16}]$

  where c_0 to c_{14} represent information symbols and c_{15} to c_{16} represent check symbols.

- c_{15} is calculated as follows

$$c_{15} = \sum_{0}^{14} (k_i \times c_i)$$

- c_{16} is calculated as follows

$$c_{16} = \sum_{0}^{14} c_i$$

- where the constant vector k is defined as:

  k_0=0xF, k_1=0xE, .., k_{14}=0x1 (one can assume k_{15}=0x1 and k_{16}=0x1 for correction purposes)

- bit 1 of c_{15}, and bits 3 and 1 of c_{16} are inverted after encoded

104.3.4 Decoding

- the corrupt codeword is defined as 17 symbols:

  $[r_0, r_1, r_2, r_3, r_4, r_5, r_6, r_7, r_8, r_9, r_{10}, r_{11}, r_{12}, r_{13}, r_{14}, r_{15}, r_{16}]$

- the corrupt codeword can also be defined as 17 uncorrupt symbols and an error:

  $[c_0, c_1, c_2, c_3, c_4, c_5, c_6, c_7, c_8, c_9, c_{10}, c_{11}, c_{12}, c_{13}, c_{14}, c_{15}, c_{16}] + [e_x]$

  where the error is defined as e_x, e being the unknown magnitude and
  x being the unknown index position in the codeword

- recalculated checksum rc_0 is calculated as follows (k_i is as defined above, x being the unknown index)

- recalculated rc_1 is calculated as follows

- syndrome s_0 is calculated as follows

- syndrome s_1 is calculated as follows, which gives the magnitude (not applicable to c_{15} and c_{16})

GRIP
Apr 2024, Version 2024.1
1750
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

$$rc_0 = \sum_0^{14}(k_i \times r_i) = \sum_0^{14}(k_i \times c_i) + (k_x \times e_x)$$

$$rc_1 = \sum_0^{14} r_i = \sum_0^{14} c_i + e_x$$

$$s_0 = rc_0 + r_{15} = \sum_0^{14}(k_i \times r_i) + \sum_0^{14}(k_i \times c_i) = k_x \times e_x$$

$$s_1 = rc_1 + r_{16} = \sum_0^{14} r_i + \sum_0^{14} c_i = e_x$$

- in case s_0 and s_1 are both non-zero, to located the error in range c_0 to c_{14}, multiply error magnitude e_x with each element of the constant vector defined above:

$$k_i e_x = k_i \times s_1 = k_i \times e_x \qquad i = [0,14]$$

- search the resulting vector to find the element matching syndrome s_0, the resulting index i points to the error location (applicable only to i in [0, 14])

$$k_i e_x \Leftrightarrow k_i \times e_x$$

- finally perform the correction (applicable only to i in [0, 14])

$$c_i = r_i - s_1 = r_i - e_x = (c_i - e_x) \times e_x = c_i - e_x + e_x = c_i$$

- when s_0 is zero and s_1 is non-zero, the error is located in checksum r_{15}, no correction is necessary

- when s_1 is zero and s_0 is non-zero, the error is located in checksum r_{16}, no correction is necessary

- when s_0 and s_1 are both zero, no error has been detected, no correction is necessary

- bit 1 of r_{15}, and bits 3 and 1 of r_{16} are inverted before decoded

104.3.5 EDAC Handling

EDAC handling on NANDFCTRL is based on hardware/software co-design. There is no auto-write or auto-read of EDAC bytes. The software has to ensure that EDAC bytes are writen or read from the NAND device.

For example lets assume lpaddr is set to 1023 meaning the data that is going to be protected is 1024 bytes and total EDAC size is 256 bytes. In this case, if the full protected page data is going to be writen or read the size of operation should be set to 1024+256=1280 bytes. The lpaddr will ensure that edac bits are written to or read from spare buffer. If the operation is done on a size which is smaller than the page then the EDAC has to be read/write with the correct offset with a second operation. For example if bytes 4-8 needs to be written, after writing 4 bytes from column address 4 another operation needs to be done for 1 byte from column address 1024+(4/4)=1025 this will ensure that the byte which protects the word between byte 4-8 is written to NAND device. Same applies for read operation. The second EDAC operation can be done simply with the command change column.

104.4 Registers

The core is programmed through registers mapped into APB address space. Vendor and device identifier

*Table 2046.*NANDFCTRL registers

APB address offset	Register
0x00	Core control register
0x04	Core status register
0x08	Interrupt pending register
0x0C	Capability register
0x10	Buffer 0 row address register
0x14	Buffer 0 column address register
0x18	Buffer 0 command register
0x1C	Buffer 0 control / status register
0x20*	Buffer 1 row address register
0x24*	Buffer 1 column address register
0x28*	Buffer 1 command register
0x2C*	Buffer 1 control / status register
0x30	Programmable timing register 0

Table 2047.0x00 - CTRL - Core control register

31															16
LPADDR															
0xFFFF															
rw															

15		13	12	11	10	9	8	7	6	5	4	3	2	1	0
R			DW	CMDO	R	AHBERREN	EDACEN	R	EDO	ABORT	TMODE			WP	RST
0			0	*	0	0	0	0	0	0	0			1	0
r			rw*	rw	r	rw	rw*	r	rw*	rw*	rw*			rw	rw

31:16　　　Last page address (LPADDR) - This field should be set to the last addressable byte in a flash memory page, not including the spare area. The core uses these bits to know when to switch to the internal buffers for the page's spare area. For example: If the flash memory devices have a page size of 4096 bytes (and an arbitrary sized spare area for each page) this field should be set to 0xFFF (= 4095). The actual number of bits used for this field depends on the size of the implemented buffers. The number of bits can be found by reading the *pbits* field of the *Capability register* and adding one. Reset value: 0xF..F

15:13　　　Reserved (R) - Always reads zero.

12　　　Data width (DW) - Sets the default data lane width. 0 = Core uses 8-bit data lanes. 1 = Core uses 16-bit data lanes. This can be overridden for individual commands by setting the *dwo* bit in the *Buffer command* register. This bit is only available if the *dw16* bit in the *Capability register* is 1. Reset value 0.

11　　　Command bit order (CMDO) - When this bit is set to 0 the ONFI command bytes are mapped to the core's data lane(s) as follows: Cmd bit 0 -> Data lane bit 7, Cmd bit 1 -> Data lane bit 6., and so on.

　　　When this bit is set to 1 the commands are mapped as follows: Cmd bit 0 -> Data lane bit 0, Cmd bit 1 -> Data lane bit 1, and so on. Reset value equals the value of the *cmdo* bit in the *Capability register*.

10　　　Reserved (R) - Always reads zero.

9　　　AHB error response generation (AHBERREN) - If this bit is set then the core will generate an AMBA error response if the EDAC detects an uncorrectable error, or if the fault tolerance logic for the internal buffers report and uncorrectable error, upon and AHB read. If this bit is not set when an uncorrectable error is detected, the core's output signal *error* is set high for one clock cycle instead. This bit is only present when the EDAC is implemented or when the internal buffers are implemented with either byte parity and DMR or only byte parity. The *ft* bits in the *Capability register* shows which fault tolerance that is implemented, and the *edac* bit in the *Capability register* shows if EDAC is implemented. Reset value 0.

8　　　EDAC enable (EDACEN) - When this bit is set the EDAC is enabled. This bit is only present when the EDAC is implemented. The *edac* bit in the *Capability register* shows if EDAC is implemented or not. Reset value 0.

7　　　Reserved (R) - Always reads zero.

6　　　EDO data output (EDO) - If programmable timing is implemented (indicated by the *prgt* field in the *Capability register*) then this bit should be set if EDO data output cycles should be used. See ONFI 2.2 Specification for more information. If programmable timing is not implemented then this bit is read-only. When programmable timing is not implemented the EDO is only enabled when timing mode 5 is selected and tm5_edoen generic is set to 1.

5　　　Command abort (ABORT) - This bit can be set to 1 to abort a command that for some reason has put the core in a dead lock waiting for the *rb* input signal to go high. This could happen for example if a program or erase command was issued while the memory was in write protect mode. This bit is automatically cleared by the core. Reset value 0. Only available if the *rev* field in the *Capability register* > 0, otherwise always 0.

4:2　　　Timing mode (TMODE) - If programmable timing is not implemented (indicated by the *prgt* field in the *Capability register*) then writing this field changes the core's internal timing mode. See ONFI 2.2 Specification for more information on the different timing modes. Note that in order to change timing mode on the flash memory devices a SET FEATURES command needs to be issued. This is not done automatically when writing these bits. Timing mode 0 i always supported. Additional supported timing modes is indicated by the *tm[5:1]* bits in the *Capability register*. Should not be written while a command is in progress. Note that if this field is written with a value matching a timing mode that is not supported, then the core will operate in timing mode 0 (even though this field still changes to the invalid value). If programmable timing is implemented then this field is not present. Reset value: 0b000

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Table 2047.0x00 - CTRL - Core control register

1	Write protect (WP) - When this bit is set to 1 the core puts the flash memory devices in write protect mode by asserting the *wp* signal. In write protect mode, the memories won't respond to PROGRAM or ERASE commands. If the core is active when software writes this bit there is a delay before the actual write protect signal goes low. Software can use the *wp* field in the *Core status register* to see when the signal has changed value. Reset value: 1
0	Software reset (RST) - If software writes this bit to 1 the core is reset, and a RESET (0xFF) command is issued to all targets on all attached flash memory devices. The only difference between a software reset and a hardware reset / power up is that the core does not reset it's *tmode* field (described above) nor the *Programmable timing registers* during software reset. The reason for this is that the flash memory devices does not change timing mode after receiving a RESET command. This bit is cleared automatically. Reset value: 0

Table 2048.0x04 - STAT - Core status register (read only)

31				24	23	22	21	20	19	18	17	16
		R			FTNERRFLAGS		R		FTAERRFLAGS		R	
		0			0		0		0		0	
		r			wc*		r		wc*		r	

15		12	11		9	8			4	3	2	1	0
EERRFLAGS			R			STATE				R		WP	RDY
0			0			0				0		1	0
wc*			r			r				r		r	r

31:24	Reserved (R) - Always reads zero.
23:22	Fault tolerance error flags on NAND side (FTNERRFLAGS) - The bits in this field indicates the following errors:
	Bit 22: Uncorrectable error in buffer 0.
	Bit 23: Uncorrectable error in buffer 1.
	If the fault tolerance logic for the internal buffers indicates an error when the buffers are read during a NAND flash write operation the corresponding error flag in this register is set. These bits can be cleared by writing a 1 to them. The error flag for each buffer is also automatically cleared when an AHB write access occurs to that buffer (independent of address). These bits are only present when the internal buffers are implemented with either byte parity and DMR or only byte parity. The *ft* bits in the *Capability register* shows which fault tolerance that is implemented. Reset value 0.
21:20	Reserved (R) - Always reads zero.
19:18	Fault tolerance error flags on AHB side (FTAERRFLAGS) - The bits in this field indicates the following errors:
	Bit 18: Uncorrectable error in buffer 0.
	Bit 19: Uncorrectable error in buffer 1.
	If the fault tolerance logic for the internal buffers indicates an error when the buffers are read over AHB the corresponding error flag in this register is set. These bits can be cleared by writing a 1 to them. The error flag for each buffer is also automatically cleared when an AHB read access occurs to that buffer with an address which is at offset 0 in the page data buffer for any data lane. For example, if the core is configured with four data lanes and 4096 byte large page buffers, then an AHB read access with offsets 0x0000, 0x1000, 0x2000, and 0x3000 (with consecutive address scheme) would reset the error flag for buffer 0. These bits are only present when the internal buffers are implemented with either byte parity and DMR or only byte parity. The *ft* bits in the *Capability register* shows which fault tolerance that is implemented.
	When these bits get set then the core's output signal *err* is also set high for one clock cycle, if the *ahberren* bit in the *Core control* register is not set.
	Reset value 0.
17:16	Reserved (R) - Always reads zero.

*Table 2048.*0x04 - STAT - Core status register (read only)

15:12	EDAC error flags (EERRFLAGS) - The different bits indicate the following errors:
	Bit 12: Correctable error in buffer 0.
	Bit 13: Correctable error in buffer 1.
	Bit14: Uncorrectable error in buffer 0.
	Bit 15: Uncorrectable error in buffer 1.
	If the EDAC detects an error while an internal buffer is being read over AHB the corresponding error flag in this register is set. These bits can be cleared by writing a 1 to them. The error flags for each buffer are also automatically cleared when an AHB read access occurs to that buffer with an address which is at offset 0 in the page data buffer for any data lane. For example, if the core is configured with four data lanes and 4096 byte large page buffers, then an AHB read access with offsets 0x0000, 0x1000, 0x2000, and 0x3000 (with the consecutive address scheme) would reset the error flag for buffer 0. These bits are only present when the EDAC is implemented. The *edac* bit in the *Capability register* shows if EDAC is implemented or not.
	When the correctable error status bits get set then the core's output signal *err* is also set high for one clock cycle. The *err* output is also set for one cycle if the error flags for uncorrectable errors get set and the *ahberren* bit in the *Core control* register is not set.
	Reset value 0x0.
11:9	Reserved (R) - Always reads zero.
8:4	Core state - Shows the core's internal state. Implemented for debugging purposes. 0 = reset, 1-2 = idle, 3-8 = command state, 9-11 = address state, 12-15 = data in state, 16-18 = data out state, 19-31 = unused.
3:2	Reserved (R) - Always reads zero.
1	Write protect (WP) - Shows if the flash memory devices are in write protect mode or not. 0 = Not in write protect mode. 1 = In write protect mode. Reset value: 1
0	Core ready (RDY) - After a power up / reset this bit will be cleared. Once the core is done with it's reset procedure (waiting for ready signal from all flash memory devices and issuing a RESET command) this bit is set to 1. Reset value: 0

*Table 2049.*0x08 - IPEND - Interrupt pending register

31		2	1	0
R			B1IRQ	B0IRQ
0			0	0
r			wc	wc

31:2	Reserved (R) - Always reads zero.
1	Buffer 1 interrupt (B1IRQ) - This bit is set to one when an interrupt linked to buffer 1 is generated. Software can clear this bit by writing 1 to it. Only present if the *b1en* bit in the *Capability register* indicates that buffer 1 is implemented. Reset value: 0
0	Buffer 0 interrupt (B0IRQ) - This bit is set to one when an interrupt linked to buffer 0 is generated. Software can clear this bit by writing 1 to it. Reset value: 0

*		0	*	*	*	*		0	*	*	*	'	
r		r	r	r	r	r		r	r	r	r	r	

31:28 Revision (REV) - Indicates the revision of the core.

27 Reserved (R) - Always reads zero.

26 Programmable timing (PRGT) - 0 = Data interface timing is set at implementation time and not programmable. 1 = Data interface timing is programmable (only reset values are set at implementation time). Reflects value of VHDL generic *progtime*.

25 Separate buffers (SEPB) - Indicates if the buffers for the data lanes are shared or separate. 0 = All data lanes share buffers. 1 = All data lanes have their own buffers. When 0 a command with a data in phase should only be issued to one target and lane. A command with a data out phase can still be issued to several lanes but with the limitation that the same data will be sent to all lanes. When set to 1 several lanes can be read at the same time, and lanes can be written with individual data simultaneously. Reflects value of VHDL generic *sepbufs*.

24 Command bit order (CMDO) - Indicates the reset value for the *cmdo* bit in the *Core control register*. Reflects value of VHDL generic *cmdorder*.

23:22 Fault tolerant buffers (FT) - These bits indicate if the internal buffers in the core is implemented with fault tolerance. 0b00 = no fault tolerance, 0b01 = Byte parity DMR, 0b10 = TMR, 0b11 = Byte parity, no DMR. Reflects value of VHDL generic *ft*.

21 Reserved (R) - Always reads zero.

20 Buffer 1 enabled (B1EN) - If this bit is 1 then the core implements both buffer 0 and buffer 1, otherwise only buffer 0 is implemented. See section 104.2.2 for more information about the buffer structure. Reflects value of VHDL generic *b1en*.

19 EDAC support (EDAC) - If this bit is 1 then the core implements error detection and correction on data read from the NAND flash memory. See section 104.3 for details. Reflects value of VHDL generic *edac*.

18 16-bit memory support (DW16) - If this bit is 0 the core only support 8-bit memories. If this bit is 1 the core support both 8-bit and 16-bit memories. Only available if the *rev* field > 0, otherwise always 0. Reflects value of VHDL generic *dwidth16*.

17:14 Spare area buffer address bits (SBITS) - This field indicates how many address bits that are implemented for the buffers for the pages spare area. Add one to the value of this field to get the number of bits. The size of the buffers are $2^{(SBITS+1)}$ Reflects value of VHDL generic *sbufsize*.

13:10 Page buffer address bits (PBITS) - This field indicated how many address bits that are implemented for the page buffers. Add one to the value of this field to get the number of bits. The size (in bytes) of the buffers are $2^{(PBITS+1)}$ Reflects value of VHDL generic *pbufsize*.

9 Timing mode 5 support (TM5) - If the core does not support programmable timing (indicated by *prgt* bit described above) then this bit is 1 if the core supports timing mode 5. If programmable timing is implemented, or if the core does not support timing mode 5 then this bit is 0. Reflects value of VHDL generic *tm5*.

8 Timing mode 4 support (TM4) - If the core does not support programmable timing (indicated by *prgt* bit described above) then this bit is 1 if the core supports timing mode 4. If programmable timing is implemented, or if the core does not support timing mode 4then this bit is 0. Reflects value of VHDL generic *tm4*.

7 Timing mode 3 support (TM3) - If the core does not support programmable timing (indicated by *prgt* bit described above) then this bit is 1 if the core supports timing mode 3. If programmable timing is implemented, or if the core does not support timing mode 3then this bit is 0. Reflects value of VHDL generic *tm3*.

*Table 2050.*0x0C - CAP - Capability register (read only)

6	Timing mode 2 support (TM2) - If the core does not support programmable timing (indicated by *prgt* bit described above) then this bit is 1 if the core supports timing mode 2. If programmable timing is implemented, or if the core does not support timing mode 2then this bit is 0. Reflects value of VHDL generic *tm2*.
5	Timing mode 1 support (TM1) - If the core does not support programmable timing (indicated by *prgt* bit described above) then this bit is 1 if the core supports timing mode 1. If programmable timing is implemented, or if the core does not support timing mode 1 then this bit is 0. Reflects value of VHDL generic *tm1*.
4:2	Number of flash memory devices (NLANES) - This field indicates how many 8-bit/16-bit data lanes (minus one) the core can access, i.e. number of write enable signals. A write enable signal can be connected to one or more targets (i.e. one or more flash memory devices). Reflects value of VHDL generic *nlanes*.
1:0	Number of targets per device (NTARGS) - This field indicates how many individual targets (minus one) the core can access, i.e. number of chip enable signals. A flash memory device can have one or more targets, each with an individual chip enable signal. Reflects value of VHDL generic *ntargets*.
	Starting from Revision 3, core can support up to 32 number of targets. Since this field can only encode up to four targets, if the number of targets is higher than four this field will show four. In order to get correct number of targets when the number of targets is higher than four the extended capability register with offset 0x40 must be used.

*Table 2051.*0x10,0x20 - ROW - Buffer row address register

31	24	23	0
R		ROWADDR	
0		NR	
r		rw*	

31:24	Reserved (R) - Always reads zero.
23:0	Row address (ROWADDR) - This field sets the three byte row address, which is used to address LUNs, blocks and pages. As described in the ONFI 2.2 specification the least significant part of the row address is the page address, the middle part block address, and the most significant part is the LUN address. Exactly how many bits that are used for each part of the address depends on the architecture of the flash memory. Software needs to write this field prior to issuing any command that has an address phase that includes the row address. The core ignores this field if the command doesn't use the row address. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

*Table 2052.*0x14,0x24 - COL - Buffer column address register

31	16	15	0
SIZE		COLADDR	
NR		NR	
rw*		rw*	

31:16	Command data size (SIZE) - If a command has a data out or data in phase then software needs to set this field to the size of the data that should be read / written. Software does not need to set this field for the commands SET FEATURES, GET FEATURES, READ STATUS, or READ STATUS ENHANCED their data phases are always the same size. The core also ignores this field if the command issued doesn't have a data phase, as for example BLOCK ERASE. The actual number of bits used for this field depends on the size of the implemented buffers. The number of bits can be found by reading the *pbits* field of the *Capability register* and adding one. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.
15:0	Column address (COLADDR) - This field sets the two byte column address, which is used to address into a flash memory page. See the ONFI 2.2 specification for more information about column address. Software needs to write this field for those commands that have an address phase that includes the column address, as well as for those special commands that only have a one byte address phase (SET FEATURES; GET FEATURES; READ ID, READ UNIQUE ID, and READ PARAMETER PAGE). The core uses this field as an offset into the buffers when reading / writing data. The exception is the one byte address commands mentioned above, which always store their data in the beginning of the buffers. This field is ignored by the core if the command only uses the row address. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

*Table 2053.*0x18, 0x28 - CMD - Buffer command register

31	21	20	19	18	17	16	15	8	7	0
RESERVED		DWO	R	SEL	SC2	CD	CMD2		CMD1	
0		0	0	NR	NR	NR	NR		NR	
r		rw*	r	rw*	rw*	rw*	rw*		rw*	

31:21 Reserved (R) - Always reads zero.

20 Data width override (DWO) - Set this bit to 1 to override the *dw* bit in the *Core control register* for the current command. If this bit is 0, then the *dw* bit in the *Core control register* decides whether to use an 8-bit or 16-bit data lane for the current command. This bit is only available if the *dw16* bit in the *Capability register* is 1. Reset value 0.

19 Reserved (R) - Always reads zero.

18 Command select (SEL) - This bit is used to select between commands that have the same opcode in the first command cycle. This applies to the CHANGE WRITE COLUMN and COPYBACK PROGRAM commands, which both have a first command byte with the value of 0x85. If a COPYBACK PROGRAM is to be executed, this bit should be set to 0. If a CHANGE WRITE COLUMM command is to be executed, this bit should be set to 1. If the *rev* field in the *Capability register* > 0 then this bit is also used to select between a PAGE PROGRAM and a SMALL DATA MOVE (with opcode 0x80). If the SMALL DATA MOVE should be executed then this bit should be set to 1, otherwise it should be set to 0. The core ignores this bit for all other commands. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

17 Skip second command phase (SC2) - If this bit is set and a program command (PAGE PROGRAM, COPYBACK PROGRAM, or CHANGE WRITE COLUMN) is being executed the core skips the second command phase for that command and jumps back to idle state once all data has been written. This is done in order to support the CHANGE WRITE COLUMN command, which needs to be executed in between the first and second phase of the program command. If a CHANGE WRITE COLUMN command is required during a PAGE PROGRAM, the PAGE PROGRAM command is issued with SC2 set to 1. After that when issuing a CHANGE WRITE COLUMN command if more than one CHANGE WRITE COLUMN commands needs to be issued all the ones apart from the last one is issued with SC" set to 0. The last CHANGE WRITE COLUMN command is issued with SC2 set to '1' this way the PAGE PROGRAM command is ended. See the ONFI 2.2 specification for details on the CHANGE WRITE COLUMN command.

   *Starting from revision 4 of the core it is possible to use skip command phase if both CMD1 and CMD2 is set to READ ("00"). In this case the core will issue a single READ ("00") command. This can be used to generate the first "00" command for a two-plane read which exists in some of the NAND devices.

   This bit is ignored by the core for all other commands. . This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

16 Common data (CD) - Sometimes, for example for the SET FEATURES command, it is desirable to send the same data on all data lanes. If this is the case, software can write the data to send in the buffer corresponding to the first data lane and then set to this bit to 1. When the core executes the command it will then send the same data on all lanes without the need for software to fill all the corresponding buffers. Needs to be set to 0 if individual data should be send to the devices. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

15:8 Second command phase (CMD2) - If the command to execute is a two byte (two phase) command then software should write the second byte of the command to this field. The core ignores this field for commands that only have one command phase. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

7:0 First command phase (CMD1) - Software should write this field with the first byte of the command to execute. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

*Table 2054.*0x1C,0x2C - BCS - Buffer control / status register

31 27	26	25	24	23 16	15 8	7 4	3 2	1	0
R	INV	BSY	RUN	R	LANESEL	TARGSEL[3:0]	R	IRQM	EXE
0	0	0	0	0	NR	NR	0	1	0
r	rw	wc	r	r	rw*	rw*	r	rw*	rw*

31:27   Reserved (R) - Always reads zero.

26   Invalid command (INV) - This bit is set to one if an invalid command is written to the *Buffer command register* when the *exe* bit is written. This bit is cleared automatically once a new command is started. Reset value: 0

25   Buffer busy (BSY) - Core sets this bit to 1 when a command is being executed. Once the command is done (*run* bit is cleared) software can clear this bit by writing 1 to it. While this bit is set it prevents software from writing to the buffer. This bit is write clear, but only when the *run* bit is zero. Reset value: 0

24   Command running (RUN) - Core sets this bit to 1 when a command is being executed, and clears it again automatically once the command is done. While this bit is set it prevents software from accessing the buffer. Reset value: 0

23:16   Reserved (R) - Always reads zero.

15:8   Data lane select (LANESEL) - The core uses this field to select which of the connected 8-bit/16-bit data lanes to send the command to (which write enable (WE) signals to assert). (A write enable signal can be connected to one or more flash memory devices but only one of the targets is selected at a time.) The least significant bit in this field corresponds to the first connected data lane (WE(0)) etc. The actual number of bits implemented equals the *nlanes* field in the *Capability register* plus one. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

7:4   Target select (TARGSEL)[3:0] - The core uses this field to select which targets from [3:0] to send the command to (which chip enable (CE) signals to assert). The least significant bit in this field corresponds to the first target (CE(0)) etc. (A chip enable signal can be connected to one or more flash memory devices, all on different 8-bit/16-bit memory lanes. One or more chip enable signals can be connected to a flash memory device, depending on how many targets the device implements.) The actual number of bits implemented equals the *ntargs* field in the *Capability register* plus one. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

***Important note:** Starting from Revision 3 the core supports up to 32 targets. When the core is configured to have up to four targets there is no additional action needed. But when the core is configured to use more than four targets the control of targets starting from the fifth one and onwards are controlled by an extended targsel register. If the core is configured to use more than four targets please read the section " 0x44 / 0x48- Extended Buffer target select register" below carefully.

3:2   Reserved (R) - Always reads zero.

1   Interrupt mask (IRQM) - If this bit is set to 1 an interrupt will be generated when the command linked to the corresponding buffer has been executed. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero. Reset value: 1

0   Execute command (EXE) - When software writes this bit to 1 the core sends the command programmed into the corresponding *Buffer command register* to the lanes and targets selected by the *lanesel* and *targsel* field in this register. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero. Reset value: 0

*Table 2055.*0x30 - TIM0 - Programmable timing register 0

Table 2057.0 x38 - TIM2 - Programmable timing register 2 (only present if programmable timing is implemented, which is indicated by *prgt* bit in *Capability* register)

31:24	Reserved (R) - Always reads zero.
23:16	ALE to data loading time (tADL) - Length of tADL in clock cycles, minus one. See ONFI 2.2 specification for more information. Reset value calculated from VHDL generic *sysfreq* to match value for timing mode 0.
15	Reserved (R) - Always reads zero.
14:8	WP transition to WE low (tWW) - Length of tWW in clock cycles, minus one. See ONFI 2.2 specification for more information. Reset value calculated from VHDL generic *sysfreq* to match value for timing mode 0.
7:6	Reserved (R) - Always reads zero.
5:0	Ready to RE low (tRR) - Length of tRR in clock cycles, minus one. See ONFI 2.2 specification for more information. Reset value calculated from VHDL generic *sysfreq* to match value for timing mode 0.

Table 2058. 0x3C - TIM3 - Programmable timing register 3 (only present if programmable timing is implemented and core revision is bigger or equal to 2, which is indicated by *prgt* bit and *REV* bits in *Capability* register)

31	6	5	0
R		tREH	
0		*	
r		rw*	

31:6	Reserved (R) - Always reads zero.
5:0	RE high hold time (tREH) - Length of tREH in clock cycles, minus one. For backward compatibility purposes the value of tREH is set to the value of tRP when TIM0 register is updated. As a result if the required tREH value is different than tRP, then the TIM3 has to be updated after TIM0 is updated. It should be noted that if tREH value is set something different than tRP, the tRC (tRP+tREH) timing should be met. See ONFI 2.2 specification for more information. Reset value calculated from VHDL generic *sysfreq* to match value for timing mode 0.

Table 2059. 0x40 - Extended capability register

31	5	4	0
R		NTARGS	
0		*	
r		r	

31:5	Reserved (R) - Always reads zero.
4:0	Number of targets per device (NTARGS) - This field indicates how many individual targets the core can access, i.e. number of chip enable signals. A flash memory device can have one or more targets, each with an individual chip enable signal. Reflects value of VHDL generic *ntargets*.

Table 2060. 0x44 / 0x48- Extended Buffer target select register

+46 31 7758650 | frontgrade.com/gaisler

Table 2060. 0x44 / 0x48- Extended Buffer target select register

31:4	Target select (TARGSEL) [31:4] - This register should be used if the number of targets are larger than four.

The core uses this field to select which targets from [31:4] to send the command to (which chip enable (CE) signals to assert). The least significant bit in this field corresponds to the fifth target (CE(4)) etc. (A chip enable signal can be connected to one or more flash memory devices, all on different 8-bit/16-bit memory lanes. One or more chip enable signals can be connected to a flash memory device, depending on how many targets the device implements.) The actual number of bits implemented equals the *ntargs-4* field in the *Capability register* plus one. This field can only be written if the *bsy* bit in the *Buffer control / status register* is zero.

***Important note:** This register is added on revision 3 in order to be able to use more than four targets. This register should be used together with 0x1C,0x2C - BCS - Buffer control / status register (for the corresponding buffer). When using this register, first the required target configuration for [31:4] should be written to this register. After that the target configuration for [3:0] should be set while writing to BCS - Buffer control / status register(bitfield[7:4] of the corresponding buffer). Since the targetsel field can not be changed after a command is executed it is highly recommended that to write this register first before writing to command register in order to avoid software mistakes. |
| [3:0] | Reserved (R) - Always reads zero. |

Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x059. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

104.5   Timing Modes

It is highly recommended to use programmable timing to be able to customize timing, which is needed when additional timing delays are needed to be accounted like I/O delays. In addition it gives the flexibility to correct timing errors by software. See ONFI specification 2.2 for more details about timing.

104.5.1 Timing Register Values when Programmable Timing is Disabled

This section shows how the timing counter values are calculated when programmable timing is disabled. It should be noted that this values are calculated without taking additional delays into account, for example the delay from the NANDFCTRL core outputs to NANDFLASH DEVICE or vice versa. Hence it is highly recommended to use programmable timing, to mitigate additional delays and manage custom timing.

The values are floored if there is a remainder after the division. The following calculations show which values are used instead of the values that are defined in the timing registers when programmable timing is not enabled.

CLOCK_PERIOD = `1000000/sysfreq (sysfreq is a generic)`

tWW = 100/CLK_PERIOD (TM0,TM1,TM2,TM3,TM4,TM5)

tCCS = 500/CLK_PERIOD (TM0,TM1,TM2,TM3,TM4,TM5)

tADL = 200/CLK_PERIOD (TM0); 100/CLK_PERIOD (TM1); 100/CLK_PERIOD (TM2); 100/CLK_PERIOD (TM3); 70/CLK_PERIOD (TM4); 70/CLK_PERIOD (TM5);

tCS = 70/CLK_PERIOD (TM0); 35/CLK_PERIOD (TM1); 25/CLK_PERIOD (TM2); 25/CLK_PERIOD (TM3); 20/CLK_PERIOD (TM4); 15/CLK_PERIOD (TM5);

tRHW = 200/CLK_PERIOD (TM0); 100/CLK_PERIOD (TM1); 100/CLK_PERIOD (TM2); 100/CLK_PERIOD (TM3); 100/CLK_PERIOD (TM4); 100/CLK_PERIOD (TM5);

GRIP

Apr 2024, Version 2024.1

1762

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

tRP = 50/CLK_PERIOD (TM0); 30/CLK_PERIOD (TM1); 25/CLK_PERIOD (TM2); 20/CLK_PE-RIOD (TM3); 20/CLK_PERIOD (TM4); 16/CLK_PERIOD (TM5);

tREH = 50/CLK_PERIOD (TM0); 20/CLK_PERIOD (TM1); 15/CLK_PERIOD (TM2); 10/CLK_PERIOD (TM3); 10/CLK_PERIOD (TM4); 7/CLK_PERIOD (TM5);

tWH = 30/CLK_PERIOD (TM0); 15/CLK_PERIOD (TM1); 15/CLK_PERIOD (TM2); 10/CLK_PE-RIOD (TM3); 10/CLK_PERIOD (TM4); 7/CLK_PERIOD (TM5);

tWHR = 120/CLK_PERIOD (TM0); 80/CLK_PERIOD (TM1); 80/CLK_PERIOD (TM2); 60/CLK_PERIOD (TM3); 60/CLK_PERIOD (TM4); 60/CLK_PERIOD (TM5);

tWP = 50/CLK_PERIOD (TM0); 25/CLK_PERIOD (TM1); 17/CLK_PERIOD (TM2); 15/CLK_PE-RIOD (TM3); 12/CLK_PERIOD (TM4); 10/CLK_PERIOD (TM5);

tWB = 200/CLK_PERIOD (TM0); 100/CLK_PERIOD (TM1); 100/CLK_PERIOD (TM2); 100/CLK_PERIOD (TM3); 100/CLK_PERIOD (TM4); 100/CLK_PERIOD (TM5);

tRR = 40/CLK_PERIOD (TM0); 20/CLK_PERIOD (TM1); 20/CLK_PERIOD (TM2); 20/CLK_PE-RIOD (TM3); 20/CLK_PERIOD (TM4); 20/CLK_PERIOD (TM5);

If TM5 mode is intended to be used when programmable timing is disabled, the user has to calculate if the *tRC* period is going to be less than 30 ns. If it less than 30 ns the tm5_edoen generic shall be set to 1 according to ONFI 2.2 specification. In other cases tm5_edoen should be set to 0.

104.5.2 tROH timing

tROH timing is equal to tRHW timing. Since minimum tRHW timing is equal to maximum tROH timing when minimum tRHW timing is met the tROH timing is met implicitly.

104.5.3 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers. The Flash interface signals have asynchronous reset.

104.5.4 Core instantiation

The core maps all usage of RAM on the *syncram* (or *syncramft* if *ft* generic is not set to 0) component from the technology mapping library (TECHMAP). The size of the instantiated RAM is determined by the *pbufsize, sbufsize, nlanes,* and *sepbufs* generics. Fault tolerance - byte parity DMR or TMR - can be added to the RAM by setting the *ft* generic to 1 or 2.

Note that both the *ft* and *edac* generics need to be set to 0 unless the core is used together with the fault tolerant GRLIB.

The core implements one interrupt, mapped by means of the *pirq* VHDL generic.

104.5.5 Scan test support

The VHDL generic *scantest* enables scan test support. If the core has been implemented with scan test support and the *testen* input signal is high, the core will:

• disable the internal RAM blocks when the *scanen* signal is asserted.

• use the *testoen* signal as output enable signal.

• use the *testrst* signal as the reset signal for those registers that are asynchronously reseted.

The *testen*, *scanen*, *testrst*, and *testoen* signals are routed via the AHB slave interface.

104.6 Implementation

104.6.1 Endianness

The cores endianess can be configured using the settings in the GRLIB configuration package (see GRLIB User's Manual).

104.7 Configuration options

Table 2061 shows the configuration options of the core (VHDL generics).

*Table 2061.*Configuration options

Generic name	Function	Allowed range	Default
hsindex	AHB slave index	0 - NAHBSLV-1	0
haddr0	AHB slave address for BAR 0. See section 104.2.2 for explanation of address scheme.	0 - 16#FFF#	16#000#
haddr1	AHB slave address for BAR 1. See section 104.2.2 for explanation of address scheme.	0 - 16#FFF#	16#001#
hmask0	AHB slave address mask for BAR 0. If set to zero, BAR 0 is disabled. See section 104.2.2 for explanation of address scheme.	0 - 16#FFF#	16#FFF#
hmask1	AHB slave address mask for BAR 1. If set to zero, BAR 1 is disabled. See section 104.2.2 for explanation of address scheme.	0 - 16#FFF#	16#FFF#
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#
pirq	APB irq number.	0 - NAHBIRQ-1	0
memtech	Memory technology used for the buffers.	0 - NTECH	inferred
sysfreq	System clock frequency in kHz.	1 - 1 000 000	50000
ntargets	Number of targets = Number of chip select signals connected to the core. A flash memory device can have one or more targets.	1 - 32	2
nlanes	Number of 8-bit/16-bit data lanes = Number of write enable signals. A write enable signal can be connected to one or more targets (i.e. one or more flash memory devices).	1 - 8	8
dwidth16	0 = Core implements 8-bit data lanes. 1 = Core implements 16-bit data lanes.	0 - 1	0
pbufsize	Size of each page buffer (in bytes). One or two page buffers are implemented for each connected flash memory device (depends on value of generic *buf1en.*). Generic needs to be set to a value equal to or greater than the flash memory device's page area. Value also needs to be a power of two.	8, 16, 32 ... 32768	4096
sbufsize	Size of each spare area buffer (in bytes). One or two spare buffers are implemented for each connected flash memory device (depends on value of generic *buf1en.*). Generic needs to be set to a value equal to or greater than the flash memory device's page spare area. Value also needs to be a power of two.	8, 16, 32 ... 32768	256
tm1	Enable support for timing mode 1 in the case with fixed data interface timing (*progtime* generic set to 0). This generic has no effect if the *progtime* generic is set to 1.	0 - 1	0

*Table 2061.*Configuration options

Generic name	Function	Allowed range	Default
tm2	Enable support for timing mode 2 in the case with fixed data interface timing (*progtime* generic set to 0). This generic has no effect if the *progtime* generic is set to 1.	0 - 1	0
tm3	Enable support for timing mode 3 in the case with fixed data interface timing (*progtime* generic set to 0). This generic has no effect if the *progtime* generic is set to 1.	0 - 1	0
tm4	Enable support for timing mode 4 in the case with fixed data interface timing (*progtime* generic set to 0). This generic has no effect if the *progtime* generic is set to 1.	0 - 1	0
tm5	Enable support for timing mode 5 in the case with fixed data interface timing (*progtime* generic set to 0). This generic has no effect if the *progtime* generic is set to 1.	0 - 1	0
tm5_edoen	Enable EDO data output cycles when timing mode 5 is used in the case fixed data interface timing (progtime generic set to 0). This generic has no effect if the *progtime* generic is set to 1. This generic is only available if the core revision is bigger or equal to 2.	0 - 1	0
nsync	Number of synchronization registers on R/B input. (Data input is always synchronized through one set of registers.)	0 - 3	2
ft	This generic determines if fault tolerance should be added to the buffers. 0 = no fault tolerance, 1 = Byte parity DMR, 2 = TMR. 3 = Byte parity, no DMR, 5 = Technology specific protection. Note that this generic needs to be set to 0 if the core is used together with the GPL version of GRLIB, since that version does not include any fault tolerance.	0 - 3, 5	0
oepol	Polarity of pad output enable signal.	0 - 1	0
scantest	Enable scan test support.	0 - 1	0
edac	Enable EDAC support. See section 104.3.1 for EDAC information. Note that this generic needs to be set to 0 if the core is used together with the GPL version of GRLIB, since that version does not include any fault tolerance.	0 - 1	0
cmdorder	Sets the default way the ONFI command bytes are mapped to the core's data lane(s). When set to 0 the commands are mapped as follows: Cmd bit 0 -> Data lane bit 7, Cmd bit 1 -> Data lane bit 6., and so on. When this bit is set to 1 the commands are mapped as follows: Cmd bit 0 -> Data lane bit 0, Cmd bit 1 -> Data lane bit 1, and so on.	0 - 1	1
sepbufs	When set to 0 all data lanes share the same internal memory buffers. When set to 1 all data lanes have their own internal memory buffers. When set to 0 a command with a data in phase should only be issued to one target and lane at the time. A command with a data out phase can still be issued to several lanes and targets but with the limitation that the same data will be sent on all lanes. When set to 1 several lanes can be read at the same time, and lanes can be written with individual data simultaneously.	0 - 1	1

*Table 2061.*Configuration options

Generic name	Function	Allowed range	Default
progtime	When set to 0 the data interface timing for the different timing modes are set at implementation time from the *sysfreq* generic. When set to 1 the data interface timing is programmable through APB registers (reset values are set at implementation time from the *sysfreq* generic). Maximum system frequency when this generic is set to 1 is 1 GHz.	0 - 1	0
buf1en	When this generic is set to 1 then both buffer 0 and buffer 1 are implemented. If set to 0, only buffer 0 is implemented. See section 104.2.2 for more information about the buffer structure.	0 - 1	1

104.8 Signal descriptions

Table 2062 shows the interface signals of the core (VHDL ports).

*Table 2062.*Signal descriptions

Signal name	Field	Type	Function	Active
rst	N/A	Input	Reset	Logical 0
clk	N/A	Input	Clock	-
apbi	*	Input	APB slave input signals	-
apbo	*	Output	APB slave output signals	-
ahbsi	*	Input	AHB slave input signals	-
ahbso	*	Output	AHB slave output signals	-
nandfi	rb	Input	Ready/Busy signal	-
	di(63:0) [2]	Input	Data input (used both for 8-bit and 16-bit lanes)	-
	dih(63:0) [2]	Input	Data input (upper byte for 16-bit lanes)	-
nandfo	ce(3:0) [3]	Output	Chip enable	Logical 0
	we(7:0) [4]	Output	Write enable	Logical 0
	do(63:0) [2]	Output	Data output (used both for 8-bit and 16-bit lanes)	-
	doh(63:0)[2]	Output	Data output (upper byte for 16-bit memories)	-
	cle	Output	Command latch enable	Logical 1
	ale	Output	Address latch enable	Logical 1
	re	Output	Read enable	Logical 0
	wp	Output	Write protect	Logical 0
	err	Output	EDAC / Buffer error on AHB access	Logical 1
	oe	Output	Output enable	[5]

* see GRLIB IP Library User's Manual

[2] The actual number of data input/output signals used depends on core configuration. Eight bits are used for each lane.

[3] The core drives one chip select signal for each target, i.e. on or more attached flash memory devices.

[4] The core drives one write enable signal for each 8-bit/16-bit data lane, i.e. one or more attached flash memory devices.

[5] The polarity of the output enable signal is implementation dependent.

104.9 Signal definitions and reset values

The signals and their reset values are described in table 2063.

Table 2063. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
rb	Input	Ready/Busy signal	-	-
d(63:0) [1]	Input/Output	Data (used both for 8-bit and 16-bit lanes)	-	-
dh(63:0) [1]	Input/Output	Data (upper byte for 16-bit lanes)	-	-
ce(3:0) [2]	Output	Chip enable	Logical 0	Logical 1
we(7:0) [3]	Output	Write enable	Logical 0	Logical 1
cle	Output	Command latch enable	Logical 1	Logical 0
ale	Output	Address latch enable	Logical 1	Logical 0
re	Output	Read enable	Logical 0	Logical 1
wp	Output	Write protect	Logical 0	Logical 1
err	Output	EDAC / Buffer error on AHB access	Logical 1	Logical 0
oe	Output	Output enable	[4]	[4]

[1] The actual number of data input/output signals used depends on core configuration. Eight bits are used for each attached flash memory device.

[2] The core drives one chip select signal for each target, i.e. on or more attached flash memory devices.

[3] The core drives one write enable signal for each 8-bit data lane, i.e. on or more attached flash memory devices.

[4] The polarity of the output enable signal is implementation dependent.

104.10 Library dependencies

Table 2064 shows the libraries used when instantiating the core (VHDL libraries).

Table 2064. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions

104.11 Timing

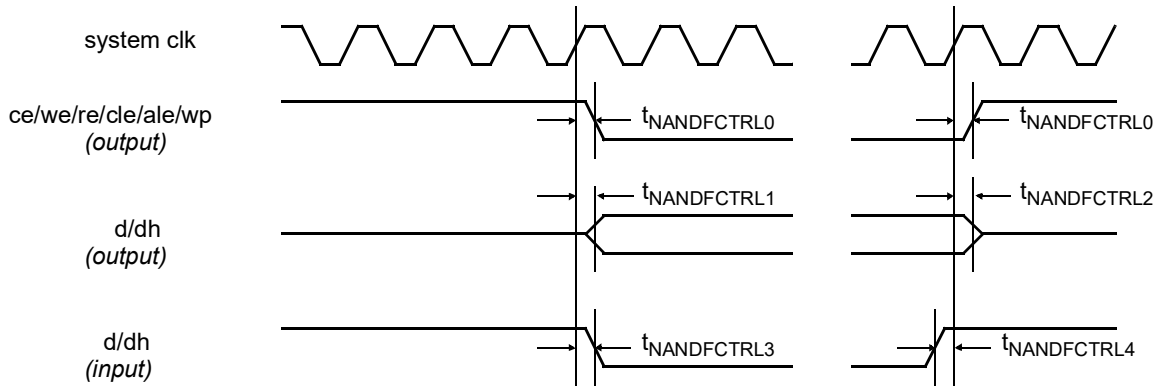
The timing waveforms and timing parameters are shown in figure 282 and are defined in table 2065.


Figure 282. Timing waveforms

*Table 2065.*Timing parameters

Name	Parameter	Reference edge	Min	Max	Unit
$t_{NANDFCTRL0}$	clock to output delay	rising *clk* edge	TBD	TBD	ns
$t_{NANDFCTRL1}$	clock to non-tri-state delay	rising *clk* edge	TBD	TBD	ns
$t_{NANDFCTRL2}$	clock to tri-state delay	rising *clk* edge	TBD	TBD	ns
$t_{NANDFCTRL3}$	input to clock hold	rising *clk* edge	TBD	-	ns
$t_{NANDFCTRL4}$	input to clock setup	rising *clk* edge	TBD	-	ns

Note: The *rb* input is re-synchronized internally. The signal does not have to meet any setup or hold requirements.

104.12 Instantiation

This example shows how the core can be instantiated. The instantiated core has all its generics, except *hsindex, pindex*, *paddr*, and *pirq* at their default values. The impact of the generics can be seen in table 2061.

```

105   NANDFCTRL2 - NAND Flash Memory Controller with Direct Memory Access

105.1   Overview

Note: This IP core manual describes a NAND flash memory controller which is under development. Some features are described as not implemented and will be implemented over time together with additional extensions. See individual sections.

The NANDFCTRL2 core is a memory controller for NAND flash memory devices. The core is designed to operate with Open NAND Flash Interface (ONFI) 4.0 flash memory devices. It can communicate with multiple parallel NAND flash memory devices. The core provides an AMBA AHB master to perform data write and read accesses. Configuration through generics supports a vast variation of memory devices including support for up to 64 individually addressable targets via chip enable signals, 32 ready-busy signals and 16 channels. For write accesses, it is possible to issue the same command to several targets and channels at once by selecting multiple targets or channels.

The core supports EDAC using a configurable BCH code implementation, supporting up to 60-bit correcting capability. When using EDAC, NANDFCTRL2 will automatically split the NAND flash memory area into data area, spare area, and flag area. The core also supports automatic data randomization. Randomization and EDAC may be independently enabled or disabled.

The core supports up to 3 different NAND flash memory configurations and up to 2 ECC configurations simultaneously, configured through generics. In addition to generic configuration, configuration of NANDFCRTL2 is done through a set of registers, accessible through the AHB and APB interfaces.

An access to a NAND flash memory device through NANDFCTRL2 is done using a descriptor which holds necessary information to perform an access. These descriptors may be transferred to the core using either the APB or AHB interface. Multiple accesses can be setup in AHB area memory via descriptors in a linked list. This allows NANDFCTRL2 to operate more autonomously and fetch the descriptors one by one using the AHB interface.

Other key features of the core are

*   Time out monitoring using the ready-busy input signals.

*   A user-controlled external digital output signal, which may be used for e.g. SEFI handling.

A PHY should typically be used between the controller and the flash memory devices.

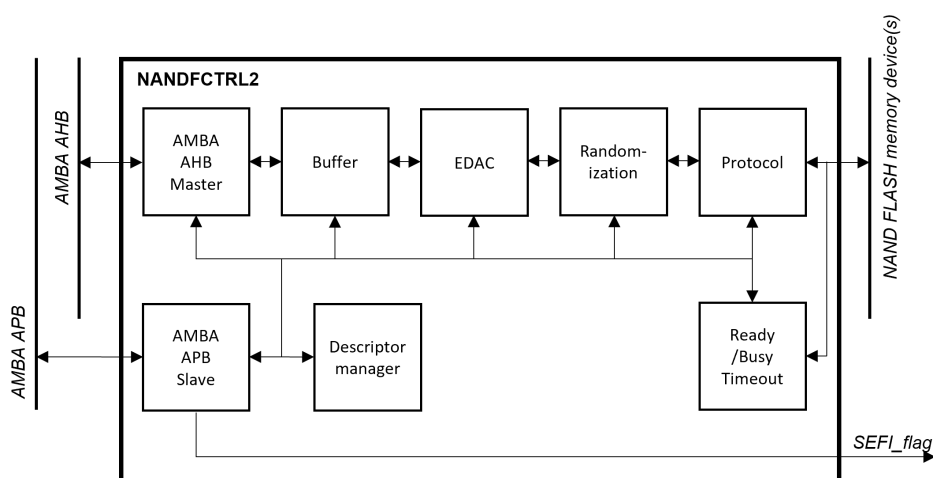
For details about the actual NAND flash memory interface, NAND flash memory architecture, and ONFI 4.0 command set, please refer to the *Open NAND Flash Interface specification, revision 4.0*, hereafter called the ONFI 4.0 specification.


Figure 283. Block diagram

105.1.1 Limitations of current revision and planned features

The core is under development and available with limitation in functionality and features as described in the following list:

- All mandatory ONFI commands are implemented and supported as well as some vendor-specific commands. See section 105.1.2 for details.

- SDR data interface, 8-bit data bus, timing mode 0-5 is supported, with EDO.

- NV-DDR2 and NV-DDR3 data interface, 8-bit data bus, timing mode 0-10 is supported.

- NV-DDR data interface is not supported.

- The alternative way of using the Read Status command continually pulsing RE_n or leaving RE_n low is not supported.

- NAND flash memory die data bus size of 16 bits is not supported.

- Scatter and gather are currently only supported when using SDR data interface. Support in NV-DDR2 and NV-DDR3 are planned to be added.

SLC Mode Disable	DFh		
Read Single Soft Bit	00h	34h	
Read Page with Soft Information	33h	30h	Requires the feature 97h to be set
Soft information readout	36h		

105.2 Physical interface, data interface and timing modes

105.2.1 Physical interface

NANDFCTRL2 should typical be used together with a PHY, refer to the NANDFCTRL2 PHY section of this manual. An instantiation example of NANDFCTRL2 together with a PHY is included in the end of this NANDFCTRL2 chapter.

105.2.2 Interface configurability

The pin interface of the core can be configured to support many different memory configurations as well as several devices in parallel. This is done through the three generics *nrofce*, *nrofrb* and *nrofch*. *nrofce* sets the number of CE_N signals. *nrofrb* sets the number of RB_N and SEFI_FLAG signals. *nrofch* controls the other signals (DQ(7:0), DQS, DQ_OE, DQS_OE, CLE, ALE, RE_N, WE_N and WP_N).

There are also control and status signals used by the PHY where ddr_mde, ddr_valid, datai_valid are set by *nrofch* and ifsel, t_dqsh, t_dqsl, t_reh, t_rp and phy_ready are shared for all channels in the PHY.

This gives the user the possibility to configure the core for a specific system including:

• Memory package configuration.

• Number of memory devices on a PCB design.

• PCB configuration, including possible pin-sharing of one or more signals.

GRIP

Apr 2024, Version 2024.1

1773

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

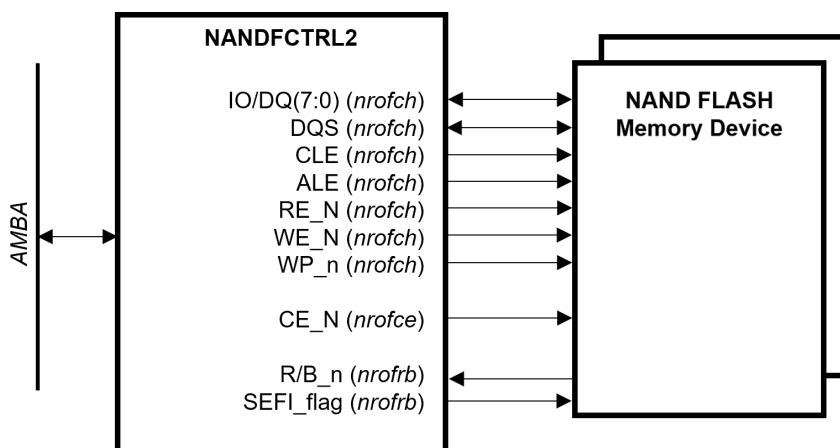
+46 31 7758650 | frontgrade.com/gaisler


Figure 284. Interfaces

Some NAND flash memory devices does not populate all signals in direct relation to the *nrofch* generic. One example is a device using 8 RE_n and 8 WE_N signals but 1 ALE, 1 CLE, 1 WP and 1 8-bit data bus. In this case *nrofch* should be set to the higher value and the controller should enable the *channel mode* bit in the *Core control register 0*. Channel mode is described in more detail in section 105.5.

105.2.3 Data interfaces and timing modes

NANDFCTRL2 supports the data interfaces NV-DDR2, NV-DDR3 and SDR configured by the *IFSEL* field in the *Core control 0 register*.

Timing mode 0-5, including Extended data output (EDO) are supported in SDR. Timing mode 0-10 are supported in NV-DDR2 and NV-DDR3. Timing mode is configured through a number of programmable timing parameters. Those timing parameters are fully programmable via the *Programmable timing registers (0-11)* and EDO is controlled by the *EDO* field in the *Core control 0 register*. The actual time is derived from these timing registers and the frequency of the core clock and the PHY clock. The dependence of the PHY clock is only applicable when running NV-DDR2 or NV-DDR3 data interface.

The programmable timing registers are mapped by name to the corresponding timing parameters in ONFI 4.0. The user must ensure that the timing parameter registers are set according to the constraints in ONFI 4.0, chapter 4 and the NAND flash memory device.

105.2.4 Data interface SDR

The ONFI 4.0 timing parameters which should be programmed by the user are listed in the table below. All timing parameters are derived from the frequency of the core clock when configured to SDR.

+46 31 7758650 | frontgrade.com/gaisler

Table 2068. Timing parameters in SDR

Timing Parameter	Description	Clock	Comment
tCS	CE_n setup time	Core clock	Should be configured to the value of tCS3.
tWW	WP_n transition to WE	Core clock	
tRR	Ready to RE_n low	Core clock	
tWB	WE_n high to SR[6] low	Core clock	
tRHW	RE_n high to WE_n low	Core clock	
tWHR	WE_n high to RE_n low	Core clock	
tADL	ALE to data loading time	Core clock	
tCCS	Change Column setup time	Core clock	
tREH	RE_n high hold time	Core clock	
tRP	RE_n pulse width	Core clock	
tWH	WE_n high hold time	Core clock	
tWP	WE_n pulse width	Core clock	
tVDLY	Delay prior to issuing the next command after a new Volume is selected using the Volume Select command	Core clock	
tCS_VOL	CE_n setup time for Volume Select command.	Core clock	This timing parameter is required for some flash devices that have a longer CE_N setup time than tCS/tCS3 for the Volume select command. In case the target flash device doesn't specify the Volume select setup time specific this parameter should be configured to the same value as tCS/tCS3. Not that this is not an ONFI timing parameter.

In addition the timing parameters needs to comply with the following requirements:

- tCS should always be configured to the value of tCS3, as specified in ONFI 4.0 errata 005.
- tRP should always be configured to a higher value than tREA.
- tWH and tWP needs to be configured to comply with the requirement of tWC.
- tREH and tRP needs to be configured to comply with the requirement of tRC.

If the timing parameters above form a valid configuration, other timing requirements are either fulfilled through design, or handled by the NAND flash memory devices. See the ONFI 4.0 specification for details about the different timing parameters.

105.2.5 Data interface NV-DDR2 and NV-DDR3

The ONFI 4.0 timing parameters which should be programmed by the user are listed in the table below. In NV-DDR2 and NV-DDR3 mode the timing parameters are derived from either the core clock or the phy clock, as indicated in the same table.

Table 2069. Timing parameters in NV-DDR2 and NV-DDR3

Timing Parameter	Description	Clock	Comment
tCS	CE_n setup time	Core clock	Should be configured to the value of tCS3.
tWW	WP_n transition to WE	Core clock	
tRR	Ready to RE_n low	Core clock	
tWB	WE_n high to SR[6] low	Core clock	
tRHW	RE_n high to WE_n low	Core clock	
tWHR	WE_n high to RE_n low	Core clock	
tADL	ALE to data loading time	Core clock	
tCCS	Change Column setup time	Core clock	
tREH	RE_n high hold time	PHY clock	Used by PHY.
tRP	RE_n pulse width	PHY clock	Used by PHY.
tWH	WE_n high hold time	Core clock	
tWP	WE_n pulse width	Core clock	
tCALS	CLE and ALE setup time	Core clock	Should be configured to tCALS2 if ODT is enabled.
tCSD	ALE, CLE, WE_n hold time from CE_n high	Core clock	
tCHZ	CE_n high to output Hi-Z	Core clock	
tWPRE	DQS write preamble	Core clock	Should be configured to tWPRE2 if ODT is enabled.
tRPST	Read postamble	Core clock	
tDQSRH	DQS hold time after (RE_n low or RE_t/RE_c crosspoint)	Core clock	This parameter is equal to the number of clock cycles and not minus as other timing parameters, see the register section for more information.
tWPST	DQS write postamble	Core clock	
tWPSTH	DQS write postamble hold time	Core clock	
tDQSL	DQS low level width	PHY clock	Used by PHY.
tDQSH	DQS high level width	PHY clock	Used by PHY.
tVDLY	Delay prior to issuing the next command after a new Volume is selected using the Volume Select command	Core clock	
tCS_VOL	CE_n setup time for Volume Select command.	Core clock	This timing parameter is required for some flash devices that have a longer CE_N setup time than tCS/tCS3 for the Volume select command. In case the target flash device doesn't specify the Volume select setup time specific this parameter should be configured to the same value as tCS/tCS3. Not that this is not an ONFI timing parameter.

In addition the timing parameters needs to comply with the following requirements:

• tCS should always be configured to the value of tCS3, as specified in ONFI 4.0 errata 005.

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- tWH and tWP needs to be configured to comply with the requirement of tWC.

- tREH and tRP needs to be configured to comply with the ONFI requirement of tRC. tRC needs to be configured to an integer value of core clock periods.

- tDQSL and tDQSH needs to be configured to comply with the ONFI requirement of tDSC. tDSC needs to be configured to an integer value of core clock periods.

If the timing parameters above form a valid configuration, other timing requirements are either fulfilled through design, or handled by the NAND flash memory devices. See the ONFI 4.0 specification for details about the different timing parameters.

105.3 AMBA interface and accessing the flash memory device

The core features an AMBA AHB master with DMA and an AMBA APB slave interface. The APB registers hold all configuration and status bits of the core.

105.3.1 Descriptor

An access to a NAND flash memory device through the core is done by setting up and triggering a *descriptor*. A descriptor is the information which is used and expected to be updated per access. Their names are prefaced with the word *Descriptor*.

There are two methods of doing this. The first method is by setting up a linked list of descriptors in an AHB memory area and letting the AHB master of NANDFCTRL2 fetch them over the AHB interface.

The other method is to configure an individual descriptor by setting the appropriate register fields through the APB interface.

105.3.2 Linked list mode

When using linked list mode, the descriptors are realised as a linked list in the host system's AHB area memory. The key benefit of using this mode is to offload the host processor, and to do accesses back-to-back without manual operations with the CPU between them.

To set up the controller to use a linked list, the following information must be transferred over the APB interface

- The *LLM* bit in the *CTRL0 register* shall be 1.

- The *Linked list pointer registers* shall point to the first descriptor in the linked list

When these are set and the rest of the descriptor is configured, setting the *Descriptor trigger* register will start the execution of the linked list.

The information in a single descriptor must be arranged in the AHB memory according to the following table.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

*Table 2070.*Memory offset and layout of a descriptor block.

Address offset	Register
0x00	Descriptor command register
0x04	Descriptor target select 0 register
0x08	Descriptor target select 1 register
0x0C	Descriptor channel select register
0x10	Descriptor ready/busy select register
0x14	Descriptor row register
0x18	Descriptor column & size register
0x1C	Descriptor status register
0x20	Descriptor ECC status register
0x24, 0x28, 0x2C	Reserved addresses
0x30	Descriptor data pointer low register
0x34	Reserved address
0x38	Descriptor linked list pointer low register
0x3C	Reserved address

Each descriptor has an *EN* bit, which is used to signal whether a descriptor has yet been processed. The handshake mechanism is such that after the host system has set the *EN* bit to '1', it will not change any fields in that descriptor. Conversely, when the *EN* bit is '0', NANDFCTRL2 will not change that descriptor. In practice, this gives the following behaviour.

If an individual descriptor has the *EN* bit in the descriptor command register, NANDFCTRL2 will execute that descriptor and fetch the next one at the AHB memory location specified in the linked list pointers. If the *EN* bit in a descriptor is '0'*,* the controller does not execute that descriptor and considers the linked list to be terminated. Upon completion of a descriptor, including communication with the NAND flash memory device and possible data transfer, the core will update the status word of the descriptor in memory, and set the EN bit to '0'.

For an example of setting up a linked list, see section 105.12.2

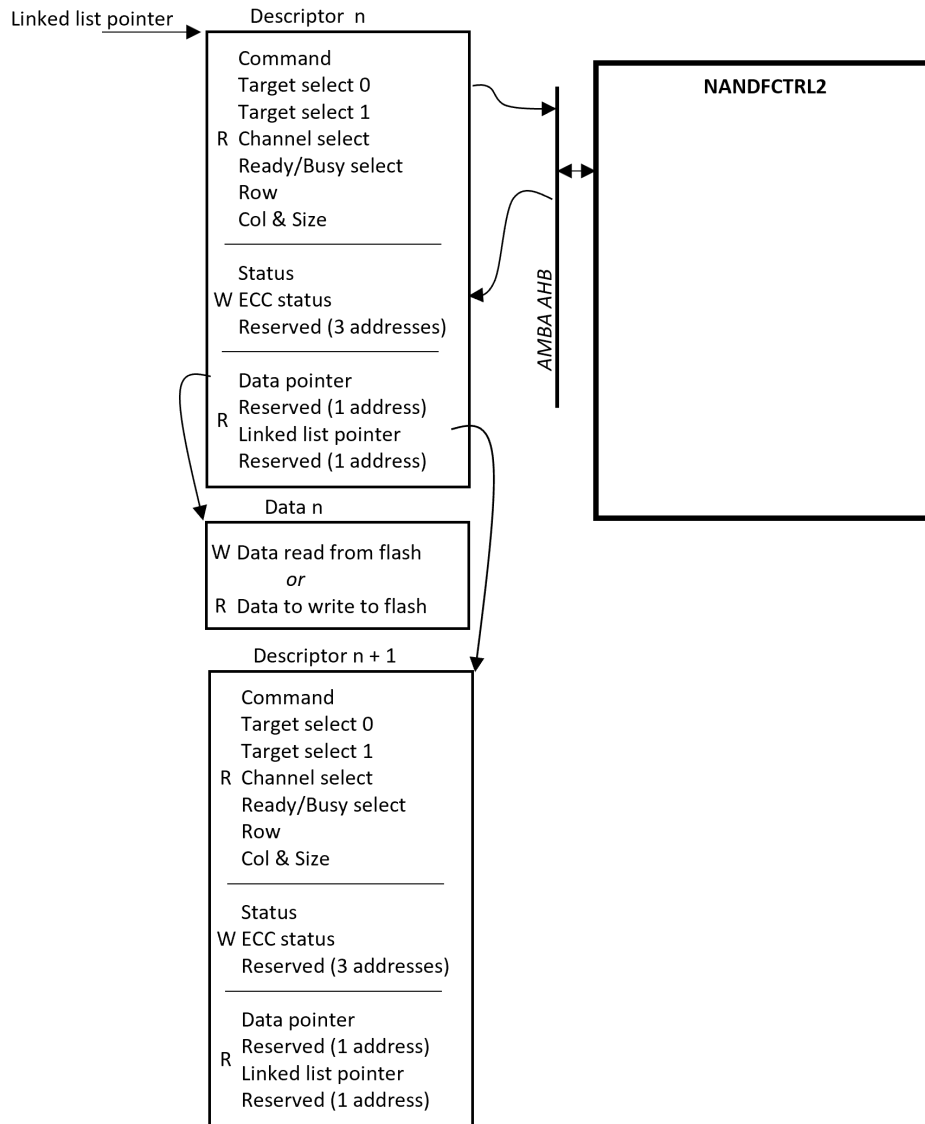

Figure 285. Example of a linked list

105.3.3 Register mode

When using register mode, a descriptor is realised by setting the registers whose names start with *Descriptor* using the APB interface. This mode is chosen by setting the *LLM* bit in the *CTRL0 register* to 0.

After the descriptor has been set to its appropriate values, the descriptor is triggered by setting the *Descriptor trigger* to 1. After the descriptor has been completely processed, the *EN* bit will be set to 0 by the hardware, while leaving the other configuration registers unchanged.

105.3.4 DMA and Data-in and Data-out registers

An ONFI 4.0 compliant NAND flash memory device has configuration and status register as well as a flash memory array, for more details see the ONFI 4.0 specification.

GRIP

Apr 2024, Version 2024.1

1779

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

A NAND flash memory device's registers may be accessed using either the AHB bus via DMA master or the dedicated datain/dataout registers. Accesses can be done with either option with the restriction that a maximum of 16 bytes may be used with the APB option.

The choice of data source is determined by the DMA selection bit *DD* (DMA Disable) in the *Descriptor command register*.

If DMA mode is used, the memory location of the data is determined by a data pointer in the descriptor.

The APB interface mode is only supported in Register mode, i.e when the *LLM* bit in the *CTRL0 register* is set to 0.

The EDAC and randomization features are not supported when the APB interface is used, see section 105.4.2 and 105.4.3 for more information about EDAC and randomization.

Note that the interrupt behavior might be different depending on this setup, e.g for a read command an interrupt is generated when data is available in the Data-in register(s) or when the transfer over the AHB bus is completed.

105.4 Flash Memory Array

This section includes some preliminaries regarding a NAND flash memory device, related core features, and the different ways NANDFCTRL2 can be used to access the array efficiently. For details about a specific NAND flash memory, please refer to the corresponding data sheet.

Memory array data is typically transfered over the AHB bus using DMA.

105.4.1 Flash Memory Device

Recall that a NAND flash memory device has configuration and status registers as well as a flash memory array. The device holds one or more page registers that may be viewed as divided into data and spare area.

105.4.2 Error Detection And Correction

A NAND flash memory device typically comes with a requirement on some type of error correction, see the ONFI 4.0 specification section 3.4. In addition to correction, the core also has an implementation of a detection algorithm for uncorrectable errors.

The EDAC typically works on sizes which are smaller than the page data area dividing it into smaller partitions which here are referred to as chunks. For this reason a fixed layout scheme for the data area of the page is used when EDAC is enabled. Those chunks can be split into data chunks and the ECC produced check bytes. The number of ECC-generated check bytes in the chunk may allow for some extra bytes in the end of a page in the spare area. Those bytes are here referred to as flag area and may be used for any purpose.

The core implements a configurable BCH EDAC. Up to 2 blocks with different configuration may be instantiated simultaneously. The EDAC may be bypassed at runtime for each access. See the BCH encoder and decoder chapters for more information.

The number of check bytes per chunk produces depends on the generics and is equal to

• 2 * ceiling(eccX_cap * eccX_gfsize / 16)

i.e, the number bits necessary, rounded up to nearest even number of bytes.

The data chunks are placed in the page data area and the check bytes in the spare area.

The figure below shows 3 typical examples how the core splits the page register into data chunks, preserve bad block area, chunks of check bytes and flag area.

GRIP

Apr 2024, Version 2024.1

1780

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler
Figure 286. Page - example of page layout (set by generic parameters).

105.4.3 Randomization

Some NAND flash memory devices put a requirement on randomizing of the data.

The core has support for a generic-controlled pseudo-randomization algorithm, with periodicity and randomness behaviour in accordance with the requirements for e.g. NAND Flash Memory Device UT81NDQ512G8T. The algorithm uses the row and column addresses as seed input. This ensures the randomization is invertible regardless of start address for read or write commands.

Should randomization not be required, this functionality can be bypassed during runtime.

See section 105.10 for more details regarding the randomization.

105.4.4 Preserve Bad Block Mark

A NAND flash memory device comes with factory bad block marks on defective blocks.

The core has a feature for preserving those two bytes. This may be useful during e.g. initial setup or debugging when the bad block mark must not be overwritten by mistake. When the *BBM* field is set to '1' in *CTRL0 register* the controller avoids using the first 2 bytes in spare area for PAGE WRITE and CHUNK WRITE accesses.

Note that it is still possible to write to these 2 bytes by explicitly by setting the page column address to these bytes (See section •).

Note that when using the Preserve Bad Block feature and randomization, those two bytes will not be randomized.

105.4.5 Memory Selection

The core supports up to 3 memory configurations and 2 ECC configurations simultaneously. Those are set through generics and are size of data area, size of spare area, size of chunk size, ecc capability and ecc gf size. Each memory configuration is connected to a ECC configuration through a selection generic. The user setup select memory configuration, which includes ecc configuration, to access with the *MSEL* field in the *CTRL0 register*.

The following 3 memory and ECC configurations are the ones NANDFCTRL2 will be configured to support using the default values of the generics.

• page size of 16 kbytes data size and 2208 bytes spare size, 16 chunks of 1024 bytes each and 60 error detection and correction capability.

• page size of 8 kbytes and 448 bytes spare size, 16 chunks of 512 bytes each and 16 error detection and correction capability.

GRIP
Apr 2024, Version 2024.1

1781

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- page size of 4 kbytes and 224 bytes spare size, 8 chunks of 512 bytes each and 16 error detection and correction capability.

105.4.6 Configuring the NAND flash array - Set and Get Feature

The core can be used for setting and reading NAND flash device's configuration. When the core is using the set or get feature command, the row address field is used for the feature address. Recall that the row address is three bytes. Should only two bytes be needed for the address, the lower bytes are used.

105.4.7 Accessing the flash array - Chunk Access

If the configured size and address equal a chunk size and an integer multiple of a chunk size respectively, this type of access will be performed. The core will write data to the data area of the page register.

If EDAC is enabled the core will automatically write the check bytes to the corresponding part of the spare area when the data area is accessed. If Preserve Bad Block is enabled the placement of the check bytes will have an offset of 2 bytes. Note that spare area is only written when EDAC or randomization is enabled.

If randomization is enabled and EDAC disabled, the data area will be randomized. The spare area corresponding to where the check bytes would have been placed will be filled with pseudo-randomized data. Writing the last chunk of a page will also randomize the flag area of that page.

The number of accesses (a combination of Page Program and Change Write Column / Change Read column) the core perform will depend on configuration of EDAC and randomization. The core updates the descriptor status and then generates an interrupt.

If more than one chunk of data is to be programmed, several accesses will be required before starting the flash array programming, i.e. with a 10h command.

105.4.8 Accessing the flash array - Whole Page Access

If the configured size is equal to the data area for the selected memory, this type of access will be performed. The core will perform a loop of Chunk Accesses for all chunks and program the data into the NAND flash memory array. Randomization, EDAC and Preserve Bad block work in the same way as for Chunk Accesses, meaning that the whole page including flag area will be programmed if EDAC or Randomization is enabled and Preserve Bad block is disabled. The core generates an interrupt upon completion if enabled.

105.4.9 Accessing the flash array - Free size

The NAND flash memory page register can be accessed freely up to 4096 bytes. If the address and size do not trigger a Chunk Access nor Whole Page Access, this type of access will be performed.

The core will write the data to the page register. If randomization is enabled, the data will be randomized. The core generates an interrupt upon completion if enabled.

EDAC is not supported for this type of access.

If more data than the NANDFCTRL2 maximum of 4096 bytes is to written to a page, more than one free size access of the page register, several accesses will have to be performed before starting the flash array programming, i.e. with a 10h command.

Care must be taken in order to not accidentally overwrite the factory bad block mark using this type of access and configured column address.

GRIP
Apr 2024, Version 2024.1

1782

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

105.4.10 Accessing the flash array - Gather

If the user has one or more fragments of a size which is not a multiple of a chunk, this feature may be used.

When writing to the NAND flash memory array, if EDAC is enabled and the size of the access does not equal one chunk nor one page, this type of access will be performed.

When NANDFCTRL2 enters gather mode, it will stay in gather mode until a write is finished, i.e. a *Change Write Column* command is terminated with 0x10.

When in gather mode, NANDFCTRL2 will accept one or more fragments of size no more than one chunk, glue them together, add checkbits and write to the NAND flash memory array. When using this feature, the user must ensure the following conditions are met.

- No fragment is more than one chunk.

- The total size before terminating is no more than one page.

- EDAC is on during the entire access. Randomization does not toggle during the entire access.

105.4.11 Accessing the flash array - Scatter

If one or more fragments of an ECC protected memory which do not equal en exact chunk are to be read, this feature may be used.

When reading from the NAND flash memory array, if EDAC is enabled and the size of the access does not equal one chunk nor one page, this type of access will be performed.

When NANDFCTRL2 enters scatter mode, the controller will leave scatter mode on the first command which is not CHANGE READ COLUMN.

When in scatter mode, NANDFCTRL2 will transmit one or more fragments of size no more than one chunk, correct any bit flips, up to the configured capability and send them to the desired data area. When using this feature, the user must ensure the following conditions are met.

- No fragment is more than one chunk.

- The total size before terminating is no more than one page.

EDAC is on during the entire access. Randomization does not toggle during the entire access.

105.5 Channel and target selection

The core features the possibility to write to any number of channels and targets simultaneously, with the same command and data payload, using the *Descriptor target select* and the *Descriptor channel select registers*. Read is limited to one channel and target per access. In the case of more than one channel or target activated simultaneously the lowest active will be used.

Configuration of which R/B_n signal to listen to on a per access basis, using the *Descriptor ready/ busy select register*. Incorrect setting lead to the core monitoring wrong target and thus not appropriately detecting when an access is finished.

Some NAND flash memory devices use 8 RE_N and WE_N signals while only 1 ALE, CLE, WP and 1 8-bi IO data bus. To support these devices the controller features a control bit named *Channel mode* located in the *Core control register 0*. When this bit is set to 1 only bit 0 and 8 will be valid for CLE, ALE and IO0-8, e.g.

ALE(0) = CH_SEL(0) or CH_SEL(1) or … or CH_SEL(7)

ALE(8) = CH_SEL(8) or CH_SEL(9) or … or CH_SEL(15)

Channel mode is only supported when using the SDR data interface.

Note that WP are always handled separately and are not effected.

105.6 Clock, Reset, Abort and Stop linked list

105.6.1 Clock

NANDFCTRL2 works as a bridge from the so called sys clk used by the host system and the AMBA interface, through the so called core clk used by the core of the controller, to the so called phy clk of the PHY. Refer to NANDFCTRL2_PHY chapter of this manual for more information of the specific PHY.

The core performs clock-domain crossing synchronization between the system and the core clock, and the core clock and phy clock, domains by mean of handshake mechanisms, meta-stabilization and dual port buffers.

The phy clock of the PHY should be 4 times the core clock and the two clocks should be synchronous and the positive edges must align.

The core features several options to reset or abort the core itself and the NAND flash memory device.

105.6.2 Hard reset

Activating the reset signals to the core resets the core itself, while leaving the connected NAND flash memory device(s) in its current state. The core's reset behavior depends on the GRLIB configuration, section 105.15.2 for more information.

To prevent the risk of double-driving any of the bi-directional signals between the controller and the flash device(s) the controller will set and keep these signals as inputs for the generic *rst_cycles* core clock cycles. This state is indicated by the *RDY* status bit in the *Core status 0 register* is cleared to '0' while the reset is active and for *rst_cycles* core clock cycles. The controller will ignore any descriptor trigger (*DT* field in the *Descriptor command register*) while *RDY* is '0'.

Depending on which state the flash device is in when the hard reset is activated, it might be needed to reset the flash device before starting the next operation.

105.6.3 Soft reset

Setting the *RST* bit in the *Core control 2 register* activates a soft reset. This will reset the APB registers but nothing else of the core.

It is not possible to combine abort and soft reset in one access. Such a request needs to be split into a sequence of two accesses.

105.6.4 Sending reset command

The core can be used to transmit an ONFI command to reset parts of, or the entire, NAND flash memory device, while leaving the core in its current state.

105.6.5 Abort

The core implements an abort function. This can be useful if the core is in an unknown state, with soft reset as an additional option. When the abort function is triggered, NANDFCTRL2 will safely abort the current operation. If the core, at the time of abort, is processing a descriptor, it will interrupt processing that descriptor and terminate and transfer over the ONFI bus but continue transmitting over the AHB bus. After the abort has been executed, the core will write the final descriptor registers and stop the linked list if in linked list mode. An AMBA interrupt is generated if enabled.

An abort can be triggered in the following ways

- Setting the *ABORT* bit in the *Core control 2 register* to '1'.

- The core detects an invalid command.

- Timeout from the NAND flash memory device.

GRIP
Apr 2024, Version 2024.1

1784

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- AHB error.

- Errors on internal RAM memories.

In the same way as described in the Hard reset section 105.6.2, the controller will be set in a reset state for *rst_cycles* core clock cycles indicated with the *RDY* field in the *Core status 0 register*.

Note that it is possible to configure the core incorrectly so it will get stuck. Causes include programming a NAND flash memory device that are in Write Protect mode or selecting an incorrect R/B_n signal that is not going busy.

In the event where the core or the NAND flash memory device has ended up in a stuck state, the user can check that the NAND flash memory device is not busy by reading the *RBSTS field* in the *Core Status 3 register* prior to issuing any command.

Depending on which state the flash device is in when the abort is triggered, it might be needed to reset the flash device before starting the next operation.

It is not possible to combine abort and soft reset in one access. Such a request needs to be split into a sequence of two accesses.

105.6.6 Stop linked list

It is possible to stop an ongoing linked list by using the Stop Linked list feature. Setting the *STOP_LL field* in the *Core control 2 register* to '1' will complete the current active descriptor and then stop the linked list.

105.7 Programmable Timeout with SEFI handling

The core handles timeouts in the event that a R/B_n signal does not respond as expected.

All commands which use a R/B_n signal to detect when a command has been executed can be monitored using the *Programmable timeout register*. An R/B_n signal will be monitored if it has been selected in the *Descriptor ready/busy select register* and the *Programmable timeout register* is configured to a non-zero value.

When the core issues a command that expects an R/B_n response, the timeout block will load the value in the *Programmable timeout register* and start to count down shortly after the time *tWB* configured in the *Programmable timing 1 register*. The value in this register corresponds to the same number of core clock cycles to be used. If the counter hits 0 an interrupt is issued (the *TO field* in *Core status 1 register* indicates if any timeout occurred and the *Core status 2 register* indicates which R/B_n signal that triggered it).

The timeout feature is disabled for accesses configured to not wait for R/B (the *SRB field* in the *Descriptor command register* set to '1').

The user can use the digital output signal SEFI_FLAG (one per R/B_n signal) to handle the timeout externally. This is done by setting the corresponding bit in the *Core control 4 register*.

105.8 Interrupts

There are several interrupt sources which can generate interrupt. Each source has an enable bit in *CTRL1 register* and a corresponding status bit in *STS1 register*. There is also a main IRQ bit that selects if an interrupt should be generated on the AMBA bus. The Interrupt status bits are sticky and are cleared when a '1' is written to corresponding bit. Several of the interrupt sources have a corresponding status bit on descriptor level in the *Descriptor status register*. Several of the interrupt sources also have an additional enable bit in the *Descriptor command register* that can be used to disable interrupts per access.

The interrupt sources are:

IRQ-CERRDL - Correctable error in downlink syncrams.

IRQ-CERRUL - Correctable error in uplink syncrams.

IRQ-UCERRDL - Uncorrectable error in downlink syncrams.

IRQ-UCERRUL - Uncorrectable error in uplink syncrams.

IRQ-STOPLL - Stop linked list.

IRQ-ABORT - Abort.

IRQ-TMOUT - Timeout from timeout block.

IRQ-CMD - Invalid command.

IRQ-DL - An error in DMA Downlink access (read error).

IRQ-UL - An error in DMA Uplink access (write error).

IRQ-ECC - An uncorrectable checksum error from the BCH decoder.

IRQ-DS - A descriptor has finished.

105.9 Error detection and correction

The core uses parametrized BCH encoder(s) and decoder(s) with configurable capability and chunk size of 512 byte or 1024 byte. It supports up to 60-bit correcting capability. Up to 2 blocks with different configurations may be instantiated simultaneously.

For details regarding their implementations, please see thee BCH encoder and BCH decoder chapters.

If error correction is activated, for each READ command the following statistics are collected

- the number of corrected errors in the worst correctable chunk during this READ in field *CEC* in register *Descriptor ECC status*. Note uncorrectable chunks are ignored in this field.

- the total number of corrected errors in this READ in field *CE* in register *Descriptor ECC status*. Note uncorrectable chunks are ignored in this field.

- if any error correction was unsuccessful in field *UE* in register *Descriptor status*.

- in which chunk(s) error correction was unsuccessful in field *ECFAIL* in register *Descriptor status*.

In addition, an ECC IRQ is issued every time a chunk isn't correctly decoded (if enabled). However, the core does not stop any ongoing access or active linked list independent of the result from the decoder.

105.10 Randomization

The randomization feature can be turned off by either the *rnd* generic or the *RD* field in the *Descriptor command register*.

If activated, the randomization produces a pseudo-random bitmask based on the page and column address of the data. The periodicity of the randomizer is one nand flash block. The randomization and derandomization are identical.

105.10.1 Algorithm

Each page within a block is getting a unique seed and thus creates a unique sequence. The sequence generation is based on a 64-bit starting point and an LSFR with polynomial $x^{64} + x^4 + x^3 + x + 1$. Should the column be non-zero, then the sequence is fast-forwarded the appropriate number of steps. This ensure that parts of a write can be read, and the device is still able to derandomize it.

105.11 Write Protect

A flash memory device can be set in Write Protect mode using the WP_n pin.

The core controls those pins through the *Core control 3 register*, one bit per channel. Setting any of those bits to '1' will activate the corresponding WP_n pin. If the field is updated while the controller is executing another command, the WP_n pin will be updated after that command is finished. The status can be monitored in the *WP field* of the *Core status 0 register*.

105.12 Usage and examples

105.12.1 Configuration and start

To use NANDFCTRL2, it has to be instantiated with generic parameters that configure its usage, see section 105.16 for more details. General setup and run-time configuration of the core are done through a number of APB registers and a descriptor which can be placed in the APB area or memory elsewhere. Status is placed both in the descriptor and in the other registers.

Data interface is configured using the *IFSEL* field in the *Core control 0 register*. Configuration of timing mode is done in the *Programmable timing register 0-11* and the *EDO* bit in the *Core control 0 register*. For all accesses, the core decodes and selects the timing to be used from the timing registers and the frequency of the core and phy clocks.

The interrupt mask is configured in the *Core control 1 register* and the Ready/Busy timeout is setup in the *Programmable Timeout 0 register*. Interrupt status and timeout status can be read in the *Core Status 1* and *Core status 2 registers*. There is also a number of descriptor interrupt enable bits in the *Descriptor command register* which can be used to disable interrupts per descriptor access. Note that both interrupt enable bits in *Core control 1 register* and in *Descriptor command register* needs to be set for the core to generate an interrupt. Several of the interrupt status bits are also available on descriptor level in the *Descriptor status register*.

The *Core control 0 register* hold the setting of EDAC enable (*EE* bit), Data randomization enable (*RE* bit), Preserve bad block (*BBM* bit) and Memory Selection (*MSEL* field). In addition Linked List Mode is enabled setting the *LLM* field to '1'.

If the AHB bus is used, the *DD* bit in the *Descriptor command register* must be '0' and the *Descriptor data pointer registers* must point to where data should be fetched or written. If *DD* is set to '1' and the current operation has a write data payload, assure the *Data-out registers* are properly configured. If data is read from the flash memory device it will be stored in the *Data-in registers* (when *DD* is set to '1'). Note that the *DD* field is placed in the descriptor and can be updated per access.

If linked list mode should be used, configure *LLM* to '1' and setup the *Linked list pointer registers* to the first descriptor in memory. Note that the last descriptor in a linked list shall have its *EN* bit set to 0 to stop reading the linked list. This descriptor will not be executed. If register mode should be used, configure the descriptor over APB (*Descriptor registers*).

Setup the Descriptor registers *Descriptor target select 0, Descriptor channel select register* and *Descriptor ready/busy select register* for accessing the correct flash memory device(s).

Setup the Row address in the *Descriptor row register* for the current access. The *RowAddr* field is used for Row address but is also utilized for commands having an address phase that is not three bytes long. Those commands includes Read ID, Read Unique ID, Read Parameter Page, Get Features, Set features, LUN Set Features, LUN Get Features, ZQ Calibration Long and ZQ Calibration Short. In the case of using one or two bytes, the lower bytes should be used. Note that if randomization is enabled the row address needs to be set correctly even if the specific access doesn't require it. This is due to the reason that the randomization algorithm utilize the row address.

Configure the Column address and size in the *Descriptor column & size register*. The *COLADDR* field is used for column address only. The *SIZE* field is used for defining the number of bytes in the data phase. Software does not need to set this field for the commands Set Features, Get Features, Read

Status, or Read Status Enhanced their data phases are always the same size. The core also ignores this field if the command issued doesn't have a data phase, as for example BLOCK ERASE.

Setup the *Descriptor command register* including the remaining descriptor-specific configuration fields. Those are described in more detail in the next section 105.12.2.

A Descriptor access is started by setting the *DT* bit in the *Core control 2 register*. If the *EN* bit in the *Descriptor command register* is set the core starts to fetch a descriptor. If the *EN* bit is cleared the descriptor will not be considered valid and will not be executed. The *DA* bit in the *Core Status 0 register* can be monitor if the current access is ongoing. In linked list mode the *DA* bit will stay high until the last descriptor is done.

The *Descriptor status register* holds the *UE* bit which indicates the BCH decoder have one or more uncorrectable errors. The *ECFAIL* field in the same register indicates which chunk(s) that was uncorrectable. The *INV* field in the same register indicates that the last access was invalid. The *Descriptor ECC status register* holds additional information from the BCH decoder including the number of corrected errors in the worst chunk (*CEC* field) and the total number of corrected errors over all chunks (*CE* field).

Non-descriptor accesses includes updating Write Protect, updating sefi_flag, send soft reset, abort and stop linked list. Updating the WP_N pin is done by changing the corresponding bit the *Core control 3 register*. The WP field in the *Core status 0 register* can be used to monitor if the WP_n value has been updated. Note that it might be a latency from updating WP control until the actual value is updated in case the controller is busy with another access. Updating the sefi_flag pin is done by setting the corresponding bit in the *Core control 4 register*. A soft reset is initialized by setting the *RST* bit in the *Core control 2 register*. It resets all APB registers of the core.

The *RDY* field in the *Core status 0 register* indicates if the controller has completed its reset procedure or not. Descriptor trigger (*DT* field in the *Descriptor command register*) will be ignored while the RDY field is set to '0'.

The *DA* field in the *Core status 0 register* indicates that the controller is executing one or a sequence of descriptors. It is prohibited to update any control signals while *DA* is set to '1'.

The *RBSTAT* field in the *Core Status register 3* can be used to monitor the current value of each R/B_n pin.

105.12.2 Configuring a descriptor access

Some ONFI operations can be executed with a NANDFCTRL2 single descriptor access, while other might require a chain of accesses (multiple-access) to achieve the wanted sequence. Refer to section 105.1.2 for which commands that are supported in this revision of the IP. A single-access always starts with a command (*cmd1)* and can be followed by different combinations of address phase, datain or dataout phase, second command and wait for ready/busy depending on the configuration of the *Descriptor command register*. Below are the fields in the register described.

The *cmd1* field holds the first command byte to be executed. This corresponds to the 1st cycle in ONFI 4.0 specification table 90.

The *cmd2* field holds the second command byte to be executed. This corresponds to the 2nd cycle in ONFI 4.0 specification table 90. This field is ignored for commands only having a first command or accesses where the *sc2* field is set.

The *Pre-cache* field should be used for cache read operations when randomization is enabled and the randomization seed should use the previous commands configuration.

Sub_cmd. Commands starting with *cmd1* = 0x80 or 0x85 will have different address phase and different timing depending on the setting of *sub_cmd,* see the ONFI 4.0 Specification for more information. The sub_cmd can be configured for a "normal" program operation, Small data move, Change Write Column or Change Row Address. The core ignores this field for all other commands.

SA. THIS FIELD IS NOT IMPLEMENTED IN THIS REVISION OF THE IP AND MUST BE SET TO 0.

Skip data (*SD*) can be used for accesses that should exclude the data phase. One example is Read Parameter Page that can be read with a data phase directly, or without data phase followed by a Change Read Column command.

The *sc2* field is used to skip the second command of the access. For some commands it is not possible to explicitly decode if both *cmd1* and *cmd2* should be used, and *sc2* needs to be set specifically. This includes accesses with *cmd1* = 0x80 or 0x85. One example is a page program combined with one Change Write Column, where the first access will be *cmd1* = 0x80 with *sc1* = 1, and the second (and final) access will be *cmd1* = 0x85 and *cmd2* = 0x10. The core ignores this field for commands for all other commands.

The *ED* field can be used to disable EDAC for the current access.

The *RD* field can be used to disable Randomization for the current access.

The *IRQ_DS, IRQ_ECC, IRQ_UERRDL and IRQ_UERRUL* fields can be used to disable descriptor interrupt(s) for the current access.

The *DD* field, DMA Disable, is described in the previous section.

SRB. When this field is disabled the core will wait for the selected R/B_n signals to go '0' followed by a '1'. If this field is enabled the core will skip wait for any R/B_n signals. In the case of a read operation the core will go back to an idle state and a new access is needed to read the data once the memory device is in a ready state.

105.12.3 First setup example

1. In the case the core is in an unknown state and have not been reset, the user can abort any ongoing operation by setting the *Abort* bit in the *Core control 2 register* and wait for the operation to complete by reading the *Abort* bit in the *Core status 1 register* and the *RDY* bit in the *Core status 0 register*.

2. Send a soft reset by setting the *RST* bit of the *Core control 2 register* to reset all APB registers.

3. Setup Core control registers and Timing registers and Timeout register.

4. Setup Target, Channel and Ready/Busy in Descriptor.
Desired targets and channels are selected using their dedicated registers: *Descriptor target select register*, *Descriptor channel select register* and *Descriptor ready/busy select register.*

5. Issue a RESET command to selected targets using CMD1 = 0xFF.

6. Perform a READ_ID for selected target to scan for NAND flash device.

7. Perform a READ PARAMETER PAGE for selected target.

8. Setup Core Control registers and Timing registers accordingly with information from parameter page.

9. Get/Set Feature (Target/LUN) if needed as part of setup.

10. Make sure the flash memory is not in write protect mode by reading the *WP* fields in the *STS0 register,* otherwise the WP bit can be cleared to deselect Write Protection signal in *CTRL3 register*.

105.12.4 General setup example

1. Setup Target, Channel and Ready/Busy in Descriptor.

2. Setup command CMD1 or commands CMD1 & CMD2 to the *DCMD register*, and set the control bits accordingly to usage. Select if an interrupt should be generated when the command is finished and set EN bit to '1'.

3. Setup row address (or just an address) via *DROW register* if needed.

+46 31 7758650 | frontgrade.com/gaisler

4. Setup column address via *DCOLSIZE register* if needed. Setup size via *DCOLSIZE register* if needed. Commands that reads or writes data needs to setup size.

5. Start execution by writing '1' to *DT* bit in the *CNTRL2 register.*

Once an access has been started software can wait for an interrupt if the core was configured to generate IRQ_DS or monitor STS0 to find out if the descriptor is active.

105.12.5 Changing data interface

Configuration of the nand flash device(s) and the controller to the NV-DDR2 data interface requires a few steps.

1. Configure NANDFCTRL2 to SDR data interface using *IFSEL* and the *Programmable timing registers.*

2. Configure NANDFCTRL2 for a Set Feature command which configures the nand flash device(s) to NV-DDR2 data interface.

3. Configure NANDFCTRL2 for NV-DDR2 data interface using *IFSEL* and the *Programmable timing registers.*

105.12.6 Write chunk example

It is possible to write to the data area with one chunk per access. It is then necessary to loop over all chunks and write them one by one using PAGE_PROGRAM command and multiple CHANGE_WRITE_COLUMN commands interleaved.

1st chunk written should have PAGE_PROGRAM for CMD1 and SC2 set to '1'. Size should be chunk size and column address set to aligned column address for the 1st chunk. Chunk 2 to n-1 should have CMD1 set to CHANGE_WRITE_COLUMN. Sub-command SUB_CMD should be set to Change_write_column. Size should be set to chunk size and column address set to aligned column address for the selected chunk. Last chunk should have CMD1 set to CHANGE_WRITE_COLUMN and CMD2 set to 0x10 (2nd cycle of PAGE PROGRAM), SC2 cleared to '0' and sub-command SUB_CMD should be set to Change_write_column. Size should be set to chunk size and column address set to aligned column address for the last chunk.

This setup creates a PAGE_PROGRAM with correct cmd1 cycle and cmd2 cycle with CHANGE_WRITE_COLUMNS inserted in between with cmd1 cycle.

If any write to spare area has to be performed after data area access, the last chunk must set SC2 to prevent a write access to start.

105.12.7 Read chunk example

It is possible to read from the data area with one chunk per access. It is then necessary to loop over all chunks and read them one by one.

1st chunk read should have PAGE_READ command setup in CMD1 and CMD2. Size should be chunk size. Chunk 2 to n should have CMD1 and CMD2 set to CHANGE_READ_COLUMN. Size should be set to chunk size and column address set to aligned column address for the selected chunk.

This setup creates a PAGE_READ with correct CMD1 cycle and CMD2 cycle followed by CHANGE_READ_COLUMNS cycles.

105.12.8 Write data example

It is possible to write to the whole data portion of a page with one access using PAGE_PROGRAM command and size equal to whole data area. NANDFCTRL2 will then loop over all chunks and write them one by one using PAGE_PROGRAM command with interleaved CHANGE WRITE COLUMN commands.

105.12.9 Read data example

It is possible to read from the whole data portion of a page with one access using PAGE_READ command and size equal to whole data area. NANDFCTRL2 will then loop over all chunks and read them one by one using page read command and sequences of CHANGE_READ_COLUMN commands.

105.12.10 Write spare example

A write access to the spare area is done via CHANGE_WRITE_COLUMN and size set to desired size.This presumes that the data area has been accessed before and that the 2nd cycle of PAGE_PROGRAM has not been issued. The 2nd cycle of PAGE_PROGRAM can be set as CMD2.

105.12.11 Read spare example

A read access from the spare area is done via CHANGE_READ_COLUMN and size set to desired size. This presumes that a READ_PROGRAM has been issued before.

3		DMA write error (UL).
		This is set when there is an error in DMA Uplink.
2		ECC error (ECC).
		This is set when the BCH decoder detects an uncorrectable chunk.
1		Descriptor finished (DS).
		This is set when the descriptor is finished.
0		Main Interrupt (IRQ)
		This is set when an AMBA interrupt have been issued.

105.13.8 Core status 2 register

*Table 2079.*0x028 - STS2 - Core status 2 register

31		16
	TMOUT	
	0	
	wc	

15		0
	TMOUT	
	0	
	wc	

31:0 Ready/Busy timeout (TMOUT).
This is set when there is an Ready/Busy timeout. There is one bit per RB_n signal, i.e. Ready/Busy Tmout signal 0 corresponds to bit 0.

105.13.9 Core status 3 register

*Table 2080.*0x02c - STS3 - Core status 3 register

31		16
	RBSTS (31:16)	
	0	
	r	

15		0
	RBSTS (15:0)	
	0	
	r	

31:0 Ready/Busy Status (RBSTS) for RB_n signals 0-31
The register shows the current status for each R/B_n input signal.
The least significant bit in this field corresponds to the lowest ready busy signal (RB_n(0)) etc.
The actual number of bits implemented equals the *nrofrb* field +1 in the *Capability 0 register*.

0	0	0	0	0	0	0	0		0	0	0	0	0	0	0
rw	rw	rw	rw	rw	rw	rw	rw		rw	rw	rw	rw	r	rw	rw

31:24   Second command phase (CMD2)
If the command to execute is a two byte (two phase) command then software should write the second byte of the command to this field. This field corresponds to the 2nd cycle in the ONFI 4.0 specification table 90.
The core ignores this field for commands that only have one command phase, or if SC2 is set.

23:16   First command phase (CMD1)
Software should write this field with the first byte of the command to execute. This field corresponds to the 1st cycle in the ONFI 4.0 specification table 90.

15   Descriptor uncorrectable error in downlink (IRQ_UERRDL)
This field should be set together with the corresponding field in the *Core control 1 register*.

14   Descriptor (IRQ_UERRUL)
This field should be set together with the corresponding field in the *Core control 1 register*.

13   Descriptor (IRQ_ECC)
This field should be set together with the corresponding field in the *Core control 1 register*.

12   Pre-cache (PRECH)
When enabled the controller use the previous commands settings as input to the randomization block. This should be used for cache read operations when randomization is enabled.

11   Data DMA disable (DD)
0: enable data read /write over DMA.
1: disable data read/write over DMA (i.e. use data-in and data-out registers).
Selects if data is read via the Data-in registers or data is written via the Data-out registers via APB or via AHB DMA master.

10   EDAC disable (ED)
0: the *EE* bit in the *Core control register* 0 is used as specified in its description.
1: the *EE* bit in the *Core control register* 0 is ignored and EDAC is bypassed for the current descriptor.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

*Table 2101.*0x160 - DCMD - Descriptor command register

9	Data Randomization disable (RD)
	0: the *RE* bit in the *Core control register* 0 is used as specified in its description.
	1: the *RE* bit in the *Core control register* 0 is ignored and data randomization is bypassed for the current descriptor.
8:7	Sub command (SUB_CMD)
	This field is used to specify how an access with CMD1 = 0x80 or 0x85 should be executed. The different settings will use different length of the address phase (2 or 5 bytes) and use different timing parameters (tCCS or tADL).
	0: Ordinary usage of CMD1 (all different PAGE PROGRAM commands).
	1: Small Data Move.
	2: Change Write Column.
	3: Change Row Address.
6	Skip Ready/Busy (SRB)
	0: The controller waits for the selected R/B_n signals to go low and high.
	1: The controller do not wait for the R/B_n signal. In the case of a read operation that triggers the memory device to go busy the controller will go to an idle state and not read any data. A new access is required to read the data once the memory device is in a ready state.
5	Skip Address (SA)
	NOTE: THIS FUNCTION IS NOT SUPPORTED FOR THIS REVISION OF THE IP.
4	Skip Data (SD)
	0: The data phase will be included in the descriptor access.
	1: The data phase will be excluded in the descriptor access.
3	Skip second command phase (SC2)
	For some command (cmd1 = 0x80 or 0x85) it is not possible to decode if both cmd1 and cmd2 shall be used and it is necessary to explicitly exclude cmd2 using this bit.
2	Reserved.
1	Descriptor interrupt (IRQ_DS)
	This field should be set together with the corresponding field in the *Core control 1 register*.
0	Descriptor Enable (EN)
	NANDFCTRL2 will execute the descriptor when the descriptor is triggered by setting the *DT* bit of the *Core Control 2 register* if this bit is set, otherwise the descriptor is not valid and will not be executed.
	0: The descriptor is invalid and is disregarded by the core.
	1: The descriptor is valid and enabled

105.13.35 Descriptor row register

Table 2106. 0x174- DROW - Descriptor row register

31			24	23			16
RESERVED				ROWADDR(23:16)			
0				0			
r				rw			

15							0
ROWADDR(15:0)							
0							
rw							

31:24	Reserved.
23:0	Row Address (ROWADDR) This field sets the three byte row address, which is used to address LUNs, blocks and pages. As described in the ONFI 4.0 specification the least significant part of the row address is the page address, the middle part block address, and the most significant part is the LUN address. (7:0) first address byte to flash device, (15:8) second address byte to flash device, (23:16) third address byte to flash device. Exactly how many bits that are used for each part of the address depends on the architecture of the flash memory. Software needs to write this field prior to issuing any command that has an address phase that includes the row address, as well as for those special commands that have a one or two byte address phase (SET FEATURES; GET FEATURES; READ ID, READ UNIQUE ID, READ PARAMETER PAGE, LUN Set Features, LUN Get Features, ZQ Calibration Long and ZQ Calibration Short). The core ignores this field if the command doesn't use the row address.

105.13.36 Descriptor column & size register

Table 2107. 0x178 - DCOLSIZE - Descriptor column & size register

31							16
SIZE							
0							
rw							

15							0
COLADDR							
0							
rw							

31:16	Command data size (SIZE) If a command has a data out or data in phase then software needs to set this field to the size of the data that should be read / written. Software does not need to set this field for the commands SET FEATURES, GET FEATURES, READ STATUS, or READ STATUS ENHANCED since their data phases are always the same size. The core also ignores this field if the command issued doesn't have a data phase, as for example BLOCK ERASE.
15:0	Column address (COLADDR) This field sets the two byte column address, which is used to address into a flash memory page. See the ONFI 4.0 specification for more information about column address. (7:0) first column byte to flash device, (15:8) second column byte to flash device.

105.14 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0C5.
For description of vendor and device identifiers see GRLIB IP Library User's Manual.

105.15 Implementation

105.15.1 Technology mapping

The core has four technology mapping VHDL generics: *memtech_uldl*, *memtech_ecc0*, *memtech_ecc1* and *tech*. The generic *memtech_uldl, memtech_ecc0* and *memtech_ecc1* controls the technology used for memory cell implementation of uplink and downlink FIFOs, ecc block 0 and ecc block 1. The generic *tech* controls the technology used for the R/B_n synchronization flip-flops.

105.15.2 Reset

The core changes reset behavior depending on settings in the GRLIB configuration package (see GRLIB User's Manual). Additionally, some of the outputs from the core are always asynchronously reset including *ce_n*, *datao*, *dataoe* and *dqsoe*.

105.15.3 Endianness

The core is designed for big-endian and little-endian systems. NANDFCTRL2 automatically detects the endianness of the system by reading a dedicated sideband signal included in the AMBA records.

105.16 Configuration options

Table 2115 shows the configuration options of the core (VHDL generics).

Table 2115. Configuration options

Generic name	Function	Allowed range	Default
hindex	AHB master index.	0 - NAHBMST-1	0
pindex	APB slave index.	0 - NAPBSLV-1	0
pirq	APB irq number.	0 - NAHBIRQ-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFE#
ahbbits	Width of AHB read/write data buses and maximum access size.	32, 64	AHBDW
memtech_uldl	Memory technology used for in uplink and downlink	0 - NTECH	inferred(0)
memtech_ecc0	Memory technology used for in ECC block 0	0 - NTECH	inferred(0)
memtech_ecc1	Memory technology used for in ECC block 1	0 - NTECH	inferred(0)
tech	Technology used for the R/B_n synch flip-flops	0 - NTECH	inferred(0)
nrofce	Number of chip select signals connected to the core.	1 - 64	8
nrofch	Number of channels (controls IO0-15, DQS, RE_N, WE_N, CLE, ALE, WP_N and OE) connected to the core.	1 - 16	8
nrofrb	Number of RB_n and SEFI_FLAG signals connected to the core.	1 - 32	8
rnd	Enable randomization support.	0 - 1	1
mem0_data	Data size of page in bytes.	4096, 8192, 16384	16384
mem0_spare	Spare size of page in bytes. Note that the spare size needs to be larger than the size of the ECC produces check bytes.	2 - 4096	2208
mem0_sel	Mapping memory setting to a specific ECC block.	0 - 1	0
mem1_data	Data size of page in bytes.	4096, 8192, 16384	8192

*Table 2115.*Configuration options

Generic name	Function	Allowed range	Default
mem1_spare	Spare size of page in bytes. Note that the spare size needs to be larger than the size of the ECC produces check bytes.	2 - 4096	448
mem1_sel	Mapping memory setting to a specific ECC block.	0 - 1	1
mem2_data	Data size of page in bytes.	4096, 8192, 16384	4096
mem2_spare	Spare size of page in bytes. Note that the spare size needs to be larger than the size of the ECC produces check bytes.	2 - 4096	224
mem2_sel	Mapping memory setting to a specific ECC block.	0 - 1	1
ecc0_gfsize	Size of internal symbols in ECC 0. This generic should be set to the lowest value fulfilling the following constraint: $ecc0\_gfsize > log2\ (8*ecc0\_chunk + ecc0\_gfsize*ecc0\_cap)$	13, 14	14
ecc0_chunk	Number of data bytes for ECC 0 (note that this is the size of the data chunk and not including the ECC bytes).	512, 1024	1024
ecc0_cap	Error correction capability of ECC 0. If 0, then no BCH block is instantiated.	0 - 60	60
ecc1_gfsize	Size of internal symbols in ECC 1. This generic should be set to the lowest value fulfilling the following constraint: $ecc1\_gfsize > log2\ (8*ecc1\_chunk + ecc1\_gfsize*ecc1\_cap)$	13, 14	13
ecc1_chunk	Number of data bytes for ECC 1 (note that this is the size of the data chunk and not including the ECC bytes).	512, 1024	512
ecc1_cap	Error correction capability of ECC 1. If 0, then no BCH block is instantiated. ECC 0 needs to be implemented (ecc_cap > 0) for ECC 1 to be instantiated.	0 - 60	16
rst_cycles	rst_cycles controls the time the controller keeps the bi-directional signals to the nand flash device(s) as inputs after reset. It should be set to the number of core clock cycles that gives a total time of 100 ns, which assure the bi-directional signals are not double driven.	0 - 200	10
ft	Fault-tolerance on internal syncrams. Technology specific protection is further documented in the GRLIB-FT User's Manual (grlib-ft.pdf)	0 - 5	0
scantest	Enable scantest support.	0 - 1	0
oepol	Polarity of pad output enable signal.	0 - 1	0

106 NANDFCTRL2 PHY - NAND Flash Memory Controller PHY

106.1 Overview

This chapter specifies different PHYs that should be used between NANDFCTRL2 - NAND flash memory controller and one or more nand flash memory device(s).

The PHY handles the physical interface to the nand flash device(s) assuring the configured timing mode and performance requirements are achieved including DDR. It uses control signals from NANDFCTRL2 including selection of SDR and NV-DDR2/3 data interface and timing parameter.

106.2 NANDFCTRL2 Generic NV-DDR2 PHY

The nandfctrl2_generic_nvddr2_phy supports the NV-DDR2, NV-DDR3 and SDR data interface.

106.2.1 Clocks and constraints

The PHY uses a core clock (clk_core) and a phy clock (clk_phy). There are some constraints on the clocks that needs to be fulfilled:

- clk_core should be the same clock as the core clock of NANDFCTRL2.
- clk_phy must be four times the clk_core.
- clk_phy must be synchronous to clk_core.
- clk_core positive edge must match a clk_phy positive edge.

106.2.2 Configuration options

Table 2119 shows the configuration options of the core (VHDL generics).

Table 2119. Configuration options

Generic name	Function	Allowed range	Default
NROFCE	Number of chip select signals connected to the core.	1 - 64	8
NROFCH	Number of channels (controls DQ0-7, DQS, RE_N, WE_N, CLE, ALE, WP_N, DQ_OE, DQS_OE, DR_MDE, DDR_VALID and DATAI_VALID).	1 - 16	8
NROFRB	Number of RB_n signals.	1 - 32	8
NROFSEFI	Number of SEFI_FLAG signals.	0 - 32	
SCANTEST	Enable scantest support.	0 - 1	0

107   NOELVSYS - High-performance RISC-V RV64GC Processor Subsystem

107.1   Overview

NOEL-V is processor core that can be configured to conform to the 32-bit (RV32) or 64-bit (RV64) RISC-V architecture. It is designed for embedded applications, combining high performance with low complexity and low power consumption.

The NOELVSYS block combines the NOEL-V processor with essential peripherals needed to create a NOEL-V based system-on-chip
Figure 287. NOELVSYS subsystem block diagram

107.1.1 Standard configurations

Various standard configurations are provided that target both FPGA and ASIC implementations.

D-Cache	4x4k	4x4k	4x4k	2x4k	2x4k	
TCM (I/D)	NA**	NA**	NA**	NA**	NA**	Tightly-coupled memory (not yet implemented)

*   May be updated/changed in future releases.

**   To be enabled in future releases.

[Note: Configurations can be updated when new features are available and standardization of more extension are complete.]

The High-performance (**HP**) configuration is defined to primarily target ASIC implementations. The General-purpose (**GP**) is more suited for large/medium FPGA implementations. The Minimal configuration (**MC**) is defined for smaller FPGAs. The "lite" version is a limited version (to reduce resource utilization) of the standard configuration without reducing the feature-set in a significant way.

107.1.2 RISC-V specification

107.1.3 Integer unit

The NOEL-V integer unit implements the RISC-V RV64GCH and RV32GCH specification, including hardware multiply and divide instructions, floating-point instruction, compressed instruction, the hypervisor extension and also sub-sets of the bit-manipulations extension. The dual-issue pipeline consists of 7 stages with separate instruction and data cache interfaces (Harvard architecture).

+46 31 7758650 | frontgrade.com/gaisler

107.1.4 Level 1 cache

NOEL-V has separate instruction and data caches, each with a 64 bit interface towards the CPU pipeline. The instruction cache maintains one valid bit per cache line and buffer forwarding during line-refill to minimize refill latency. The data cache has one valid bit per cache line, uses write-through policy and implements a four double-word write-buffer. Bus-snooping on the AHB bus is used to maintain cache coherency for the data cache. Both data and instruction caches supports up to 16 KiByte size and 4-ways set associativity. The cache line size is 32 bytes and replacement policy is LRU.

[Note: the size of data and instruction cache depends on the standard configuration selected.]

107.1.5 Floating-point unit

The NOEL-V floating point unit implements the RISC-V F and D extensions, i.e. single and double precision floating point operations. A fully pipelined high-performance GRFPUnv or an iterative nanoFPUnv version can be configured. Note that the GRFPUnv is provided separately.

107.1.6 Memory management unit

A Memory Management Unit is integrated into the NOEL-V cache controller. It implements the full RISC-V specification, and provides mapping between multiple 64/32-bit virtual address spaces and physical memory. A hardware table-walk is implemented, and the MMU has separate fully associative TLBs for instructions and data (and G-stage when hypervisor is available).

[Note: For RV64 only Sv39 (i.e. 39 bit virtual addressing using a three level page table) is available. RV32 only supports Sv32.]

107.1.7 Physical Memory Protection unit

The NOEL-V supports the standard RISC-V PMP. This allows for region based memory protection, whether an MMU is available or not.

107.1.8 Virtualization support

The NOEL-V implements the Hypervisor extension. This extension is enabled for the HPP and GPP standard configurations. All mandatory and some optional features of the extension are implemented, including the extension of the MMU to support two-stage address translation (with hardware page table walk).

[Note: The virtualization currently only supports RV64 Sv39x4. Currently the PLIC interrupt controller do not support directly assignments of interrupts to guests virtual machines. This will be added in future releases.]

107.1.9 On-chip debug support

The NOEL-V subsystem includes functionality to allow non-intrusive debugging on target hardware. Through a debug module interface, full access to all processor registers is provided. The debug interface also allows single stepping, setting hardware breakpoints, and instruction tracing. An internal trace buffer can monitor and store executed instructions, which can later be read out via the debug interface.

Interfaces to access the debug functionality are connected using a dedicated AHB port that does not interfere with normal operation.

107.1.10 Interrupt interface

A core local interrupt controller is included in the subsystem to support local interrupts (which is described in the RISC-V privileged architecture standard v1.10). This controller supports software

interrupts, the timer interrupts, and the external interrupt (generated via the platform interrupt controller PLIC).

Core Local Interrupt controller register:

The subsystem also includes a platform interrupt controller (PLIC, following the RISC-V Platform-Level Interrupt Controller Specification). The controller supports multiple harts, 32 interrupt sources, and 8 priority levels. Fore each hart, 4 context are defined.

*Table 2135.*PLIC context maping

5	Hart 1 supervisor-level external interrupts
6	Hart 1 Reserved
7	Hart 1 Reserved
8	...

107.1.11Standard peripherals

The NOELVSYS block includes standard APBUART and GPTIMER peripherals as are typically expected by software.

107.1.12AMBA interface

An AMBA 2.0 AHB bus is included in the subsystem. Each processor's cache system implements an AMBA AHB master, to load and store data to/from the caches, that is connected to the AHB bus. During line refill, incremental bursts are generated to optimise the data transfer. The AMBA interface can be configured to either 64 or 128-bit data width.

External slaves (memory controllers) and masters (peripheral DMA) are connected to the subsystem via ports. The external AHB slaves may either be narrow (support maximum 32-bit width) or wide (support full width of AMBA bus).

An APB controller is also included in the subsystem for the internal peripherals, and additional external peripherals may be connected via a subsystem port.

107.1.13 Power-down mode

The WFI (Wait For Interrupt) instruction is currently implemented as a NOP. A proper power-down mode will be added in future releases.

107.1.14 Multi-processor support

To support Multiprocessor systems the A (Atomic) extension is implemented. The write-through L1-caches combined with the snooping mechanism guarantees memory coherency in shared-memory systems.

107.2 NOEL-V integer unit

107.2.1 Overview

The NOEL-V integer unit contains the main processor pipeline and implements the integer part of the RISC-V instruction set. The implementation is focused on high performance and has the following main features:

- 7-stage dual issue instruction pipeline
- Separate instruction and data cache interfaces
- Hardware multiplier and divider
- Dynamic branch prediction, branch target buffer and return address stack
- Four ALUs supporting all standard operations, two of them late in the pipeline to reduce stalls

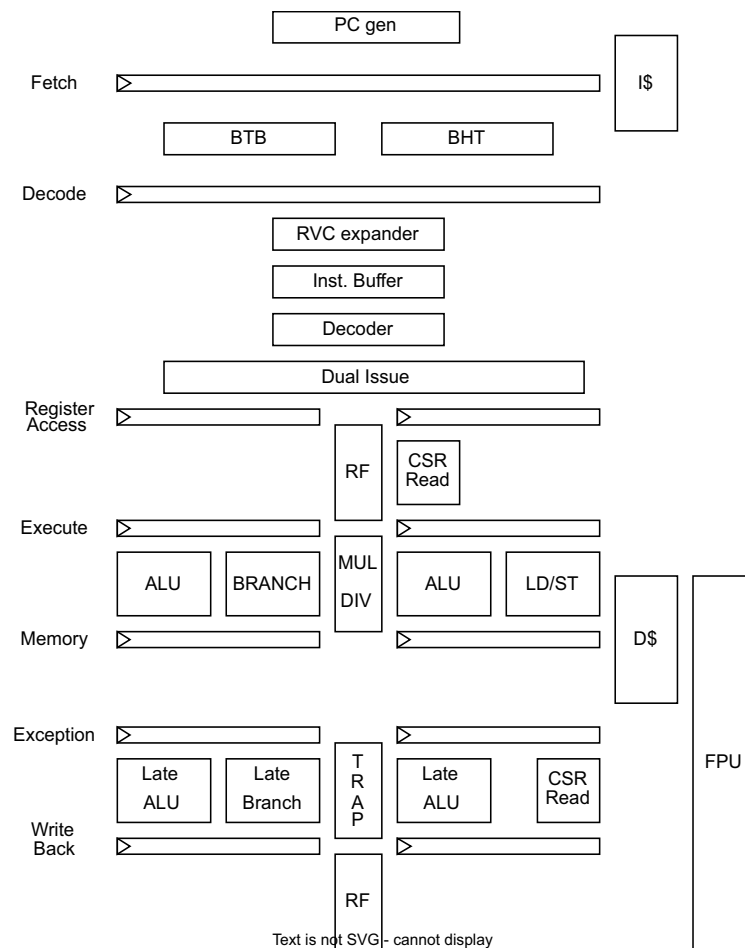
Figure 288 shows a block diagram of the integer unit (and FPU integration).


Figure 288. NOEL-V integer unit datapath diagram

107.2.2 Instruction pipeline

The NOEL-V integer unit uses a dual-issue instruction pipeline with seven stages:

GRIP
Apr 2024, Version 2024.1

1841

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

1. FE (Instruction Fetch): A 64-bit word (holding two to four instructions) is fetched from the instruction cache. The instructions are valid at the end of this stage and are latched inside the IU.
2. DE (Decode): Two instructions at a time are decoded and the branch target addresses are generated. It is determined if dual issue is possible and which instruction goes into which lane of the following stages.
3. RA (Register access): Operands are read from the register file or from internal data bypasses. This is also where pipeline bubbles are inserted to enable dependencies to be satisfied.
4. EX (Execute): ALU, logical, and shift operations are performed in both lanes. Some operations (CLMUL) from the bitmanipulation extension is only supported in one lane. For memory operations (e.g., LD) and for JAL/JALR, the address is generated.
5. ME (Memory): Read data is received from the data cache if accessed. Store data is generated and fed into the data cache inputs at this time.
6. XC (Exception) Exceptions and interrupts are resolved. For cache writes, the data update takes place inside the cache memory on this cycle. Late ALUs and branch unit with full standard functionality are included in this stage to allow delayed dependency resolution.
7. WR (Write-back): The results of ALU and cache operations are written back to the register file.

107.2.3 Interlocks

Additional conditions that can extend an instruction's duration in the pipeline are listed below.

Branch interlock: A mispredicted control flow change will lead to annulation of the predicted instructions, and fetching of the non-predicted target, losing the cycles gained by prediction.

Memory access hold: During cache miss processing or when blocking on the store buffer, the pipeline will be held still until the data is ready, effectively extending the execution time of the instruction causing the miss by the corresponding number of cycles. Note that since the whole pipeline is held still, hold cycles will not mask other delays.

Divide/remainder: These operations will hold the pipeline until finished.

FPU instructions generating integer results: These operations will hold the pipeline until finished.

CSR fflags access: Accessing the FPU flags must wait for all FPU instructions to complete first.

Unresolvable dependencies: When trying to use data results before they are available, the instruction pair will be delayed as needed. The late ALUs in the pipeline will often help avoid this.

Back-to-back store: Smaller than 32 bit writes are not allowed back-to-back.

CSR read: A read from a recently written CSR must wait until the former completed.

Memory access after CSR write: Some CSR writes may affect following a load/store, so it must wait.

Fence instructions, CSR writes that can affect following instruction, and instructions that change privilege mode, will cause a pipeline flush.

107.2.4 Branch predictor and branch target buffer

The pipeline implements a branch predictor in the decode stage. The predictor is configurable at build-time. The pipeline can also be switched over to a static always-taken prediction mode to improve timing predictability.The branch predictor is a two-level per-address adaptive, using per-address pattern history tables (PAp).

A branch target buffer is implemented to predict branch targets in the fetch stage to avoid a one-cycle gap between branches and the target instruction. There is also a return-address-stack to improve handling of subroutine calls.

107.2.5 Late ALU

Late ALUs and a late branch unit are implemented to allow ALU and branch operations normally done in the EX stage to be deferred to the XC state. This allows masking the load and multiply to ALU/branch operation latency, as well as allowing some dependent instructions to be paired.

107.2.6 Hardware breakpoints

A trigger module (following the RISC-V Debug Specification) is implemented to support Match Control triggers and a instruction count trigger. The core has support for two hardware breakpoint registers. The Match control trigger is able to match on instruction, PC, read/write address or read/write data. Currently only action 1 (Enter Debug Mode) is supported. Read/write data triggers will fire after the data access. All other triggers will be fired before the trigger event is executed.

107.2.7 Instruction trace buffer

The instruction trace buffer consists of a circular buffer that stores executed instructions. This is accessed only through the processor's debug port via the Debug Module. When the CPU is running, the following information is stored in real time, without affecting performance:

- Instruction address and opcode

- Instruction result

- Load/store data

- Trap/Interrupt information

- Privilege mode

- 32-bit time tag

107.2.8 Processor reset operation

The processor is reset by asserting the RESET input for at least 4 clock cycles. The following table indicates the reset values of a subset of the registers which are affected by the reset.

Table 2136. Processor reset values

Register	Reset value
PC (program counter)	0xC0000000

By default, the execution will start from address 0xC0000000. This can be changed from the debug port before the integer unit is started.

107.3 Dual issue pairing and Optimization Guide

This chapter assumes that a full standard configuration of NOEL-V is used. That is, with both pipelines active and containing late ALUs and a late branch unit, as well as the pipelined FPU.

107.3.1 The NOEL-V pipeline

The NOEL-V instruction pipeline (see 288) is capable of issuing and retiring two instructions per cycle, compressed or not. Compressed instructions obviously use less instruction cache space, but that is their only impact on performance. The discussion below does not concern itself with this.

There is currently no instruction fusion. If that is eventually added, it is possible that compressed instructions might be advantageous.

Instructions are always fetched 8 bytes at a time, from aligned addresses. This does not mean, however, that two instructions that were fetched together will necessarily be paired in the pipeline. There may be buffered instructions available, for example due to the use of compressed instructions.

The integer side of the pipeline is currently strictly in-order - no instruction will ever "pass by" another during execution, invisibly or not. Only a few instructions take more than one cycle to actually execute, so the forwarding mechanism in the pipeline will usually allow instructions in an imme-

GRIP
Apr 2024, Version 2024.1

1843

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

diately following pair to depend on results from the previous pair without penalty. Even dependencies within a pair can often be handled by having the second instruction execute in a late ALU.

The pipelined FPU has only a single "lane" (though there are actually three separate internal pipelines) and since most operations take more than one cycle to execute, there is only limited forwarding. FPU instructions actually pass through the integer pipeline, notifying the FPU (to issue) when they pass the execute stage, and when they reach the write-back stage (to retire/cancel). Inside the FPU, instructions will issue in-order once their dependencies can be met. But unlike on the integer side, they may complete out-of-order (both with respect to each other and the integer side). The FPU is capable of queuing a couple of instructions, so as not to stall the integer side immediately when internal dependencies block immediate issue. Data transfer from the FPU to the integer side will, however, force an immediate stall since the data is returned directly in the execute stage. Transfers the other way will never stall the integer side, and happen from the exception stage.

107.3.2 Simple optimization

While the details will be described below, they can get rather complicated. Often it is enough to follow a few relatively simple rules for reasonable performance.

- It never hurts to put more separation between dependent instructions.

- A single instruction as separation between dependent ones is usually enough for non-FPU.

- Even no separation is often OK, but avoid doing it for more than two instructions in a row.

- Only one branch or jump in a pair.

- Only one load or store in a pair.

- Avoid load in a pair directly after a pair that does a store.

- Avoid stores of smaller than 32 bit data in successive pairs.

- Avoid FPU instructions without separation (currently does not help, but will later).

- Four pairs of separation is often OK for FPU dependencies.

- Dependencies on FPU divide and square root ought to be some ~25 pairs away.

- Avoid integer division - it does not (currently) help if dependencies are far away.

107.3.3 Optimization details

The following text refers to RISC-V opcodes and NOEL-V internal instruction types.

See tables 2142 and 2143 for descriptions of these.

107.3.4 Pairing conflicts

Pairing of instructions is handled in the decode stage. After two instructions are fetched and/or removed from the fetch buffer, they are initially assumed to be paired - the first instruction in lane 0 and the second in lane1. They will stay together through the pipeline unless there is a specific reason to disallow this pairing, which would split them apart (the second one then becoming available for the next pairing).

GRIP
Apr 2024, Version 2024.1
1844
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Paired instructions will be swapped automatically between the two lanes if at least one of them can only be handled in a specific pipeline.

Table 2137. Forced lanes

Instruction type	Lane	Comment
Anything that touches memory	0	
Branches	1	
FPU operations	0	Currently. May change in the future, except for FPU load / store.
CSR accesses	0	Currently. May change in the future.
Carry-less multiplicaton (clmul / cmulr / cmulh)	0	Can only be done in the early ALU of lane 0 (could be a build option). Other special ALU operations like this may be added later.

Most of the checks for conflict refer only to the two instructions in the proposed pair. But there is also a check for a dependency on a late ALU operation in the preceding pair.

Table 2138. Register name explanation

Register	Meaning
Rd^0 / Rd^1	Destination register in lane 0/1.
$Rs1^0$ / $Rs1^1$	Source register 1 in lane 0/1.
$Rs2^0$ / $Rs2^1$	Source register 2 in lane 0/1.

Table 2139 shows pairings that are not allowed for a full-featured NOEL-V. This is before swapping lanes, so it needs to check for any necessary swapping and disallow pairings that would make such impossible.

ALU_SPECIAL	Anything
Anything	CSR write that may affect instruction execution or flush pipeline
Anything with destination (Rd^0)	$Rs1^1 = Rd^0$ or $Rs2^1 = Rd^0$, for SYSTEM / MISC-MEM / JALR / *custom-0* / OP-FP (any variant using integer Rs1 or Rs2) [2nd dependent on 1st and not simple ALU operation.]
Anything with destination (Rd^0)	$Rs1^1 = Rd^0$, for *LD / ST / AMO* [Address]
MUL (Rd^0)	$Rs2^1 = Rd^0$, for *ST / AMO* [Data]
OP / OP-32 / OP-IMM / OP-IMM-32 / LUI / AUIPC (Rd^0)	$Rs1^1 = Rd^0$ or $Rs2^1 = Rd^0$, for *MUL*
CSR Rd^0	$Rs1^1 = Rd^0$ or $Rs2^1 = Rd^0$), for any
Anything with destination (Rd^0)	$Rd^1 = Rd^0$, when either instruction is *LD* or CSR access
OP / OP-32 / OP-IMM / OP-IMM-32 / LUI / AUIPC (Rd^0) and instruction using late ALU in previous pair (RA stage), where lateRA-$Rd^0 = Rs1^0$ / $Rs2^0$ or lateRA-$Rd^1 = Rs1^0$ / $Rs2^0$	$Rs1^1 = Rd^0$ or $Rs2^1 = Rd^0$, for any [2nd dependent on 1st (which would have been handled by doing 2nd late), and late ALU is impossible due to 1st being dependent on late in RA (and thus also late).]

107.3.5 Pipeline hold and late ALU / branch

n the register access stage, it is decided whether the pipeline needs to hold (insert bubbles) or not. The "redirection" to the late ALUs or the late branch unit is also handled here.

Table 2140 shows the cases where the pairing itself requires one of the instructions to be executed late, and when earlier things in the pipeline forces a hold.

ST	Any store, including atomic instructions that store. Also store type custom instructions.	STORE / STORE-FP / AMO and some of *custom-0*

107.4 Cache system

107.4.1 Overview

The NOEL-V processor pipeline implements a Harvard architecture with separate instruction and data buses, connected to two separate caches. As long as the execution does not cause a cache miss, the cache controllers can serve one beat of an instruction fetch and one data load/store per cycle, keeping the pipeline running at full speed.

On cache miss, the cache controller will assert a hold signal, freezing the IU pipeline. After delivering the data, the hold signal is again lifted so that execution continues. The miss processing is handled by a state machine common to both the instruction and data caches.

Another important component included in the data cache is the write buffer, allowing stores to proceed in parallel to executing instructions.

Cachability (memory areas that are cachable) for both caches is controlled through the AHB plug&play address information or using a VHDL generic, see section 107.4.14.

107.4.2 Cache operation

Each cache controller has two main memory blocks, the tag memory and the data memory. At each address in the tag memory, a number of cache entries, ways, are stored for a certain set of possible memory addresses. The data memory stores the data for the corresponding ways.

For each way, the tag memory contains the following information:

- Valid bits saying if the entry contains valid data or is free. Both caches have a single valid bit for each cache line.

- The tag, all bits of the cached memory address that are not implied by the set

When a read from cache is performed, the tags and data for all cache ways of the corresponding set are read out in parallel, the tags and valid bits are compared to the desired address and the matching way is selected. In the hit case, this is all done in the same cycle to support the full execution rate of the processor.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

In the miss case, the cache will at first deliver incorrect data. However on the following cycle, a hold signal will be asserted to stall the pipeline and prevent it from proceeding with that data. After the miss has been processed, the correct data is injected into the pipeline using a memory data strobe (mds) signal, and afterwards the hold signal can be released. If the missed address is cachable, then the data read in from the cache miss will be stored into the cache, possibly replacing one of the existing ways.

The instruction cache implements a buffer forwarding scheme to reduce instruction cache miss latency. While the cache line is being read in from the AHB bus and stored into the cache memories, the data is stored temporarily in a flip flop buffer inside the cache controller. The cache can serve instructions to the pipeline directly out of this partially filled buffer. This works even in case of branches as long as the instruction flow stays on the same cache line.

107.4.3 Cache configuration

Least-recently-used (LRU) replacement is used for the caches. This maintains the order of usage for each set in the cache and replaces the one which was used least recently. The LRU information needs to be updated on every cache hit and is therefore not stored with the tags but in separate flip flops. The cache configuration (size and associativity) for the standard CPU configuration is described in Table 2125.

107.4.4 Address mapping

The addresses seen by the CPU are divided into tag, index and offset bits. Because the index is used to select the set in the cache, only a limited number of cache lines with the same index part can be stored at same time in the cache. The tag is stored in the cache and compared upon read.

1 KiB way, 32 bytes/line

PHYHIGH	10	9	5	4	0
Tag		Index		Offset	

4 KiB way, 16bytes/line

PHYHIGH	12	11	4	3	0
Tag		Index		Offset	
Figure 289. Cache address mapping examples

PHYHIGH: Highest bit in the physical address (equal 31 for system with 32-bit physical address).

107.4.5 Data cache policy

The data cache employs a write-through policy, meaning that every store made on the CPU will propagate, via the write buffer, to the bus and there are no "dirty" lines in the cache that have not yet been written out, apart from what is in the buffer. The store will also update the cache if the address is present, however a new line will not be allocated in the case when it is not.

*Table 2144.*NOEL-V Data caching behavior

Operation	In cache	Cacheable	Bus action	Cache action	Load data
Data load	No	No	Read	No change	Bus
	No	Yes	Read	Line allocated/replaced	Bus
	Yes	-	None	No change	Cache
Data store	No	No	Write (via buffer)	No change	(N/A)
	No	Yes	Write (via buffer)	No change	(N/A)
	Yes	-	Write (via buffer)	Data updated	(N/A)

107.4.6 Write buffer

The data cache contains a write buffer able to hold up to four 8, 16, 32, or 64-bit writes. For half-word or byte stores, the stored data is replicated into proper byte alignment for writing to a word-addressed device.

The write is processed in the background, so the system can keep executing while the write is being processed. The write buffer acts as a FIFO where new stores can be added continuously to allow one store per cycle throughput. Only "regular" stores that hit in the TLB are handled through the write buffer, other types of writes will be handled separately.

While a store is ongoing, any following instruction or data access that requires bus access will block until the write buffer has been emptied. Loads served from cache will however not block, due to the cache policy used there can not be a mismatch between cache data and store buffer.

Since the processor executes in parallel with the write buffer, a write error will not cause an exception to the store instruction. Depending on memory and cache activity, the write cycle may not occur until several clock cycles after the store instruction has completed. Since there is nothing that can be done about a late write buffer error, an NMI interrupt will be taken.

[Note: The NMI interrupt will be added in future releases.]

107.4.7 Operating with MMU

The MMU functionality is integrated into the cache controller. When MMU is enabled, the virtual addresses seen by the running code no longer correspond directly to the physical addresses on the AHB bus. The cache will translate each access's virtual address to its physical address in parallel with looking up the tag for that access.

The cache uses a virtually-indexed-physically-tagged (VIPT) approach, where the tags are based on the physical addresses but the address into the cache memory is based on the virtual address.

107.4.8 Snooping

The data cache includes support for AHB bus snooping. The AHB bus that the processor is connected to is monitored for writes from other masters to an address which is in the cache. If a write is done to a cached address, that cache line is marked invalid and the processor will be forced to fetch the (new) data from memory the next time it is read.

An extra tag memory, storing separate physical tags, is added to allow comparing with the physical address on the AHB bus.

The processor can snoop on itself in order to detect MMU updating page table entries, and to flush out possible aliases in the cache.

Snooping requires the way size of the cache to be equal or smaller than the MMU page size, otherwise the index into the physical and virtual tag RAM:s may not match, resulting in aliasing problems.

+46 31 7758650 | frontgrade.com/gaisler

107.4.9 Enabling and disabling cache

Both instruction and the data cache are disabled after reset. They can be enabled by writing to the custom CSR (CCTRL cache control register). See section 107.11.10. The cache tags are initialized automatically after reset to ensure that all tags are invalid.

107.4.10 Cache freeze

Each cache can be in one of three modes: disabled, enabled and frozen. If disabled, no cache operation is performed and load and store requests are passed directly to the memory controller. If enabled, the cache operates as described above. In the frozen state, the cache is accessed and kept in sync with the main memory as if it was enabled, but no new lines are allocated on read misses. The cache mode is set via the CCTRL custom CSR.

107.4.11 Flushing

The instruction cache is flushed when a FENCE.I is executed. The data cache (and also the instruction cache) can be flushed via the custom CSR (CCTRL). See section 107.11.10. Cache flushing takes one clock cycle per cache set, during which the IU will be halted. When the flush operation is completed, the cache will resume the state (disabled, enabled or frozen) indicated in the cache control register (CCTRL custom CSR). Data cache lines can also be invalidated/flushed using the instructions defined in the cache managment operations extension (cbo.inval/clean/flush). The invalidate and flush instruction invalidate the cache line (no data write back due to write-through L1 cache). The clean instruction is handled as a NOP.

107.4.12 Diagnostic access

The cache tag and data contents can be directly accessed for diagnostics via various custom instructions, see section 107.13.

107.4.13 AMBA interface

The NOEL-V cache controller has one AHB master interface to the surrounding system. The types of AMBA accesses supported and performed by the processor depend on the accessed memory area's cachability, the maximum bus width, if the corresponding cache is enabled, and if the accessed memory area has been marked as being on the wide bus.

Cachable instructions are fetched with a burst of 32-bit accesses, or 64- or 128-bit accesses depending on the cache line size and the AHB bus width.

107.4.14 Cachability

Cachability for both caches can be controlled through the AHB plug&play address information, or set manually via the *cached* VHDL generic.

For plug'n'play based cachability, the memory mapping for each AHB slave indicates whether the area is cachable, and this information is used to (statically) determine which access will be treated as cacheable. This approach means that the cachability mapping is always coherent with the current AHB configuration.

When the *cached* VHDL generic is not zero, it is treated as a 16-bit field, defining the cachability of each 256 MiB address block on the AMBA bus. For example, a value of 16#00F3# will define cachable areas in 0 - 0x20000000 and 0x40000000 - 0x80000000.

In order to access the plug'n'play information, the processor takes the ahbso vector as input. Only the static hconfig signals are used, so the use of this input will be eliminated through constant propagation during synthesis.

107.4.15 AMBA access size

Cacheable data is fetched in a burst of 64- or 128-bit accesses, depending on the cache line size and AHB bus width.

The type of AMBA accesses used, and supported by the processor, for a memory area depends on the area's cachability and the values of the *wbmask* and *busw* VHDL generics.

The area which supports 64- or 128-bit access is indicated in the *wbmask* VHDL generic. This VHDL generic is treated as a 16-bit field, defining the 64/128-bit capability of each 256 MiB address block on the AMBA bus. A value of 16#00F3# will thus define areas in 0 - 0x20000000 and 0x40000000 - 0x80000000 to be 64/128-bit capable. The maximum access size to be used in the area(s) marked with WBMASK is determined by the *busw* VHDL generic.

Store instructions result in an AMBA access with size corresponding to the executed instruction. The table below indicates the access types used for instruction and data accesses depending on cachability, wide bus mask (wbmask), and cache configuration.

| Processor operation | Accessed memory area is 32-bit only, wbmask(address) = 0 | | | Accessed memory area is on wide bus wbmask(address) = 1 | | |
| | Area not cacheable[1] | Area is cacheable[1] | | Area not cacheable[1] | Area is cacheable[1] | |
		Cache enabled[2]	Cache disabled		Cache enabled[2]	Cache disabled
Instruction fetch	Burst of 32-bit read accesses	Burst of 32-bit read accesses		Burst of 64- or 128-bit accesses[3]		
Data load <= 32-bit	Read access with size specified by load instruction	Burst of 32-bit accesses	Read access with size specified by load instruction	Read access with size specified by load instruction	Burst of 64- or 128-bit accesses[3]	Read access with size specified by load instruction
Data load 64-bit	**Length-2 burst of 32-bit read accesses**	**Burst of 32-bit read accesses**	**Length-2 burst of 32-bit read accesses**		Burst of 64- or 128-bit accesses[3]	Single 64-bit read access
Data store <= 32-bit	Store access with size specified by store instruction.					
Data store 64-bit	**Length-2 burst of 32-bit stores**			64-bit store access		

[1] Cachability is determined by the *cached* VHDL generic, if *cached* is zero then cachability is determined via AMBA PnP.

[2] Bus accesses for reads will only be made on L1 cache miss.

[3] 64- or 128-bit accesses depending on *busw* VHDL generic.

107.4.16 Error handling

An AHB ERROR response received while fetching instructions will normally cause an instruction access fault exception. However, if this occurs during streaming on an address that is not needed, the cache controller will just not set the corresponding valid bit in the cache tag. If the IU later fetches an instruction from the failed address, a cache miss will occur, triggering a new access to the failed address.

An AHB ERROR response while fetching data into the data cache will normally trigger a Load access fault exception. If the error was for a part of the cache line other than what was currently being requested by the pipeline, a trap is not generated and the valid bit for that line is not set.

An ERROR response during an MMU table walk will lead to a page fault exception, depending on which type of access that caused the table walk.

107.4.17 Snoop port

For the snooping logic, the cache controller has an ahbsi input which listens to the processor AHB bus. For correct function, this must be tied to the same AHB bus as the master interface. It is not possible to snoop on another bus or to add extra pipeline registers to the snoop port, because the snoop logic must be in sync with the master interface.

107.5 Memory management unit

107.5.1 Overview

The memory management unit is integrated into the cache controller. The MMU provides address translation of both instructions and data via page tables stored in memory. When needed, the MMU will automatically access the page tables to calculate the correct physical address. The latest translations are stored in a special cache called the translation lookaside buffer (TLB), also sometimes referred to as a Page Descriptor Cache (PDC). The MMU also provides access control, making it possible to "sandbox" unpriviledged code from accessing the rest of the system.

[Note: For RV64 only Sv39 (i.e. 39 bit virtual addressing using a three level page table) is available. RV32 only supports Sv32.]

107.5.2 MMU/Cache operation

The caches operate with physical address mapping, although the indexing can be done with the relevant part of a virtual address since it is the same. The cache tags store the physical address and each access from the pipeline is translated from virtual to physical in parallel with the tag memory read-out.

No additional clock cycles are needed by the MMU for instruction fetch, data fetch, or stores, as long as the virtual pages accessed are already cached inside the TLB. If there is a TLB miss, the page table must be traversed, resulting in a few AMBA read accesses and possibly one write-back operation.

See the RISC-V specification for the exact format of the page table.

An MMU page fault will generate the appropriate page fault exceptions. In case of multiple errors, the fault type values are prioritized as the specification requires. The cache and memory will not be modified on an MMU page fault.

107.5.3 Translation look-aside buffer (TLB)

Separate TLBs are implemented for instruction and data. The number of entries each TLB has depends on selected standard configuration. When the Hypervisor extension is enabled, a separate TLB is implemented for the G-stage address translation, the second stage of two-stage translation.

The TLBs are replaced using a pseudo-LRU algorithm. Each TLB entry has a single 'visited' bit that is set when that TLB entry is accessed, when all visited bits are set to 1 they are all cleared and the process starts over. When replacing an entry in the TLB, the lowest entry with the visited bit not set will be chosen.

107.5.4 Physical Memory Protection

PMP is configured from machine mode and makes it possible to, for example, enforce read/write/execution protection between separate tasks in a simple realtime system running in supervisor or user mode. It is also possible to enforce protection on machine mode code, by locking specific PMP entries, which cannot be undone without a system reset.

For further details, see the RISC-V documentation.

GRIP

Apr 2024, Version 2024.1

1854

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The number of PMP entries and granularity depends on selected standard configuration, see Table 2125. When MMU is included, PMP granularity cannot be smaller than the page size, 4 KiByte. Even without MMU, the granularity cannot be smaller than 8 bytes.

107.6 Floating-point unit

The NOEL-V floating point unit supports 32 and 64 bit floating point operations, according to the RISC-V standard which in turn is based on IEEE754-2008. It has its own register file and runs in parallel with the integer pipeline, except as necessary to pass results between the two units. Depending on configuration, it can be fully pipelined single-issue (GRFPUnv) or use a state machine to iteratively execute one operation at a time (nanoFPUnv).

As per the RISC-V standard, the normal IEEE754 state is kept in a CSR register - the FPU can not cause an exception (other than faulting memory accesses). Also per the standard, rounding mode can be specified statically in the instructions or dynamically via a CSR register.

107.6.1 Pipelined floting-point unit (GRFPUnv)

GRFPUnv is a high performance FPU, specially designed for the NOEL-V. It supports the RISC-V F and D extensions (single and double precision floating point), and is fully pipelined for normal FPU operations (a separate iterative unit does division and square root using Goldschmidt's algorithm). Operations always issue in-order, one at a time, but may complete out-of-order (besides for effects on execution time, this is invisible from the outside), again one at a time (except that operations returning integer results may complete at the same time as operations returning floating point results). There is no difference in performance between single and double precision operations (except for a couple of cycles in the Goldschmidt engine), but subnormal numbers have a 1-2 cycle penalty.

There is an implementation option to chose if a multiply can be done in one cycle in the target technology, or if two cycles are needed.

Implementation

In the NOEL-V, floating point instructions always pass all the way through the integer pipeline, but they are also sent to the FPU in the execution stage. For operations that give floating point results, the FPU will start working without affecting the integer pipeline. But if an integer result must be returned from the FPU, bubbles will be inserted after that stage until the result is available.

The FPU may temporarily stop accepting new operations if dependencies require an earlier operation to finish before a newer one can be started, or if the iterative Goldschmidt machinery is not yet available for a new operation. There is, however, a tiny "queue" in the FPU that enables it to accept a second operation while waiting, and only another one after that will necessitate the insertion of bubbles in the integer pipeline.

Data passes from the integer pipeline to the FPU without the former ever pausing, and eventually the integer pipeline informs the FPU about whether the instruction was committed or if something, for example misprediction, caused it to be anulled. Only operations that are reported as committed will have their results written to the FPU register file or otherwise used by the FPU. Anulled operations are removed from their place in the FPU.

For normal operations, when there are no dependencies, one floating point result can be produced every cycle. Latency varies depending on the type of operation and in some cases on the instruction mix, as well as on the values involved (subnormal numbers may need to be "normalized" early in the pipeline and subnormal results "denormalized" at the end, also some operations have special handling for NaN, infinity and zero). A diagram of the main FPU pipeline can be seen below. The FPU controller uses another two stages before an operation gets there, and operations that return integer values are done in a separate pipeline. The full latency will only be visible when an FPU operation is followed by a transfer of its result to the integer pipeline. For the latency of some directly dependent operations, see the table below.

An instruction that expects straight binary floating point data from the FPU (such as a store) will have to wait 2 cycles, in the absence of dependencies, while other results returned to the integer pipeline will take 4 cycles.
Figure 290. GRFPUnv pipeline block diagram

The "align" and "adjust" stages can often be skipped when no subnormals numbers are involved. Non-multiplies can often skip "mul", while multiplies can often skip "align2" and "add". Some operations can also skip "round", and operations that involve NaN, infinity or zero may skip some steps.

Notes on performance

Since NOEL-V is an in-order processor and GRFPUnv also always does in-order issueing of operations, it is beneficial to keep dependent operations apart. How far apart instructions must be to not cause unnecessary delays depend on the details. A general rule of thumb for GRFPUnv is that four cycles apart is often "good enough" (see below for more details), but with a dual-issue NOEL-V that is often more than four instructions (assuming some of them are non-FPU instructions).

Dependencies are mainly related to previous destinations being used as sources for later operations (Read after Write). However, there can also be a penalty for reusing a destination register (Write after Write).

Floating point operations that have been committed (they reached the end of the integer pipeline without being anulled) will always run to completion. This means that, for example, storing a floating point register value to the stack (such as on a context switch) can take a lot longer than expected. A square root might just have started executing, and a second one might be queued after it. The store of the destination register of the second square root could be waiting for dozens of cycles in the execution stage.

Table 2145. Throughput for consecutive independent instructions (tested with all the same)

Instruction	Description	Throughput
fsgn, fcvt.d.w, fmul, fadd, fmadd, fld, etc	Instructions with result written to the FPU register file	1
fmv.x.d, fsd, etc	Instructions that pass binary FPU register file data to the integer unit	2
fcvt.w.d, feq, etc	Other instructions that pass data to the integer unit	4
fdiv		21
fsqrt		26

The timings below assume that a single cycle multiplier is used, otherwise add one to the timing of operations that include a multiplication. Also, no subnormal numbers are involved, which could otherwise have added a cycle or two (depending on whether sources and/or results are subnormal).

Table 2146. Latency for consecutive dependent instructions

Instruction	Latency
fsgn fsgn fsgn...	2
fmul fmul fmul...	3
fadd fadd fadd...	4
fmadd fmadd fmadd...	5
fld fsd	7
fmadd eq	10

As the last two examples above show, latencies can be long when an instruction that returns an integer result depends on a directly preceding floating point instruction.

Copying data is best done using integer registers, where copying n elements can take n * 2 + 1 cycles by doing:

```
ld<times n> sd<times n>
```

That is, copying three elements:

```
ld sd ld sd ld sd (3 * (1 * 2 + 1) = 3 * 3 + 1 = 9 cycles)
ld ld ld sd sd sd (3 * 2 + 1 = 7 cycles)
```

If the floating point registers must be used, the same thing can be done and will take n * 3 + 1 cycles, but only for n >= 3 (due to latency inside the FPU):

```
fld<times n> fsd<times n>
```

That is, copying three elements:

```
fld fsd fld fsd fld fsd (3 * 7 = 21 cycles, see table above)
fld fld fld fsd fsd fsd (3 * 3 + 1 = 10 cycles)
```

+46 31 7758650 | frontgrade.com/gaisler

Note, that this assumes that everything is in cache. Also, the write-buffer may limit achievable performance.

107.6.2 NanoFPUnv

The iterative FPU will take short-cuts where possible, but even the simplest float->float operation will take over half a dozen cycles.

107.7 Debug system

107.7.1 Overview

The subsystem includes a debug system (including a debug module) that connects to the debug ports of all CPUs. The debug module handles reset and debug control of the CPU. An AHB access trace is also included in the debug system.

107.7.2 Start-up handling

After reset, the debug module will start up all CPUs to boot from default boot address (see Table 2136). This can be suppressed by asserting the dsubreak signal during reset. If this is set, the processor will be left in stopped state and no instructions will be executed until the user connects with a debugger and starts the processor.

107.7.3 Debug master access

The debug module provides a set of ports for AHB masters to connect to for debug access. Standard debug masters from the GRLIB library can be connected to these debug ports.

The debug module implements a transparent bridge between each debug master and the processor AHB bus, where the debug master can make accesses as if it was on the processor bus directly. However the bridge provides pipeline registers so that there are no direct combinatorial paths between the debug masters and the processor bus, or between the debug masters.

In addition to having access to the processor bus, the debug masters also have debug access to the processors themselves via a register interface that can only be accessed through the debug ports.

The debug masters can be blocked from accessing the system using the dsu_en signal.

107.7.4 Debug module

The debug module is designed according to the RISC-V External Debug Support standard (see section 107.1.2).

[Note: The debug module interface (DMI) is adapted to be used with any debug link available in GRLIB together with the GRMON debug software]

The debug module supports the following features:

- All mandatory control and status registers. This enables the run control functionality.

- Register access via Abstract command. Access support for both GPR and CSR registers.

- Program buffer (implied ebreak)

- Single step (supported via CSR access and run control)

There is no direct access to the FPU registers. The FPU register data needs to be copied to a GPR or CSR register before it can be read out. This can be done by using the program buffer.

The debug link has direct access to the AMBA bus without using the System Bus Access feature described in the standard.

107.8 AMBA bus fabric

The subsystem includes an AMBA 2.0 AHB and APB bus fabric, using the GRLIB AHBCTRL and APBCTRL IP cores. Ports are included to connect external AHB masters and AHB slaves to the processor bus, and to connect additional APB slaves to the APB peripheral bus. The system uses the AMBA Plug and play support and interrupt steering capabilities provided by the GRLIB infrastructure (see GRLIB IP Library User's Manual).

107.9 Standard peripherals

The following standard peripherals are included in the subsystem block:

- Core Local / Platform interrupt controller, used to deliver interrupts to the processors
- General purpose timer (GPTIMER), used for time keeping
- Console UART (APBUART), used for standard console output

The peripherals are connected to the subsystem's APB bus

107.10 Memory map

107.10.1 Physical memory map

The subsystem implements the following memory map as seen from the processor (using physical addresses) or from other masters on the processor bus, or from masters on the debug ports:

Table 2150. Physical bus memory map

Range	Function	Comment
0x00000000 - 0xDFFFFFFF	For use by external AHB slaves (main memory)	Typically, RAM at 0x00000000, ROM at 0xC0000000
0xE0000000 - 0xE000FFFF	Core Local interrupt controller	
0xE0010000 - 0xF7FFFFFF	For use by external AHB slaves	
0xF8000000 - 0xFBFFFFFF	Platform Interrupt controller (PLIC)	
0xFC000000 - 0xFC0000FF	Timer registers	See GPTIMER documentation
0xFC001000 - 0xFC0010FF	Console UART registers	See APBUART documentation
0xFC002000 - 0xFC0FFFFF	For use by external APB slaves	
0xFC100000 - 0xFDFFFFFF	For use by external AHB slaves	
0xFE000000 - 0xFEFFFFFF	Debug module	
0xFF000000 - 0xFFEFEFFF	For use by external AHB slaves	
0xFFF00000 - 0xFFF1FFFF	AHB trace buffer	See AHBTRACE documentation
0xFFF20000 - 0xFFFFFEFFF	For use by external AHB slaves	
0xFFFFF000 - 0xFFFFFFFF	AMBA Plug'n'play information on the debug bus	Read only.

107.11 Processor configuration and status registers (CSR)

This section defines implementation dependent fields in standard CSR and describes implemented custom CSRs.

Table 2151. Standard CSR registers (with implementation dependent fields)

CSR address	Register
0x301	MISA (ISA and extensions)
0x305/0x105/0x205	MTVEC/STVEC/VSTVEC (Trap Vector Configuration)
0x343/0x143/0x243	MTVAL/STVAL/VSTVAL (Trap Value Register)
0x34a/0x64a	MINST/HINST (Trap Instruction Register)
0x34b	MTVAL2 (Second Trap Value Register)
0x30a/0x60a	MENVCFG/HENVCFG (Environment Configuration Register)
0x10a	SENVCFG (Supervisor Environment Configuration Register)
0xF11	MVENDORID (Vendor ID)

```

107.14 Software considerations

107.14.1 Register file initialization on power up

It is recommended that the boot code for the processor writes all registers in the IU and FPU register files before launching the main application. This allows software to be portable to both FT and non-FT versions of the NOEL-V processor.

107.14.2 Start-up

To be documented.

107.15 Vendor and device identifiers

The core has vendor identifiers 0x01 (Frontgrade Gaisler) and device identifiers 0x0BD for the NOEL-V AHB master interface on the processor bus, and 0xBE for the NOEL-V RISC-V debug module (register area) on the debug ports. For description of vendor and device identifiers, see GRLIB IP Library User's Manual.

107.16 Implementation

107.16.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

GRIP
Apr 2024, Version 2024.1

1869

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

[Note: currently only synchronous reset of all registers are supported.]

107.16.2 Technology mapping

NOEL-V has two technology mapping VHDL generics, *fabtech* and *memtech*. The *fabtech* generic controls the implementation of some pipeline features, while *memtech* selects which memory blocks will be used to implement cache memories and the IU/FPU register file. *Fabtech* can be set to any of the provided technologies (0 - NTECH) as defined in the TECHMAP.GENCOMP package. See the GRLIB Users's Manual for available settings for *memtech*.

107.16.3 RAM usage

The instruction cache will use only single-port syncram instances for both tags and data.

The data cache tags can be configured into three different modes depending on the cmemconf generic. Depending on configuration it will use either syncram, syncram_2p or syncram_dp instantiations and valid bits will be either included in the tag or held separately in flip flops. The different modes are functionally equivalent.

The data cache data memory is always implemented using single-port memories. It can be configured to use memories with individual byte-write stobes if such are available in the technology. When byte strobes are not available, byte/half-word updates are handled by forwarding back read data from the same memory which may impact timing on some technologies.

107.17 Configuration options

Table 2164 shows the configuration options of the core (VHDL generics).

Table 2164. Configuration options

Generic	Function	Allowed range	Default
fabtech	Target technology	0 - NTECH	0 (inferred)
memtech	Vendor library for regfile and cache RAMs.	0 - 16#FFFFFFFF#	0 (inferred)
ncpu	Number of processors instantiated in subsystem	1 - 16	1
nextmst	Number of external masters connected to processor AHB bus Note due to limitations of VHDL, this generic must be at least 1. If no external AHB masters are implemented, select one master and use the ahbm_none constant.	1 - NAHBMST	1
nextslv	Number of external slaves connected to processor AHB bus	1 - NAHBSLV	1
nextapb	Number of external slaves connected to APB bus	0 - NAPBSLV	0
ndbgmst	Number of debug masters connected to debug ports Note due to limitations of VHDL, this generic must be at least 1. If no external debug masters are implemented, select one master and use the ahbm_none constant.	1 - NAHBMST	
cached	Fixed cachability mask. See sections 107.4 and 107.4.13 for more information.	0 - 16#FFFF#	0
wbmask	Wide-bus mask. Indicates which address ranges are 64/128 bit capable. Treated as a 16-bit vector with LSB bit (right-most) indicating address 0 - 0x10000000. See section 107.4.13 for more information.	0 - 16#FFFF#	0

108   PHY - Ethernet PHY simulation model

108.1   Overview

The PHY is a simulation model of an IEEE 802.3 compliant Ethernet PHY. It provides a complete MII and GMII interface with the basic, extended status and extended capability registers accessible through the management interface (MDIO). Not all of the functionality is implemented and many of the register bits are therefore only writable and readable but do not have any effect. Currently only the loopback is supported.

108.2   Operation

The PHY simulation model was designed to make it possible to perform simple simulations on the GRETH and GRETH_GBIT cores in GRLIB. It provides the complete set of basic, extended capability and extended status registers through the MII management interface (MDIO) and a loopback mode for data transfers. Figure 1 shows a block diagram of a typical connection.
Figure 291. Block diagram of the PHY simulation model connected to a MAC.

The PHY model provides the complete GMII and MII interface as defined by the IEEE 802.3 standard. The model can be used in any of the following modes: 10 Mbit half- or full duplex, 100 Mbit half- or full-duplex and 1000 Mbit half- or full-duplex. This support refers only to the configuration settings available through the MDIO registers. Since the datapath implementation is loopback no collisions will ever be seen on the network and operation will essentially be full-duplex all the time. In loopback mode, rx_clk and tx_clk are identical in both frequency and phase and are driven by the PHY when not in gigabit mode. In gigabit mode the gtx_clk input is used as the transmitter clock and it also drives rx_clk.

When not configured to loopback mode the PHY just sits idle and ignores transmitted packet and does not insert any activity on the receive interface. Clocks are still generated but in this case rx_clk and tx_clk does have the same frequency but not the same phase when not in gigabit mode.

A simple auto-negotiation function is provided and the supported and advertised modes are set through vhdl generics. The generic values will be directly reflected in the reset values and read-only values of all corresponding MII management registers.

108.3 Configuration options

Table 2167 shows the configuration options of the model (VHDL generics).

*Table 2167.*Configuration options

Generic	Function	Allowed range	Default
address	Address of the PHY on the MII management interface	0 - 31	0
extended_regs	Include extended register capability	0 - 1	1
aneg	Enable auto-negotiation functionality	0 - 1	1
base100_t4	Enable support for 100Base-T4	0 - 1	0
base100_x_fd	Enable support for 100Base-X full-duplex	0 - 1	1
base100_x_hd	Enable support for 100Base-X half-duplex	0 - 1	1
fd_10	Enable support for 10Base-T full-duplex	0 - 1	1
hd_10	Enable support for 10Base-T half-duplex	0 - 1	1
base100_t2_fd	Enable support for 100Base-T2 full-duplex	0 - 1	1
base100_t2_hd	Enable support for 100Base-T2 half-duplex	0 - 1	1
base1000_x_fd	Enable support for 1000Base-X full-duplex	0 - 1	0
base1000_x_hd	Enable support for 1000Base-X half-duplex	0 - 1	0
base1000_t_fd	Enable support for 1000Base-T full-duplex	0 - 1	1
base1000_t_hd	Enable support for 1000Base-T half-duplex	0 - 1	1
rmii	Set PHY in RMII mode	0 - 1	0

108.4 Signal descriptions

Table 2168 shows the interface signals of the model (VHDL ports).

*Table 2168.*Signal descriptions

Signal name	Field	Type	Function	Active

109   RGMII - Reduced Ethernet Media Access Controller

109.1   Overview

Frontgrade Gaisler's RGMII IP provides the RGMII adaptation layer between the Ethernet physical media device and the GRETH or GRETH_GBIT IP core.

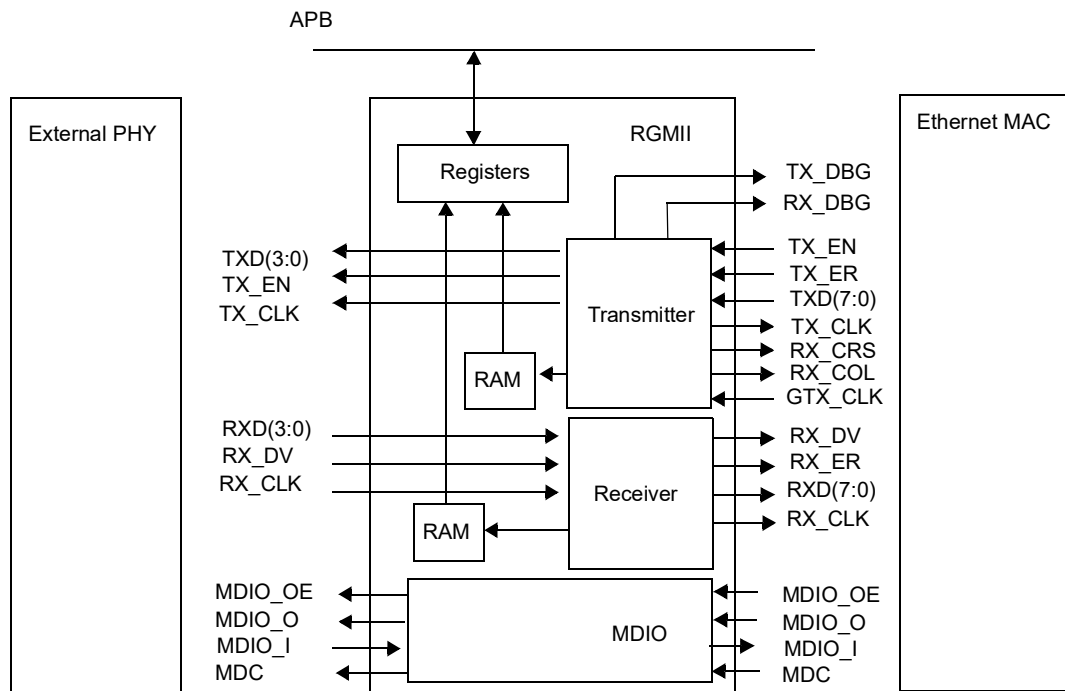
The RGMII adaptation layer supports version 2.0 of the Reduced Gigabit Media Independent interface and can dynamically switch between diffrent speed modes of operation.


Figure 292. Block diagram of the internal structure of the RGMII.

109.2   Operation

109.2.1 Protocol support

The RGMII adaptation layer supports version 2.0 of the Reduced Gigabit Media Independent interface and IEEE standard 802.3-2002 for GMII.

109.2.2 Transmit clock

The trasnsmitter clock is used by the transmit logic of the core. The transmit clock is also an output from the RGMII IP and will be used as the TX clock in the Ethernet MAC. There are three options of generating and using the transmit clock inside the IP. The VHDL generics 'no_clock_mux' and 'use90degtxclk' determines the clock mode used by the RGMII IP.

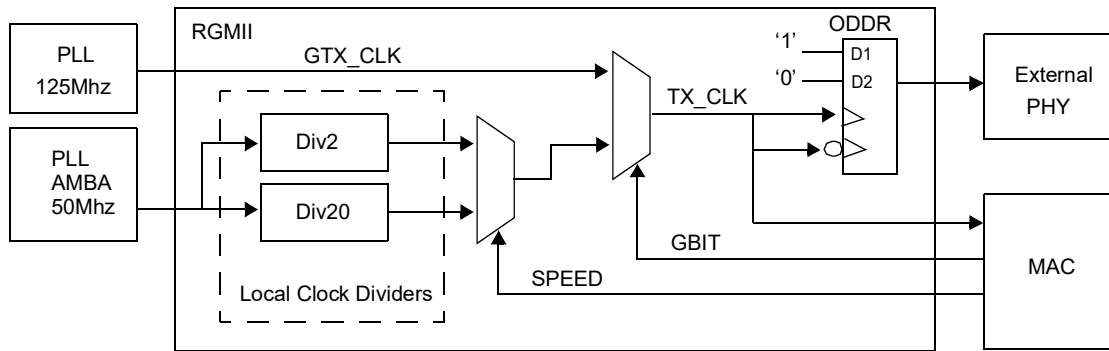
+46 31 7758650 | frontgrade.com/gaisler


Figure 293. 10/100 Mb/s transmiter clocks generated by internal logic

Figure 293 shows the clocking scheme when the transmit clock for 10Mb/s and 100Mb/s mode is generated internally. This clock mode is used when the VHDL generic 'no_clock_mux' is set to '0'. In this case user must ensure that the GMII clock frequency and AMBA clock frequency is appropriate for the line speed. That is, 50Mhz AMBA clock for 10/100 Mb/s and 125Mhz for 1000Mb/s.

Local clock resources will provide 2.5MHz and 25MHz frequency clocks for 10 Mb/s and 100 Mb/s speeds of operation, respectively. The local clock logic generates the 2.5MHz and 25MHz TX_CLK clock from the 50MHz AHB_CLK.

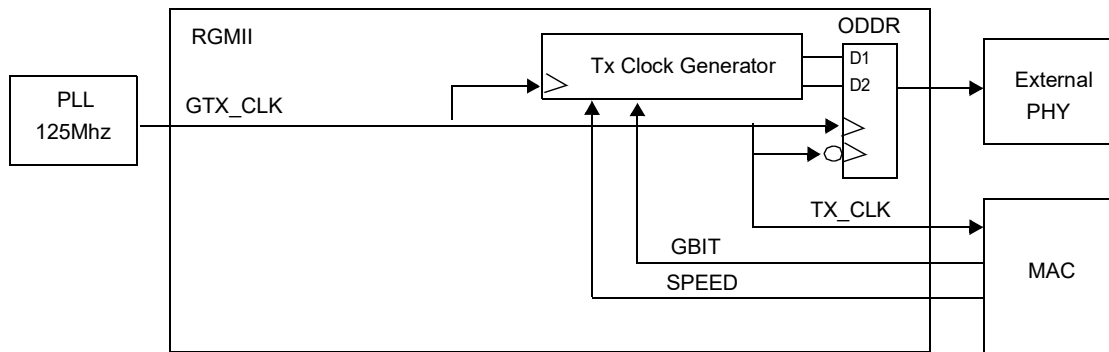
The SPEED and GBIT signals from the Ethernet MAC are used as selection pins of the local clock muxes.


Figure 294. All transmit clocks generated by internal logic

Figure 294 show an alternative clock scheme using only one clock domain for the transmitter. This clock mode is used when setting the VHDL generic 'no_clock_mux' to 1. The local clock divider is replaced by a counter in the GTX_CLK clock domain to generate bit pattern for clock generation in 10 Mb/s, 100 Mb/s, and 1 Gb/s speeds of operation.

The bit pattern is connected to the DDR output buffers data inputs and 125MHz GTX_CLK clock is connected to the DDR output buffer clock in order to generate the transmit clock to the external PHY.

Frontgrade Gaisler AB

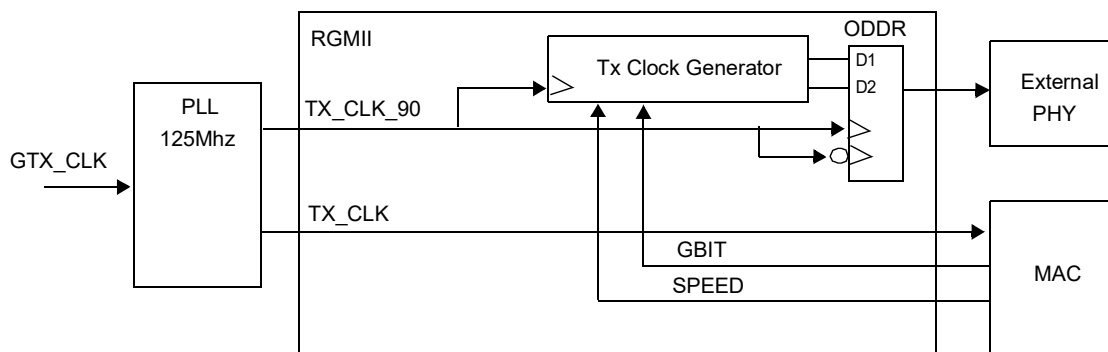
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler


Figure 295. External PHY transmit clock 90deg phase shift

The RGMII v2.0 standard specifies that the external PHY TX clock to have a setup of 2 ns with respect to the TX data. The 2ns setup can be achieved by phase shifting the external transmit clock to the external PHY by 90 degrees relative the internal MAC transmit clock. This mode is shown in figure 295 and is used when setting the VHDL generic 'no_clock_mux' to 1 and 'use90degtxclk' to 1.

109.2.3 Transmitter Operation

The transmitter is enabled when the GMII transmitter enable is high. Data is transferred from the GMII to RGMII as long as the GMII transmitter enable signal is high.

The transmitter enable signal is expected to be high during the complete transmission of the Ethernet MAC frame.

109.2.4 Side-band information

The RGMII receiver samples input data at all time. Side-band information is stored in the RGMII status register accessible via the APB interface. The status register has an address offset of 0x0.

109.2.5 MDIO Management

The RGMII IP only forwards the MDIO signals from the MDIO bus master (GRTEH/GRETH_GBIT) to the external PHY. The RGMII does not affect any MDIO transactions.

109.2.6 RAM debug support

The IP RGMII can optionally be build to include debug memories. The debug memories will record and store the last received and transmitted MAC frame. The RAM debug support is used when the VHDL generic 'debugmem' to 1.

The transmit frame buffer is accessed starting from the APB address offset 0x400 and the receive frame buffer is located at APB address offset 0x800.

109.2.7 External debug support

Interface for optionality connection to an on-chip logic analyzer for tracing and displaying of on-chip signals e.g. LOGAN IP included in the GRIP.

109.3 Media Independent Interfaces

There are several interfaces defined between the MAC sublayer and the Physical layer. The GRETH_GBIT supports the Media Independent Interface (MII) and the Gigabit Media Independent Interface (GMII).

The GMII is used in 1000 Mbit mode and the MII in 10 and 100 Mbit. These interfaces are defined separately in the 802.3-2002 standard but in practice they share most of the signals. The GMII has 9 additional signals compared to the MII. Four data signals are added to the receiver and transmitter data interfaces respectively and a new transmit clock for the gigabit mode is also introduced.

The RGMII interface uses the same signal with the additional signal tx_clk_90.

Table 2170. Signals in RGMII, GMII and MII.

MII and GMII	GMII Only	RGMII Only
txd[3:0]	txd[7:4]	tx_clk_90

109.5   Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x093. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

109.6   Implementation

109.6.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

109.7 Configuration options

Table 2179 shows the configuration options of the core (VHDL generics).

Table 2179. Configuration options

Generic	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0

110   REGFILE_3P 3-port RAM generator (2 read, 1 write)

110.1   Overview

The 3-port register file has two read ports and one write port. Each port has a separate address and data bus. All inputs are latched on the rising edge of clk. The read data appears on dataout directly after the clk rising edge. Note: on most technologies, the register file is implemented with two 2-port RAMs with combined write ports. Address width, data width and target technology is parametrizable through generics.

Write-through is supported if the function *syncram_2p_write_through(tech)* returns 1 for the target technology.

110.2   Configuration options

Table 2182 shows the configuration options of the core (VHDL generics).

*Table 2182.*Configuration options

Name	Function	Range	Default
tech	Technology selection	0 - NTECH	0
abits	Address bits. Depth of RAM is $2^{abits-1}$	see table 2183	-

111   RSTGEN - Reset generation

111.1   Overview

The RSTGEN reset generator implements input reset signal synchronization with glitch filtering and generates the internal reset signal. The input reset signal can be asynchronous.

111.2   Operation

The reset generator latches the value of the clock lock signal on each rising edge of the clock. The lock signal serves as input to a five-bit shift register. The three most significant bits of this shift register are clocked into the reset output register. The reset signal to the system is high when both the reset output register and the reset input signal are high. Since the output register depends on the system clock the active low reset output from the core will go high synchronously to the system clock. The raw reset output does not depend on the system clock or clock lock signal and is polarity adjusted to be active low.

The VHDL generic *syncrst* determines how the core resets its shift register and the reset output register. When *syncrst* is set to 1 the core's shift register will have an synchronous reset and no reset signal will be connected to the output reset register, see figure 296. Note that the core's reset output signal will always go low when the input reset signal is activated.
Figure 296.   Reset generator with VHDL generic syncrst set to 1

When *syncrst* is 0 the shift register will be reset asynchronously together with the reset output register. Figure 297 shows the reset generator when scan test support is disabled. The shift register reset will be connected to the core's normal reset input and the test reset input will be unused. When scan test support is enabled, the core's test reset input can be connected to the reset input on both registers. The reset signal to use for the registers is selected with the test enable input, see figure 298.
Figure 297.   Reset generator with VHDL generic syncrst set to 0 and scan test disabled
Figure 298.   Reset generator with VHDL generic syncrst set to 0 and scan test enabled

When *syncin* is 1 the reset input is synchronized to the same clock domain as the rstgen block.

Figure 299. Extra Reset generator logic with VHDL generic syncin set to 1 to synchronize input reset and scan test enabled

111.3   Configuration options

Table 2186 shows the configuration options of the core (VHDL generics).

*Table 2186.*Configuration options

Generic name	Function	Allowed range	Default
acthigh	Set to 1 if reset input is active high. The core outputs an active low reset.	0 - 1	0
syncrst	When this generic is set to 1 the reset signal will use a synchronous reset to reset the filter registers. When this generic is set to 1 the TESTRST and TESTEN inputs will not be used.	0 - 1	0
scanen	Setting this generic to 1 enables scan test support. This connects the TESTRST input via a multiplexer so that the TESTRST and TESTEN signals can be used to asynchronously reset the core's registers. This also requires that the generic syncrst is set to 0.	0 - 1	0
syncin	Setting this generic to 1 will add reset synchronizer to the input reset. This option can be used to break false timing paths in designs when input reset is not generated from same clock domain as the input clock of rstgen	0 - 1	0

111.4   Signal descriptions

Table 2187 shows the interface signals of the core (VHDL ports).

*Table 2187.*Signal descriptions

112 GR(2^4)(68, 60, 8, T=1) - QEC/QED error correction code encoder/decoder

112.1 Overview

The gf4_e1 VHDL package provides functions for encoding and decoding a Bose Chaudhuri Hocquenghem (BCH) type of code. It is a Quad Error Correction/Quad Error Detection (QEC/QED) code.

The data symbols are 4-bit wide, represented as GF(2^4). The has the capability to detect and correct a single symbol error anywhere in the codeword. The data is represented as 60 bits and the checksum is represented as 8 bits, and the code can correct up to four bit errors when located in the same nibble.

112.2 Code

The code has the following definition:

- there are 4 bits per symbol;
- there are 17 symbols per codeword, of which 2 symbols represent the checksum;
- the code is systematic;
- the code can correct one symbol error per codeword;
- the field polynomial is

$$f(x) = x^4 + x + 1$$

- all multiplications are performed as Galois Field multiplications over the above field polynomial
- all additions/subtractions are performed as Galois Field additions (i.e. bitwise exclusive-or)

112.3 Encoding

- a codeword is defined as 17 symbols:

  $[c_0, c_1, c_2, c_3, c_4, c_5, c_6, c_7, c_8, c_9, c_{10}, c_{11}, c_{12}, c_{13}, c_{14}, c_{15}, c_{16}]$

  where c_0 to c_{14} represent information symbols and c_{15} to c_{16} represent check symbols.

- c_{15} is calculated as follows

$$c_{15} = \sum_{0}^{14} (k_i \times c_i)$$

- c_{16} is calculated as follows

$$c_{16} = \sum_{0}^{14} c_i$$

- where the constant vector k is defined as:

  k_0=0xF, k_1=0xE, ..., k_{14}=0x1 (one can assume k_{15}=0x1 and k_{16}=0x1 for correction purposes)

112.4 Decoding

- the corrupt codeword is defined as 17 symbols:

  $[r_0, r_1, r_2, r_3, r_4, r_5, r_6, r_7, r_8, r_9, r_{10}, r_{11}, r_{12}, r_{13}, r_{14}, r_{15}, r_{16}]$

- the corrupt codeword can also be defined as 17 uncorrupt symbols and an error:

  $[c_0, c_1, c_2, c_3, c_4, c_5, c_6, c_7, c_8, c_9, c_{10}, c_{11}, c_{12}, c_{13}, c_{14}, c_{15}, c_{16}] + [e_x]$

  where the error is defined as e_x, e being the unknown magnitude and
  x being the unknown index position in the codeword

GRIP
Apr 2024, Version 2024.1

1893

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- recalculated checksum rc_0 is calculated as follows (k_i is as defined above, x being the unknown index)

$$rc_0 = \sum_0^{14} (k_i \times r_i) = \sum_0^{14} (k_i \times c_i) + (k_x \times e_x)$$

- recalculated rc_1 is calculated as follows

$$rc_1 = \sum_0^{14} r_i = \sum_0^{14} c_i + e_x$$

- syndrome s_0 is calculated as follows

$$s_0 = rc_0 + r_{15} = \sum_0^{14} (k_i \times r_i) + \sum_0^{14} (k_i \times c_i) = k_x \times e_x$$

- syndrome s_1 is calculated as follows, which gives the magnitude (not applicable to c_{15} and c_{16})

$$s_1 = rc_1 + r_{16} = \sum_0^{14} r_i + \sum_0^{14} c_i = e_x$$

- in case s_0 and s_1 are both non-zero, to located the error in range c_0 to c_{14}, multiply error magnitude e_x with each element of the constant vector defined above:

$$k_i e_x = k_i \times s_1 = k_i \times e_x \qquad i = [0,14]$$

- search the resulting vector to find the element matching syndrome s_0, the resulting index i points to the error location (applicable only to i in [0, 14])

$$k_i e_x \Leftrightarrow k_i \times e_x$$

- finally perform the correction (applicable only to i in [0, 14])

$$c_i = r_i - s_1 = r_i - e_x = (c_i - e_x) \times e_x = c_i - e_x + e_x = c_i$$

- when s_0 is zero and s_1 is non-zero, the error is located in checksum r_{15}, no correction is necessary
- when s_1 is zero and s_0 is non-zero, the error is located in checksum r_{16}, no correction is necessary
- when s_0 and s_1 are both zero, no error has been detected, no correction is necessary

112.5 Capability

The decoder has the following capabilities. It detects and corrects up to four bit errors in the same nibble. The described errors can be located anywhere in the codeword.

112.6 Operation

112.6.1 Encoder

The encoder is defined by the gf4_60_8_encode function. The function is called with the 60-bit wide data that should be encoded, and returns a 68-bit wide codeword of which bits 67 downto 8 represent the data and bits 7 downto 0 represent the checksum.

112.6.2 Decoder

The decoder is defined by the gf4_60_8_decode function.

GRIP
Apr 2024, Version 2024.1

1894

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The gf4_60_8_decode function calculates the syndromes, calculates the error magnitude and the error location, and returns a bit indicating whether an error has been detected and corrected, and the corrected data.

The function is called with a 68-bit wide codeword of which bits 67 downto 8 represent the data and bits 7 downto 0 represent the checksum. It returns the record type gf4_60_8_type, containing the 60-bit wide corrected data and an indication if an error was detected and corrected over the complete codeword.

112.7 Type descriptions

Table 2191 shows the type declarations used by the functions in the package (VHDL types).

Table 2191. Type declarations

Name	Field	Type	Function	Active
gf4_60_8_type	cerr	Std_Logic	error corrected	
	data	Std_Logic_Vector(59 downto 0)	data	

112.8 Library dependencies

Table 2192 shows the libraries used when instantiating the functions in the package (VHDL libraries).

Table 2192. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	StdLib	All	Common VHDL functions

112.9 Instantiation

This example shows how the functions in the package can be instantiated. Note that all input and outputs are synchronized to remove any timing constraints for pads in an example design. Timing analysis can then be made purely for the register-to-register paths.

```
library  IEEE;
use      IEEE.Std_Logic_1164.all;

entity gf4_60_8_encode_sync is
   port(

113 RS(24, 16, 8, E=1) - Reed-Solomon encoder/decoder

113.1 Overview

The rs_gf4_e1 VHDL package provides functions for encoding and decoding data with a Reed-Solomon code. It also provides a data type storing intermediate results from the functions.

The Reed-Solomon data symbols are 4-bit wide, represented as $GF(2^4)$. The Reed-Solomon code is a shortened RS(15, 13, 2) code, represented as RS(6, 4, 2). It has the capability to detect and correct a single symbol error anywhere in the codeword. The data is represented as 16 bits and the checksum is represented as 8 bits, and the code can correct 4-bit errors when located in the same nibble.

113.2 Capability

The Reed-Solomon decoder has the following capabilities. The described errors can be located anywhere in the codeword.

It detects and corrects any single bit error.

It detects 63% of all double bit errors and reports them as multiple bit errors.

It detects 27% of all double bit errors and reports them (incorrectly) as single bit errors.

It detects 63,5% of all triple bit errors and reports them as multiple bit errors.

It detects 36% of all triple bit errors and reports them (incorrectly) as single bit errors.

It does not detect 0,5% of all triple bit errors and reports them (incorrectly) as without errors.

It detects 63,5% of all quadruple bit errors and reports them as multiple bit errors.

It detects 36% of all quadruple bit errors and reports them (incorrectly) as single bit errors.

It does not detect 0,5% of all quadruple bit errors and reports them (incorrectly) as without error.

It detects and corrects up to four bit errors in the same nibble.

113.3 Operation

113.3.1 Encoder

The encoder is defined by the rs_16_8_encode function. The function is called with the 16-bit wide data that should be encoded, and returns 24-bit wide codeword of which bits 0 to 15 represent the data and bits 16 to 23 represent the checksum.

113.3.2 Decoder

The decoder is defined by the rs_16_8_check, rs_16_8_precorrect and rs_16_8_correct functions. The decoder has been split in three functions to facilitate pipelining, with each function being fairly balanced with respect to the depth of the resulting combinatorial logic.

The rs_16_8_check function calculates the syndrome and returns a bit indicating whether an error has been detected. Note that it can be any type of error: correctable or uncorrectable. The function is called with a 24-bit wide codeword of which bits 0 to 15 represent the data and bits 16 to 23 represent

the checksum. It returns the record type rs_16_8_type, containing the 16-bit wide data to be corrected, the syndrome and an indication if an error was detected over the complete codeword.

The rs_16_8_precorrect function is called with the intermediate result from the rs_16_8_check function. The input is the record type rs_16_8_type. It returns the record type rs_16_8_type, containing the 16-bit wide data to be corrected, the syndrome, intermediate data and an indication if an error was detected over the complete codeword.

The rs_16_8_correct function is called with the intermediate result from the rs_16_8_precorrect function. The input is the record type rs_16_8_type. It returns the record type rs_16_8_type, containing the corrected 16-bit wide data, an indication if the error was correctable or non-correctable over the complete codeword, and the union of the two.

To pipeline the decoder, the rs_16_8_check function should be called in the first stage and the intermediated result should be stored. Note that the intermediate result contains the input data required for the correction in the next stage. The rs_16_8_precorrect function should be called in the second stage. The rs_16_8_correct function should be called in the third stage.

113.4 Type descriptions

Table 2193 shows the type declarations used by the functions in the package (VHDL types).

Table 2193. Type declarations

Name	Field	Type	Function	Active

        end process;
    end architecture rtl;
```

114   RS(48, 32, 16, E=1+1) - Reed-Solomon encoder/decoder - interleaved

114.1   Overview

The rs_gf4_e1 VHDL package provides functions for encoding and decoding data with a Reed-Solomon code. It also provides a data type storing intermediate results from the functions.

The Reed-Solomon data symbols are 4-bit wide, represented as GF(2^4). The Reed-Solomon code is a shortened RS(15, 13, 2) code, represented as RS(6, 4, 2). It has the capability to detect and correct a single symbol error anywhere in the codeword. The data is represented as 16 bits and the checksum is represented as 8 bits, and the code can correct 4-bit errors when located in the same nibble.

The gf4_32_16 functions provide an interleaved RS(6, 4, 2) where the data is represented as 32 bits and the checksum is represented as 16 bits, and the code can correct two 4-bit errors when each error is located in a nibble and not in the same original RS(6, 4, 2) codeword. The codewords are interleaved nibble-wise.

114.2   Capability

The Reed-Solomon decoder has the same capabilities as the original RS(6, 4, 2) code, but distributed per original RS(6, 4, 2) codeword.

114.3   Operation

114.3.1   Encoder

The encoder is defined by the rs_32_16_encode function. The function is called with the 32-bit wide data that should be encoded, and returns 48-bit wide codeword of which bits 0 to 31 represent the data and bits 32 to 47 represent the checksum.

114.3.2   Decoder

The decoder is defined by the rs_32_16_check, rs_32_16_precorrect and rs_32_16_correct functions. The decoder has been split in three functions to facilitate pipelining, with each function being fairly balanced with respect to the depth of the resulting combinatorial logic.

The rs_32_16_check function calculates the syndrome and returns a bit indicating whether an error has been detected. Note that it can be any type of error: correctable or uncorrectable. The function is called with a 48-bit wide codeword of which bits 0 to 31 represent the data and bits 32 to 47 represent the checksum. It returns the record type rs_32_16_type, containing the 32-bit wide data to be corrected, the syndrome and an indication if an error was detected over the two complete codewords.

The rs_32_16_precorrect function is called with the intermediate result from the rs_32_16_check function. The input is the record type rs_32_16_type. It returns the record type rs_32_16_type, containing the 32-bit wide data to be corrected, the syndrome, intermediate data and an indication if an error was detected over the two complete codewords.

The rs_32_16_correct function is called with the intermediate result from the rs_32_16_precorrect function. The input is the record type rs_32_16_type. It returns the record type rs_32_16_type, containing the corrected 32-bit wide data, an indication if the error was correctable or non-correctable over the complete two codewords, and the union of the two.

To pipeline the decoder, the rs_32_16_check function should be called in the first stage and the intermediated result should be stored. Note that the intermediate result contains the input data required for the correction in the next stage. The rs_32_16_precorrect function should be called in the second stage. The rs_32_16_correct function should be called in the third stage.

115 RS(40, 32, 8, E=1) - Reed-Solomon encoder/decoder

115.1 Overview

The rs_gf4_e1 VHDL package provides functions for encoding and decoding data with a Reed-Solomon code. It also provides a data type storing intermediate results from the functions.

The Reed-Solomon data symbols are 4-bit wide, represented as GF(2^4). The Reed-Solomon code is a shortened RS(15, 13, 2) code, represented as RS(10, 8, 2). It has the capability to detect and correct a single symbol error anywhere in the codeword. The data is represented as 32 bits and the checksum is represented as 8 bits, and the code can correct 4-bit errors when located in the same nibble.

115.2 Operation

115.2.1 Encoder

The encoder is defined by the rs_32_8_encode function. The function is called with the 32-bit wide data that should be encoded, and returns 40-bit wide codeword of which bits 0 to 31 represent the data and bits 32 to 39 represent the checksum.

115.2.2 Decoder

The decoder is defined by the rs_32_8_check, rs_32_8_precorrect and rs_32_8_correct functions. The decoder has been split in three functions to facilitate pipelining, with each function being fairly balanced with respect to the depth of the resulting combinatorial logic.

The rs_32_8_check function calculates the syndrome and returns a bit indicating whether an error has been detected. Note that it can be any type of error: correctable or uncorrectable. The function is called with a 24-bit wide codeword of which bits 0 to 31 representsthe data and bits 32 to 39 represent the checksum. It returns the record type rs_32_8_type, containing the 32-bit wide data to be corrected, the syndrome and an indication if an error was detected over the complete codeword.

The rs_32_8_precorrect function is called with the intermediate result from the rs_32_8_check function. The input is the record type rs_32_8_type. It returns the record type rs_32_8_type, containing the 32-bit wide data to be corrected, the syndrome, intermediate data and an indication if an error was detected over the complete codeword.

The rs_32_8_correct function is called with the intermediate result from the rs_32_8_precorrect function. The input is the record type rs_32_8_type. It returns the record type rs_32_8_type, containing the corrected 32-bit wide data, an indication if the error was correctable or non-correctable over the complete codeword, and the union of the two.

To pipeline the decoder, the rs_32_8_check function should be called in the first stage and the intermediated result should be stored. Note that the intermediate result contains the input data required for the correction in the next stage. The rs_32_8_precorrect function should be called in the second stage. The rs_32_8_correct function should be called in the third stage.

116   RS(48, 32, 16, E=2) - Reed-Solomon encoder/decoder

116.1   Overview

The rs_gf4_e2 VHDL package provides functions for encoding and decoding data with a Reed-Solomon code. It also provides a data type storing intermediate results from the functions.

The Reed-Solomon data symbols are 4-bit wide, represented as GF(2^4). The Reed-Solomon code is a shortened RS(15, 11, 4) code, represented as RS(12, 8, 4). It has the capability to detect and correct two symbol errors anywhere in the codeword. The data is represented as 32 bits and the checksum is represented as 16 bits, and the code can correct up to two 4-bit errors when located within nibble boundaries.

116.2   Operation

116.2.1 Encoder

The encoder is defined by the rs_32_16_2_encode function. The function is called with the 32-bit wide data that should be encoded, and returns 48-bit wide codeword of which bits 0 to 31 represent the data and bits 32 to 47 represent the checksum.

116.2.2 Decoder

The decoder is defined by the rs_32_16_2_check, rs_32_16_2_precorrect and rs_32_16_2_correct functions. The decoder has been split in three functions to facilitate pipelining, with each function being fairly balanced with respect to the depth of the resulting combinatorial logic.

The rs_32_16_2_check function calculates the syndrome and returns a bit indicating whether an error has been detected. Note that it can be any type of error: correctable or uncorrectable. The function is called with a 48-bit wide codeword of which bits 0 to 31 represent the data and bits 32 to 47 represent the checksum. It returns the record type rs_32_16_2_type, containing the 32-bit wide data to be corrected, the syndrome and an indication if an error was detected.

The rs_32_16_2_precorrect function is called with the intermediate result from the rs_32_16_2_check function. The input is the record type rs_32_16_2_type. It returns the record type rs_32_16_2_type, containing the 32-bit wide data to be corrected, the syndrome, intermediate data and an indication if an error was detected.

The rs_32_16_2_correct function is called with the intermediate result from the rs_32_16_2_precorrect function. The input is the record type rs_32_16_2_type. It returns the record type rs_32_16_2_-type, containing the corrected 32-bit wide data, an indication if the error was correctable or non-correctable, and the union of the two.

To pipeline the decoder, the rs_32_16_2_check function should be called in the first stage and the intermediated result should be stored. Note that the intermediate result contains the input data required for the correction in the next stage. The rs_32_16_2_precorrect function should be called in the second stage. The rs_32_16_2_correct function should be called in the third stage.

	elp_5_1	Std_Logic_Vector(0 to 3)	indicates index of detected error in code-word, only for rs_32_16_2_correct function: 0x0 = codeword(0:3) 0x1 = codeword(4:7) 0x2 = codeword(8:11) 0x3 = codeword(12:15) 0x4 = codeword(16:19) 0x5 = codeword(20:23) 0x6 = codeword(24:27) 0x7 = codeword(28:31) 0x8 = codeword(32:35) 0x9 = codeword(36:39) 0xA = codeword(40:43) 0xB = codeword(44:47) 0xF = unidentified (can be used with erasure information)	
	elp_5_2	Std_Logic_Vector(0 to 3)	indicates index of detected error, as above	

116.4 Library dependencies

Table 2200 shows the libraries used when instantiating the functions in the package (VHDL libraries).

Table 2200. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	StdLib	All	Common VHDL functions

116.5 Instantiation

This example shows how the functions in the package can be instantiated.

The example design shows a codec for which the decoder is pipelined, with the error flag output one clock cycle earlier than the corrected data. Note that all input and outputs are synchronised to remove

117 SDCTRL - 32/64-bit PC133 SDRAM Controller

117.1 Overview

The SDRAM controller handles PC133 SDRAM compatible memory devices attached to a 32 or 64 bit wide data bus. The controller acts as a slave on the AHB bus where it occupies a configurable amount of address space for SDRAM access. The SDRAM controller function is programmed by writing to a configuration register mapped into AHB I/O address space.

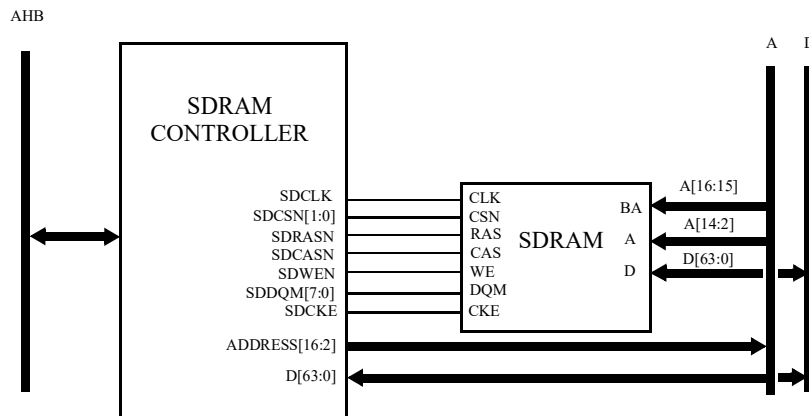
Chip-select decoding is provided for two SDRAM banks.


Figure 301. SDRAM Memory controller connected to AMBA bus and SDRAM

117.2 Operation

117.2.1 General

Synchronous dynamic RAM (SDRAM) access is supported to two banks of PC100/PC133 compatible devices. The controller supports 64M, 256M and 512M devices with 8 - 12 column-address bits, up to 13 row-address bits, and 4 banks. The size of each of the two banks can be programmed in binary steps between 4 Mbyte and 512 Mbyte. The operation of the SDRAM controller is controlled through the configuration register SDCFG (see section 117.3). The SDRAM bank's data bus width is configurable between 32 and 64 bits. When the VHDL generic *mobile* is set to a value not equal to 0, the controller supports mobile SDRAM.

117.2.2 Initialization

When the SDRAM controller is enabled, it automatically performs the SDRAM initialization sequence of PRECHARGE, 8x AUTO-REFRESH and LOAD-MODE-REG on both banks simultaneously. When mobile SDRAM functionality is enabled the initialization sequence is appended with a LOAD-EXTMODE-REG command. The controller programs the SDRAM to use page burst on read accesses and single location access on write accesses. If the *pwron* VHDL generic is 1, the initialization sequence is also sent automatically when reset is released. Note that some SDRAM devices require a stable clock of 100 us before any commands might be sent. When using on-chip PLL, this might not always be the case and the *pwron* VHDL generic should be set to 0 in such cases.

117.2.3 Configurable SDRAM timing parameters

To provide optimum access cycles for different SDRAM devices (and at different frequencies), three SDRAM parameters can be programmed through memory configuration register 2 (MCFG2): TCAS, TRP and TRFCD. The value of these fields affect the SDRAM timing as described in table 2201.

*Table 2201.*SDRAM programmable minimum timing parameters

SDRAM timing parameter	Minimum timing (clocks)
CAS latency, RAS/CAS delay (t_{CAS}, t_{RCD})	TCAS + 2
Precharge to activate (t_{RP})	TRP + 2
Auto-refresh command period (t_{RFC})	TRFC + 3
Activate to precharge (t_{RAS})	TRFC + 1
Activate to Activate (t_{RC})	TRP + TRFC + 4

If the TCAS, TRP and TRFC are programmed such that the PC100/133 specifications are fulfilled, the remaining SDRAM timing parameters will also be met. The table below shows typical settings for 100 and 133 MHz operation and the resulting SDRAM timing (in ns):

*Table 2202.*SDRAM example programming

SDRAM settings	t_{CAS}	t_{RC}	t_{RP}	t_{RFC}	t_{RAS}
100 MHz, CL=2; TRP=0, TCAS=0, TRFC=4	20	80	20	70	50
100 MHz, CL=3; TRP=0, TCAS=1, TRFC=4	30	80	20	70	50
133 MHz, CL=2; TRP=1, TCAS=0, TRFC=6	15	82	22	67	52
133 MHz, CL=3; TRP=1, TCAS=1, TRFC=6	22	82	22	67	52

When mobile SDRAM support is enabled, one additional timing parameter (TXSR) can be programmed though the Power-Saving configuration register.

*Table 2203.*Mobile SDRAM programmable minimum timing parameters

SDRAM timing parameter	Minimum timing (clocks)
Exit Self Refresh mode to first valid command (t_{XSR})	tXSR

117.2.4 Refresh

The SDRAM controller contains a refresh function that periodically issues an AUTO-REFRESH command to both SDRAM banks. The period between the commands (in clock periods) is programmed in the refresh counter reload field in the SDCFG register. Depending on SDRAM type, the required period is typically 7.8 or 15.6 µs (corresponding to 780 or 1560 clocks at 100 MHz). The generated refresh period is calculated as (reload value+1)/sysclk. The refresh function is enabled by setting bit 31 in SDCFG register.

117.2.5 Self Refresh

The self refresh mode can be used to retain data in the SDRAM even when the rest of the system is powered down. When in the self refresh mode, the SDRAM retains data without external clocking and refresh are handled internally. The memory array that is refreshed during the self refresh operation is defined in the extended mode register. These settings can be changed by setting the PASR bits in the Power-Saving configuration register. The extended mode register is automatically updated

GRIP
Apr 2024, Version 2024.1

1910

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

when the PASR bits are changed. The supported "Partial Array Self Refresh" modes are: Full, Half, Quarter, Eighth, and Sixteenth array. "Partial Array Self Refresh" is only supported when mobile SDRAM functionality is enabled. To enable the self refresh mode, set the PMODE bits in the Power-Saving configuration register to "010" (Self Refresh). The controller will enter self refresh mode after every memory access (when the controller has been idle for 16 clock cycles), until the PMODE bits are cleared. When exiting this mode the controller introduce a delay defined by tXSR in the Power-Saving configuration register and a AUTO REFRESH command before any other memory access is allowed. The minimum duration of this mode is defined by tRAS. This mode is only available when the VHDL generic *mobile* is >= 1.

117.2.6 Power-Down

When entering the power-down mode all input and output buffers, excluding SDCKE, are deactivated. All data in the SDRAM is retained during this operation. To enable the power-down mode, set the PMODE bits in the Power-Saving configuration register to "001" (Power-Down). The controller will enter power-down mode after every memory access (when the controller has been idle for 16 clock cycles), until the PMODE bits is cleared. The REFRESH command will still be issued by the controller in this mode. When exiting this mode a delay of one clock cycles are added before issue any command to the memory. This mode is only available when the VHDL generic *mobile* is >= 1.

117.2.7 Deep Power-Down

The deep power-down operating mode is used to achieve maximum power reduction by eliminating the power of the memory array. Data will not be retained after the device enters deep power-down mode. To enable the deep power-down mode, set the PMODE bits in the Power-Saving configuration register to "101" (Deep Power-Down). To exit the deep power-down mode the PMODE bits in the Power-Saving configuration register must be cleared. The controller will respond with an AMBA ERROR response to an AMBA access, that will result in a memory access, during Deep Power-Down mode. This mode is only available when the VHDL generic *mobile* is >= 1 and mobile SDRAM functionality is enabled.

117.2.8 Temperature-Compensated Self Refresh

The settings for the temperature-compensation of the Self Refresh rate can be controlled by setting the TCSR bits in the Power-Saving configuration register. The extended mode register is automatically updated when the TCSR bits are changed. Note that some vendors implements a Internal Temperature-Compensated Self Refresh feature, which makes the memory ignore the TCSR bits. This functionality is only available when the VHDL generic *mobile* is >= 1 and mobile SDRAM functionality is enabled.

117.2.9 Drive Strength

The drive strength of the output buffers can be controlled by setting the DS bits in the Power-Saving configuration register. The extended mode register is automatically updated when the DS bits are changed. The available options are: full, three-quarter, one-half, and one-quarter drive strengths. This functionality is only available when the VHDL generic *mobile* is >= 1 and mobile SDRAM functionality is enabled.

117.2.10 SDRAM commands

The controller can issue four SDRAM commands by writing to the SDRAM command field in the SDRAM Configuration register: PRE-CHARGE, AUTO-REFRESH, LOAD-MODE-REG (LMR) and LOAD-EXTMODE-REG (EMR). If the LMR command is issued, the CAS delay as programmed in SDCFG will be used, remaining fields are fixed: page read burst, single location write, sequential burst. If the EMR command is issued, the DS, TCSR and PASR as programmed in Power-Saving configuration register will be used. The command field will be cleared after a command has been exe-

GRIP
Apr 2024, Version 2024.1
1911
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

cuted. Note that when changing the value of the CAS delay, a LOAD-MODE-REGISTER command should be generated at the same time.

117.2.11 Read cycles

A read cycle is started by performing an ACTIVATE command to the desired bank and row, followed by a READ command with data read after the programmed CAS delay. A read burst is performed if a burst access has been requested on the AHB bus. The read cycle is terminated with a PRE-CHARGE command, no banks are left open between two accesses. Note that only word bursts are supported by the SDRAM controller. The AHB bus supports bursts of different sizes such as bytes and half-words but they cannot be used.

117.2.12 Write cycles

Write cycles are performed similarly to read cycles, with the difference that WRITE commands are issued after activation. A write burst on the AHB bus will generate a burst of write commands without idle cycles in-between. As in the read case, only word bursts are supported.

117.2.13 Address bus connection

The SDRAM address bus should be connected to SA[12:0], the bank address to SA[14:13], and the data bus to SD[31:0] or SD[63:0] if a 64-bit SDRAM data bus is used.

117.2.14 Data bus

The external SDRAM data bus is configurable to either 32 or 64 bits width, using the *sdbits* VHDL generic. A 64-bit data bus allows 64-bit (SO)DIMMs to be connected using the full data capacity of the devices. The polarity of the output enable signal to the data pads can be selected with the oepol generic. Sometimes it is difficult to fulfil the output delay requirements of the output enable signal. In this case, the vbdrive signal can be used instead of bdrive. Each index in this vector is driven by a separate register and a directive is placed on them so that they will not be removed by the synthesis tool.

117.2.15 Clocking

The SDRAM controller is designed for an external SDRAM clock that is in phase or slightly earlier than the internal AHB clock. This provides the maximum margin for setup and hold on the external signals, and allows highest possible frequency. For Xilinx and Altera devices, the GRLIB Clock Generator (CLKGEN) can be configured to produce a properly synchronized SDRAM clock. For other FPGA targets, the custom clock synchronization must be designed, or the inverted clock option can be used (see below). For ASIC targets, the SDRAM clock can be derived from the AHB clock with proper delay adjustments during place&route.

If the VHDL generic INVCLK is set, then all outputs from the SDRAM controller are delayed for 1/2 clock. This is done by clocking all output registers on the falling clock edge. This option can be used on FPGA targets where proper SDRAM clock synchronization cannot be achieved. The SDRAM clock can be the internal AHB clock without further phase adjustments. Since the SDRAM signals will only have 1/2 clock period to propagate, this option typically limits the maximum SDRAM frequency to 40 - 50 MHz.

117.2.16 Endianness

The core is designed for big-endian systems.

117.3 Registers

The memory controller is programmed through register(s) mapped into the AHB I/O space defined by the controllers AHB BAR1. Only 32-bit single-accesses to the registers are supported.

Table 2204. SDRAM controller registers

AHB address offset	Register
0x0	SDRAM Configuration register
0x4	SDRAM Power-Saving configuration register

Table 2205. 0x00 - SDCFG1 - SDRAM configuration register

31	30	29 27	26	25 23	22 21	20 18	17	16	15	14 0
Refresh	tRP	tRFC	tCD	SDRAM bank size	SDRAM col. size	SDRAM command	Page-Burst	MS	D64	SDRAM refresh load value
0	1	0b111	1	0	0b10	0	*	*	*	NR
rw	rw	rw	rw	rw	rw	rw	rw*	r	r	rw

31	SDRAM refresh. If set, the SDRAM refresh will be enabled.
30	SDRAM tRP timing. tRP will be equal to 2 or 3 system clocks (0/1). When mobile SDRAM support is enabled, this bit also represent the MSB in the tRFC timing.
29: 27	SDRAM tRFC timing. tRFC will be equal to 3 + field-value system clocks. When mobile SDRAM support is enabled, this field is extended with the bit 30.
26	SDRAM CAS delay. Selects 2 or 3 cycle CAS delay (0/1). When changed, a LOAD-MODE-REGISTER command must be issued at the same time. Also sets RAS/CAS delay (tRCD).
25: 23	SDRAM banks size. Defines the decoded memory size for each SDRAM chip select: "000"= 4 Mbyte, "001"= 8 Mbyte, "010"= 16 Mbyte .... "111"= 512 Mbyte.
	When configured for 64-bit wide SDRAM data bus (sdbits=64), the meaning of this field doubles so that "000"=8 Mbyte, .., "111"=1024 Mbyte
22: 21	SDRAM column size. "00"=256, "01"=512, "10"=1024, "11"=2048 except when bit[25:23]=˘111˘ then ˘11˘=4096
20: 18	SDRAM command. Writing a non-zero value will generate an SDRAM command: "010"=PRE-CHARGE, "100"=AUTO-REFRESH, "110"=LOAD-MODE-REGISTER, "111"=LOAD-EXT-MODE-REGISTER. The field is reset after command has been executed.
17	1 = pageburst is used for read operations, 0 = line burst of length 8 is used for read operations. (Only available when VHDL generic pageburst i set to 2)
16	Mobile SDR support enabled. '1' = Enabled, '0' = Disabled (read-only)
15	64-bit data bus (D64) - Reads '1' if memory controller is configured for 64-bit data bus, otherwise '0'. Read-only.
14: 0	The period between each AUTO-REFRESH command - Calculated as follows: tREFRESH = ((reload value) + 1) / SYSCLK

Table 2206. 0x04 - SDCFG2 - SDRAM Power-Saving configuration register

117.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x009. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

117.5 Implementation

117.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers. The registers driving SDRAM chip select and output enables for the SDRAM data bus have asynchronous reset.

117.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

The example design contains an AMBA bus with a number of AHB components connected to it including the SDRAM controller. The external SDRAM bus is defined on the example designs port map and connected to the SDRAM controller. System clock and reset are generated by GR Clock Generator and Reset Generator.

SDRAM controller decodes SDRAM area:0x60000000 - 0x6FFFFFFF. SDRAM Configuration register is mapped into AHB I/O space on address (AHB I/O base address + 0x100).

118 SOCBRIDGE - AHB to AHB interface through byte stream

118.1 Overview

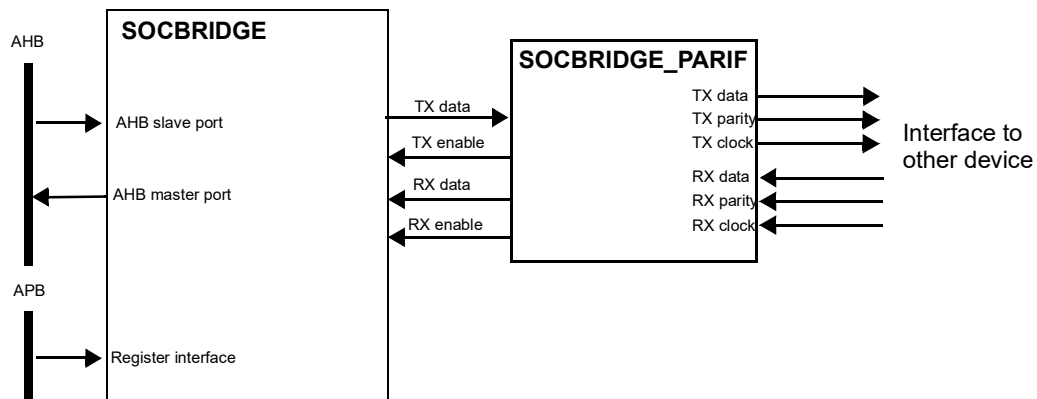
The SOCBRIDGE interfaces an AHB bus with a slave and a master port, and on the other side provides a bidirectional byte stream. Accesses to the slave port are transmitted over the byte stream. Incoming accesses over the byte stream are performed on the master port. By transferring the byte stream to another device with a corresponding SOCBRIDGE, accesses can be tunneled between the two devices. The interface may be used an expansion interface with additional I/O provided in an external companion chip or to implement a simple data transfer interface between the system-on-chip and an external device


Figure 302. Block diagram of SOCBRIDGE together with parallel interface.

118.2 Communication protocol

118.2.1 Introduction

The socbridge uses an interface based on byte streams to communicate with the other endpoint. A continuous stream of bytes are flowing in both directions. The streams are usually at the same data rate but this is not required, and the streams may have arbitrary latency/pipelining.

118.2.2 Byte stream protocol

Over the byte stream, the socbridge communicates with a simple custom protocol. This section is intended to provide a free-standing description of the protocol that is implemented in this interface.

The byte stream based protocol used by the socbridge allows six different access types: Idle, Write with address and data, write with only data, read with address, read without address, and peer error indication. There are also two types of responses sent back: write acknowledge and read response with data. The format of the commands is tabulated below. Any bit pattern not covered by the table is considered reserved for future use

Table 2210. Command and response bytes

Command	7	6	5	4	3	2	1	0	Followed by address	Followed by data	Response expected
Commands											
Idle	0	0	0	0	0	0	0	0	No	No	None
Write with address	1	0	0	0	0	size[1]			Yes, 4 bytes	Yes, according to size	Write acknowledge
Write without address	1	0	1	0	0	size[1]			No	Yes, according to size	Write acknowledge
Read with address	1	1	0	0	0	size[1]			Yes, 4 bytes	No	Read response
Read without address	1	1	1	0	0	size[1]			No	No	Read response
Peer error	0	1	0	0	1	0	0	0	No	No	None
Responses											
Write acknowledge	0	0	x^2	0	1	size[1,2]			No	No	-
Read response	0	1	x^2	0	0	size[1,2]			No	Yes, according to size	-

Notes:
1) size is given as power of two, 000 meaning 1 byte, 001 meaning 2 bytes, 010 meaning 4 bytes, and so on.
2) bit 5 and bits 2:0 in response must match command

Idle is the default command sent when there is nothing to do, or when the socbridge is not yet ready to send a response back.

Writes and read accesses are performed by sending the corresponding command, and then getting a response back from the other end.

An access may be issued either without or with an address, depending on bit 5 of the command. If an address is included, it is sent with four bytes immediately after the command byte with the most significant address byte (address bits 31:24) sent first. The address must always be aligned to the size of the transfer command.

When a transfer command without address is issued, the access is assumed to begin on the first byte after where the previous access ended. This allows for long continuous transfers of data without having to re-send the address in each command. The first read or write transfer made over the link after reset must always provide an address in order to have a known starting point. It is allowed to perform a write without address after a read or a read without address after a write, and the size of the access is not required to match the previous one. However the commands must still be sent so that the effective starting address is aligned to the access size also for accesses without address.

The endpoint performing the access must always provide responses in the same order as the commands were issued, reordering the responses is not permitted. The response must have the same value on bit 5 and bits 2:0 as the command, the purpose of this requirement is to simplify tracking of available buffer space.

The Peer error command is used to inform the other endpoint that a fatal error was detected on the link. The protocol itself does not provide any means to acknowledge or indicate that the error has been recovered, that is managed separately.

118.2.3 Implementation-specific features

Not all endpoints are expected to support the maximum size supported by the protocol, sizes of 1,2 and 4 bytes are expected to be supported by all implementations. The protocol does not provide any way to auto-detect what is supported so this has to be managed separately. The protocol also does not provide information on which address ranges are supported and where different addresses are mapped on the other end, this knowledge has to be managed separately.

GRIP
Apr 2024, Version 2024.1

1920

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Additional commands may be issued before a response has been received to the previous command, but it is the command issuer's responsibility to make sure that the other endpoint has enough space in its receive buffers to queue up the command. The protocol itself does not provide any mechanism to specify whether there is room for more commands. If the capabilities of the other endpoint is unknown then the only strategy that is guaranteed to not overflow the other endpoint is to wait for the response after each access before issuing another access.

118.2.4 Parallel interface

In order to transfer the byte streams between the two devices some form of physical layer has to be provided. The standard parallel interface transfers the bytes over an 8-bit parallel bus, together with an optional parity bit and a clock signal in each direction. In total the interface will communicate with 20 signals over the board. The parity signal implements odd parity, i.e the parity line is the inverse of the exclusive-or of the eight data lines.

One of the two sides of the parallel interface is designated as the primary side, with the other side designated as the secondary side. The primary side determines which clock frequency is to be used for the interface and provides the clock with rising edge centered in the data eye of each outgoing data byte. The secondary side delivers a data byte in the other direction for each rising edge of the clock received and at the same time toggles its outgoing clock, creating a double data-rate clock with the clock aligned to the beginning of the data eye. The reason for this difference is to allow for simple implementations on the secondary side.
Figure 303. Clocking scheme for parallel interface between primary side and secondary side. Note that on the secondary side the in/out and tx/rx signal names are reversed.

118.3 Operation

118.3.1 AHB slave access

The socbridge provides an AHB slave interface for accesses to be done across the bridge. Two separate BARs can be provided, accesses to both BARs will behave exactly the same except for the address translation (see section 118.3.6).

For reads, the socbridge will send a read command to get the data, and give wait states on the AHB interface until the response has been received. For single accesses, the bridge will send a read command with the same size as the AHB access, unless the AHB access size exceeds the maximum size supported by the other endpoint. In this case, multiple read accesses of the highest size supported will be performed to get the required number of bytes.

In case of burst read access, the socbridge will calculate the optimal size of the read command to be sent across to the other endpoint considering the AHB access size, the number of beats of the burst,

GRIP

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

and the maximum size supported by both endpoints. If an incremental burst of unspecified length is performed, the core will assume a burst length given by the ahbiblen generic.

For write access, the core uses a write-behind scheme where it will first capture the data into an internal buffer and once the access (single or burst) is received, the write command and data will be transmitted. Any following AHB access to the slave while the write transfer is ongoing will be delayed using wait states.

Certain types of AHB bursts can not be optimally handled by the socbridge but will instead be handled as single accesses. This includes wrapping bursts (both read and write) and byte-sized bursts (with hsize equal to zero). They will still be executed in a functionally correct way but may not be performed with the optimal sequence of commands.

Busy cycles are handled in accordance with the AHB standard but may in some cases during read bursts lead to overrun conditions, where the remaining read data coming in is discarded and another read command is made to fetch the following data again. Busy cycles during write bursts are always handled without any performance overhead.

118.3.2 AHB master access

Incoming read and write commands from the other end of the byte stream will be performed by the AHB master, with a response and read data sent back over the link once the access is done. If the access is larger than the bus width, the AHB master will perform a burst to get all data at once.

118.3.3 Wide buses

The core supports wide AHB buses on both the master and slave ports, the widths are configured using a configuraiton generic. The core will correctly replicate the data on the data buses for all access sizes up to the configured maximum and pick the expected byte lanes in accordance with the AHB specification, which makes it compatible both with GRLIB's wide bus scheme as well as non-GRLIB slaves using the standard data muxing.

The core will always try to use the largest access possible on the AHB master interface, there is no support to constrain the size below the maximum. In systems with mixed wide and narrow slaves reachable by the bridge's AHB master, it is up to the other side of the link to always access the narrow slaves over the bridge using individual 32-bit accesses.

118.3.4 Maximum command size

In order to support small implementations of the bridge endpoint, the commmand sizes supported can be constrained.

The core has one buffer holding the data for bursts to and from the AHB slave, and one buffer holding the data for bursts to and from the AHB master. The smallest of the local AHB slave burst buffer and the size of the other end's AHB master burst buffer determines the largest data transfer that can be sent over the link to the other end. The other end's burst buffer size is communicated to the bridge using the OMAXSZ field in the transfer control register. The local buffer sizes are configurable via generics. The local buffer sizes must always be large enough to hold a single access with the bus width configured.

Larger accesses than the maximum command size are still supported over the AHB slave interface but will be broken down into multiple commands.

118.3.5 Command queueing

On the command receiving side, the bridge has a queue to hold any additional transfer requests that come in while a transfer is in progress. This may be used on the command transmitting side to queue up additional commands before previous commands have been handled. A configuration register set-

GRIP

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

ting ORXBUFEN and a field ORXBUFSIZE is used to inform the bridge if a command queue is available in the other end and the capacity of the command queue space.

The command queueing feature is used to enqueue additional writes before write acknowledge has been received for previous writes. The improves bandwidth for cases where writes have a long latency on the other end before the acknowledge is sent back. Note that due to the single buffer in the bridge, the AHB write burst and the transmission of the commmand can still not be performed in parallel.

118.3.6 Address translation

By default the address transmitted over the byte stream is the same as the address of the AHB access but the core supports a basic address translation scheme. When enabled, the highest 8 bits of the outgoing address will be replaced by a value configured in a configuration register. Translation can be enabled individually for the two different slave BARs provided.

Translation of incoming accesses can also be enabled. This will in a similar way replace the highest 8 bits of any incoming address by a value from a configuration register.

118.3.7 Deadlock avoidance

When the bridge is used bidirectionally there is a potential deadlock condition when the AHB slaves on both sides of the link are accessed simultaneously. Since the slaves will be issuing wait states and keeping their respective AHB buses occupied, both the masters will wait indefinitely to be granted the bus they are connected to.

In order to recover from this condition, a deadlock detection scheme is implemented inside the core. If the master port is waiting to be granted and at the same time the slave port is waiting for a response from the other side of the link, a counter starts running that increments for every received IDLE byte on the byte stream. After 16 IDLE:s have been recieved in this condition, the deadlock detection triggers the AHB slave to issue a RETRY response. This frees up the bus for other masters, including the AHB master port of the bridge, to make accesses before the slave port access has completed. The slave port will issue RETRY responses to any other master that tries to access it, and return to operation once the master that originally accessed it comes back with the same access.

In order for the deadlock avoidance function to work as intended, round-robin arbitration policy needs to be used on at least one side of the bridge. This is needed in order to guarantee that the bridge's master port will be granted while the slave port is giving RETRY responses, and that the original master that was accessing the slave will eventually be granted access to the bus.

118.3.8 AHB locking considerations

The core ignores the lock related signals and does not communicate the lock state of the bus across the bridge, therefore locked accesses to the bridge will only be atomic with respect to other accesses on the bus where the access is made.

In bidirectional bridge configuration, a simultaneous locked access to the AHB slave port on both sides of the bridge may result in a deadlock condition which the deadlock avoidance logic can not resolve. This is because the locked state of the bus will take precedence over the arbitration policy and prevent any other master from accessing the bus even if the slave port issues RETRY responses.

118.3.9 AHB error handling

If the master port receives an AHB error response, any read data is replaced by all-one or all-zero data (based on the ERRVAL setting). That the error occured is otherwise not reported to the other endpoint. If detecting ERROR response from the other end is desired, a system designer could for example provide an AHB status register at a given address that could be read out through the bridge.

The bridge can also be configured to go into error state when an AHB error occurs. If this option is used, the error would have to be acknowledged before any further access can be made.

118.3.10Link error handling

The core can check for parity errors, if parity is implemented, and also detect certain protocol violations on the incoming data. If any of these errors occur then the bridge will go into "error state". In error state, any access to the slave port will be given ERROR response and commands coming in from the other endpoint will be ignored.

When the bridge is in error state, the bridge will continuously send the PeerError command to the other end to indicate that it is in error state. Receiving the PeerError command will make the other end also go into error state. To avoid loops of peer error commands, the endpoint that has received a PeerError will only send regular Idle commands.

The error state can be cleared via the register interface. Once the error condition is cleared, the bridge returns to an idle state. The endpoint that had the original error needs to be cleared first in order to stop the transmission of PeerError messages. If the other endpoint is cleared first, it will immediately see another PeerError and go back into error state.

Note that the bridge does not provide any mechanism to clear the error state on the other end of the bridge, this must be managed on system level, by accessing the other end through some other means or for example by controlling the reset line on the other endpoint.

118.3.11Link startup

After reset has been released, the core will ignore the first 16 data bytes received over the link and the core will transmit at least 32 IDLE bytes before the first command. This is intended to simplify the design by providing some margin in case reset is released at slightly different times on the two sides of the bridge, and removes the need for asynchronous resets in registers that are in the data path.

118.3.12Interrupts

The core can be configured provide an interrupt when it enters error state.

118.3.13Register interface

Configuration registers are accessed through an APB slave interface.

In order not to require a second APB interface for the interface layer, some register fields to configure the interface are also included in the socbridge. Depending on static signals in from the interface layer, these may get forced to a constant value in order to optimized out in designs where they are not needed.

118.4 Implementation

118.4.1 Physical interfaces

The main socbridge block runs entirely in the AHB bus clock domain. It expects external logic to provide the incoming data bytes from the byte stream and valid signals to indicate on which cycles new data is available and on which cycles a transmit data byte has been consumed.

118.4.2 Oversampling parallel interface

The socbridge_parif block provides an implementation of the parallel interface as described in section 118.2.4. The block is clocked by the same AHB clock used for the socbridge and can handle external data rates up to 1/8 of the AHB clock rate. The incoming clock is captured using synchronization registers for edge detection.

The interface can be configured at run time to act as either primary or secondary side of the interface. When configured as primary side, it uses a counter to divide the AHB clock down to create the outgoing clock. The timing of when the transmit data changes in relation to the outgoing clock edge can be

GRIP

Apr 2024, Version 2024.1

1924

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

configured in order to allow timing optimizations. For the incoming clock, a counter is used to time when the data is sampled relative to detected edges on the clock.

When the interface is configured to run as secondary side, it will detect rising edges on the incoming clock and use there to sample data, deliver outgoing data and toggle the outgoing clock. When configured as secondary side there are no counters or configurable delays. If the physical interface is built with only support for secondary side operation, most registers needed for primary side operation can be removed.

118.4.3 Link-clocked parallel interface

An alternative interface block called socbridge_parif_comclk is provided for simple companion chip implementations where the clock coming in on the socbridge link is also used to clock the entire system-on-chip. This block only support secondary side operation.

Having the same clock removes the need for synchronization registers and the interface block reduces down to just a register stage.

118.4.4 Cross-connection

For prototyping and verification purposes, crossbars to directly interconnect two socbridges in the same system are provided. socbridge_xcon simply interconnect two socbridges inputs and outputs with no additional logic and works when the two bridges are in the same clock domain. For the case where the bridges are in different clock domains socbridge_xcon_cdc is provide that uses asynchronous FIFOs to transfer the data between the domains.

118.4.5 Internal buffers

The socbridge contains the following data buffers, all implemented in registers:

*   master-side burst buffer, number of bytes given by mmaxburst
*   master-side request queue, number of bytes given by rxqsize
*   slave-side burst buffer, number of bytes given by smaxburst
*   common request/response transmit buffer, fixed size of 5 bytes.

118.4.6 Endianness

The core support operation on both little-endian and big-endian systems and will adjust depending on the endian side-band signal in the AMBA records

Regardless of endian-ness, the read and write data over the link is transferred byte-wise in incrementing address order (the byte at the initial address A transmitted first, followed by the byte at address A+1, the byte at address A+2, etc.). When using the bridge with opposing endian-ness on both sides, the bridge will therefore provide byte consistent access to data.

118.4.7 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

118.5 Registers

The bridge provides a configuration register area accessed over the APB bus. For forward compatibility, reserved fields should be written either with 0 or with the last read-out value, and reserved registers should not be accessed at all.

*Table 2211.*Configuration registers for SOCBRIDGE

Register address offset	Name	R/W	Reset value	Notes
0x00	Transfer configuration register	R/W	-	1
0x04	AHB configuration register	R/W	0x00000000	
0x08	Status register	R/W	0x00000000	
0x0C	Interrupt configuration register	R/W	0x00000001	
0x10	Parallel interface configuration register 1	R/W	-	1
0x14	Parallel interface configuration register 2	R/W	-	1
0x18 - 0xFC	RESERVED			

Note 1: Reset value depends on IP configuration options or external interface configuration

118.5.1 Transfer configuration register

Table 2212. 0x00 - SOCBRIDGE transfer configuration register

31				18	17	16
	RESERVED				MDIS	PCHK
	0				0	*
	r				rw	rw

15	14			3	2		0
ORQEN		ORQSIZE				OMAXSZ	
0		111111111111				010	
rw		rw				rw	

31 : 18	Reserved
17	Master disable (MDIS) - when set to 1 any incoming commands from the other end will be ignored.
16	Parity check enable (PCHK) - when set to 1 the bridge checks parity and enters error state when a parity is detected, when set to 0 parity errors are ignored. If parity is not implemented on the interface layer, this field will be constant zero.
15	Other end request queue enable (ORBEN) - set to 1 when it is known that the other end has a request queue that can take in additional commands while handling a command. When set to 0 the bridge will always wait for a response before sending any additional command.
14 : 3	Other end request queue size (ORQSIZE) - the size of the other end's request queue. Used only when ORQEN is set to 1.
2 : 0	Other end maximum acccess size. This is set to the largest size command that the other end can handle (corresponding to the mmaxburst generic setting on the other side). Size in power of two, default is 2 (4 bytes).

15 8	7 0
S1MODADDR	MMODADDR
00000000	00000000
rw	rw

31 : 30	Reserved
29	AHB master error value (MEVAL) - value to substitute in read data in case the AHB master access gets an ERROR response. If set to 1 an all-1 pattern is used, if set to 0 an all-0 pattern is used.
28	AHB master error fatal (MEFAT) - if set to 1, an ERROR response to an access by the AHB master will be treated as a fatal error and the link is put into error state.
27	Slave ignore writes (SIGWR) - when set to 1 the slave port will ignore writes and instantly give an OKAY response to the master.
26	Slave area 2 address modification enable (S2MOD) - when set to 1 accesses to the second slave BAR (if implemented) will have the most significant byte changed to the value of the S2MODADDR field. When set to 0, the AHB access address will be used directly as the command's address.
	This field is only writable if the second BAR of the slave port is implemented.
25	Slave area 1 address modification enable (S1MOD) - when set to 1 accesses to the first slave BAR (if implemented) will have the most significant byte changed to the value of the S1MODADDR field. When set to 0, the AHB access address will be used directly as the command's address.
	This field is only writable if the first BAR of the slave port is implemented
24	Master address modification enable (MMOD) - when set to 1, incoming accesses will have the most significant byte of the address used by the AHB master changed to the value of the MMODADDR field. When set to 0, the incoming address will be used directly as the AHB master address.
	This field is only writable if the master port is implemented
23 : 16	Slave area 2 address modification address value (S2MODADDR)
	This field is only writable if the second BAR of the slave port is implemented.
15: 8	Slave area 1 address modification address value (S1MODADDR)
	This field is only writable if the first BAR of the slave port is implemented.
7 : 0	Master address modification address value (MMODADDR)
	This field is only writable if the master port is implemented

119   SPI2AHB - SPI to AHB bridge

119.1   Overview

The SPI to AHB bridge is an SPI slave that provides a link between a SPI bus (that consists of two data signals, one clock signal and one select signal) and AMBA AHB. On the SPI bus the slave acts as an SPI memory device where accesses to the slave are translated to AMBA accesses. The core can translate SPI accesses to AMBA byte, half-word or word accesses. The access size to use is configurable via the SPI bus.

The core synchronizes the incoming clock and can operate in systems where other SPI devices are driven by asynchronous clocks.

GRLIB also contains a SPI master/slave controller core, without an AHB interface, where the transfer of each individual byte is controlled by software via an APB interface, see the SPICTRL core documentation for more information.
Figure 304. Block diagram, optional APB interface not shown

119.2   Transmission protocol

The SPI bus is a full-duplex synchronous serial bus. Transmission starts when a master selects a slave through the slave's Slave Select (SLVSEL) signal and the clock line SCK transitions from its idle state. Data is transferred from the master through the Master-Output-Slave-Input (MOSI) signal and from the slave through the Master-Input-Slave-Output (MISO) signal. In some systems with only one master and one slave, the Slave Select input of the slave may be always active and the master does not need to have a slave select output. This does not apply to this SPI to AHB bridge, the slave select signal must be used to mark the start and end of an operation.

During a transmission on the SPI bus data is either changed or read at a transition of SCK. If data has been read at edge n, data is changed at edge n+1. If data is read at the first transition of SCK the bus is said to have clock phase 0, and if data is changed at the first transition of SCK the bus has clock phase 1. The idle state of SCK may be either high or low. If the idle state of SCK is low, the bus has clock polarity 0 and if the idle state is high the clock polarity is 1. The combined values of clock polarity (CPOL) and clock phase (CPHA) determine the mode of the SPI bus. Figure 305 shows one byte (0x55) being transferred MSb first over the SPI bus under the four different modes. Note that the idle state of the MOSI line is '1' and that CPHA = 0 means that the devices must have data ready before the first transition of SCK. The figure does not include the MISO signal, the behavior of this line is the same as for the MOSI signal. However, due to synchronization the MISO signal will be delayed for a period of time that depends on the system clock frequency.

1933

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

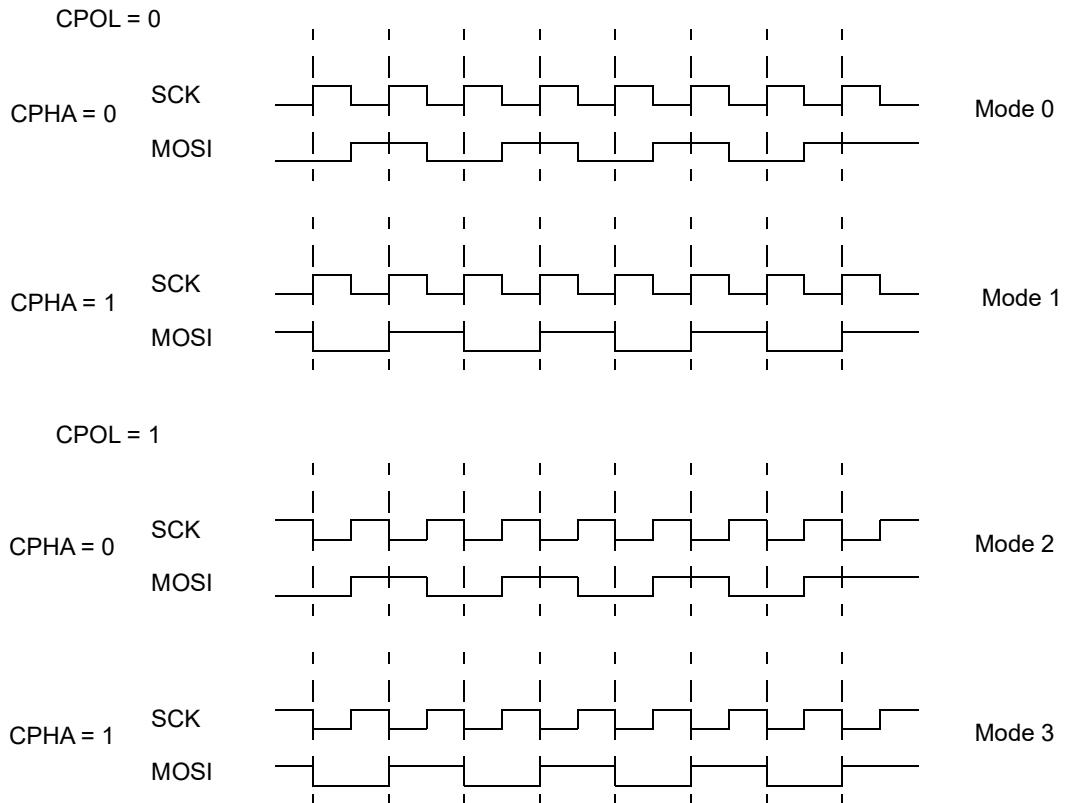
+46 31 7758650 | frontgrade.com/gaisler


Figure 305. SPI transfer of byte 0x55 in all modes

The SPI to AHB bridge makes use of a protocol commonly used by SPI Flash memory devices. A master first selects the slave via the slave select signal and then issues a one-byte instruction. The instruction is then followed by additional bytes that contain address or data values. All instructions, addresses and data are transmitted with the most significant bit first. All AMBA accesses are done in big endian format. The first byte sent to or from the slave is the most significant byte.

119.3 System clock requirements and sampling

The core samples the incoming SPI SCK clock and does not introduce any additional clock domains into the system. Both the SCK and MOSI lines first pass through two stage synchronizers and are then filtered with a low pass filter.

The synchronizers and filters constrain the minimum system frequency. The core requires the SCK signal to be stable for at least two system clock cycles before the core accepts the SCK value as the new clock value. The core's reaction to transitions will be additionally delayed since both lines are taken through two-stage synchronizers before they are filtered. In order for the slave to be able to output data on the SCK 'change' transition and for this data to reach the master before the next edge the SCK frequency should not be higher than one tenth of the system frequency of core (with the standard VHDL generic *filter* setting of 2).

The slave select input should be asserted at least two system clock cycles before the SCK line starts transitioning.

119.4 SPI instructions

119.4.1 Overview

The core is controlled from the SPI bus by sending SPI instructions. Some commands require additional bytes in the form of address or data. The core makes use of the same instructions as commonly available SPI Flash devices. Table 2221 summarizes the available instructions.

Table 2221. SPI instructions

Instruction	Description	Instruction code	Additional bytes
RDSR	Read status/control register	0x05	Core responds with register value
WRSR	Write status/control register	0x01	New register value
READ	AHB read access	0x03	Four address bytes, after which core responds with data.
READD	AHB read access with dummy byte	0x0B	Four address bytes and one dummy byte, after which core responds with data
WRITE	AHB write access	0x02	Four address bytes followed by data to be written

All instructions, addresses and data are transmitted with the most significant bit first. All AMBA accesses are done in big endian format. The first byte sent to or from the slave is the most significant byte.

119.4.2 SPI status/control register accesses (RDSR/WRSR)

The RDSR and WRSR instructions access the core's SPI status/control register. The register is accessed by issuing the wanted instruction followed by the data byte to be written (WRSR) or any value on the byte in order to shift out the current value of the status/control register (RDSR). The fields available in the SPI status/control register are shown in table 2222.

Table 2222. SPI2AHB SPI status/control register

7	6	5	4	3	2	1	0
Reserved	RAHEAD	PROT	MEXC	DMAACT	MALF	HSIZE	

7   Reserved, always zero (read only)

6   Read ahead (RAHEAD) - When this bit is set the core will make a new access to fetch data as soon as the last current data bit has been moved. Otherwise the core will not attempt the new access until the 'change' transition on SCK. Setting this bit to '1' allows higher SCK frequencies to be used but will also result in a data fetch as soon as the current data has been read out. This means that RAHEAD may not be suitable when accessing FIFO interfaces. (read/write)

5   Memory protection triggered (PROT) - '1' if last AHB access was outside the allowed memory area. Updated after each AMBA access (read only). Note that since this bit is updated after each access the RAHEAD = '1' setting may hide errors.

4   Memory exception (MEXC) - '1' if core receives AMBA ERROR response. Updated after each AMBA access (read only). Note that since this bit is updated after each access the RAHEAD = '1' setting may hide errors.

3   DMA active (DMAACT) - '1' if core is currently performing a DMA operation.

2   Malfunction (MALF): This bit is set to one by the core is DMA is not finished when a new byte starts getting shifted. If this bit is set to '1' then the last AHB access was not successful.

1:0   AMBA access size (HSIZE) - Controls the access size that the core will use for AMBA accesses. 0: byte, 1: half-word, 2: word. HSIZE = "11" is illegal.

Reset value: 0x42

119.4.3 Read and write instructions (WRITE and READ/READD)

The READD is the same as the READ instruction with an additional dummy byte inserted after the four address bytes. To perform a read operation on AHB via the SPI bus the following sequence should be performed:

GRIP
Apr 2024, Version 2024.1

1935

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

1. Assert slave select

2. Send READ instruction

3. Send four byte AMBA address, the most significant byte is transferred first

3a. Send dummy byte (if READD is used)

4. Read the wanted number of data bytes

5. De-assert slave select

To perform a write access on AHB via the SPI bus, use the following sequence:

1. Assert slave select

2. Send WRITE instruction

3. Send four byte AMBA address, the most significant byte is transferred first

4. Send the wanted number of data bytes

5. De-assert slave select

During consecutive read or write operations, the core will automatically increment the address. The access size (byte, halfword or word) used on AHB is set via the HSIZE field in the SPI status/control register.

The core always respects the access size specified via the HSIZE field. If a write operation writes fewer bytes than what is required to do an access of the specified HSIZE then the write data will be dropped, no access will be made on AHB. If a read operation reads fewer bytes than what is specified by HSIZE then the remaining read data will be dropped when slave select is de-asserted.

The core will not mask any address bits. Therefore it is important that the SPI master respects AMBA rules when performing half-word and word accesses. A half-word access must be aligned on a two byte address boundary (least significant bit of address must be zero) and a word access must be aligned on a four byte boundary (two least significant address bits must be zero).

The core can be configured to generate interrupt requests when an AHB access is performed if the core is implemented with the APB register interface, see the APB register documentation for details.

119.4.4 Memory protection

The core is configured at implementation time to only allow accesses to a specified AHB address range (which can be the full 4 GiB AMBA address range). If the core has been implemented with the optional APB register interface then the address range is soft configurable and the reset value is specified with VHDL generics.

The VHDL generics *ahbaddrh* and *ahbaddrl* define the base address for the allowed area. The VHDL generics *ahbmaskh* and *ahbmaskl* define the size of the area. The generics are used to assign the memory protection area's address and mask in the following way:

Protection address, bits 31:16 (*protaddr[31:16]*): ahbaddrh
Protection address, bits 15:0 (*protaddr[15:0]*): ahbaddrl
Protection mask, bits 31:16 (*protmask[31:16]*): ahbmaskh
Protection mask, bits 15:0 (*protmask[15:0]*): ahbmaskl

Before the core performs an AMBA access it will perform the check:

(((incoming address) xor (protaddr)) and protmask) /= 0x00000000

If the above expression is true (one or several bits in the incoming address differ from the protection address, and the corresponding mask bits are set to '1') then the access is inhibited. As an example, assume that *protaddr* is 0xA0000000 and *protmask* is 0xF0000000. Since *protmask* only has ones in the most significant nibble, the check above can only be triggered for these bits. The address range of allowed accessed will thus be 0xA0000000 - 0xAFFFFFFF..

The core will set the configuration register bit PROT if an access is attempted outside the allowed address range. This bit is updated on each AHB access and will be cleared by an access inside the allowed range. Note that the (optional) APB status register has a PROT field with a slightly different behavior.

119.5 Registers

The core can optionally be implemented with an APB interface that provides registers mapped into APB address space.

Table 2223. APB registers

APB address offset	Register
0x00	Control register
0x04	Status register
0x08	Protection address register

119.6 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x05C. For a description of vendor and device identifiers see the GRLIB IP Library User's Manual.

119.7 Implementation

119.7.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

119.7.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

119.8 Configuration options

Table 2228 shows the configuration options of the core (VHDL generics). Two different top level entities for the core is available. One with the optional APB interface (spi2ahb_apb) and one without the APB interface (spi2ahb). The entity without the APB interface has fewer generics as indicated in the table below.

*Table 2228.*Configuration options

Generic name	Function	Allowed range	Default
hindex	AHB master index	0 - NAHBMST	0
ahbaddrh	Defines bits 31:16 of the address used for the memory protection area	0 - 16#FFFF#	0
ahbaddrl	Defines bits 15:0 of the address used for the memory protection area	0 - 16#FFFF#	0
ahbmaskh	Defines bits 31:16 of the mask used for the memory protection area	0 - 16#FFFF#	0
ahbmaskl	Defines bits 15:0 of the mask used for the memory protection area	0 - 16#FFFF#	0
resen	Reset value for core enable bit (only available on the spi2ahb_apb entity).	0 - 1	0
pindex	APB slave index (only available on the spi2ahb_apb entity).	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR (only available on the spi2ahb_apb entity).	0 - 16#FFF#	0
pmask	MASK field of the APB BAR (only available on the spi2ahb_apb entity).	0 - 16#FFF#	16#FFF#
pirq	Interrupt line driven by APB interface (only available on the spi2ahb_apb entity).	0 - NAHBIRQ-1	0
oepol	Output enable polarity	0 - 1	0
filter	Low-pass filter length. This generic should specify, in number of system clock cycles plus one, the time of the shortest pulse on the SCK clock line to be registered as a valid value.	2 - 512	2
cpol	Clock polarity of SPI clock (SCK)	0 - 1	0
cpha	Clock phase of SPI communication	0 - 1	0

120   SPICTRL - SPI Controller

120.1   Overview

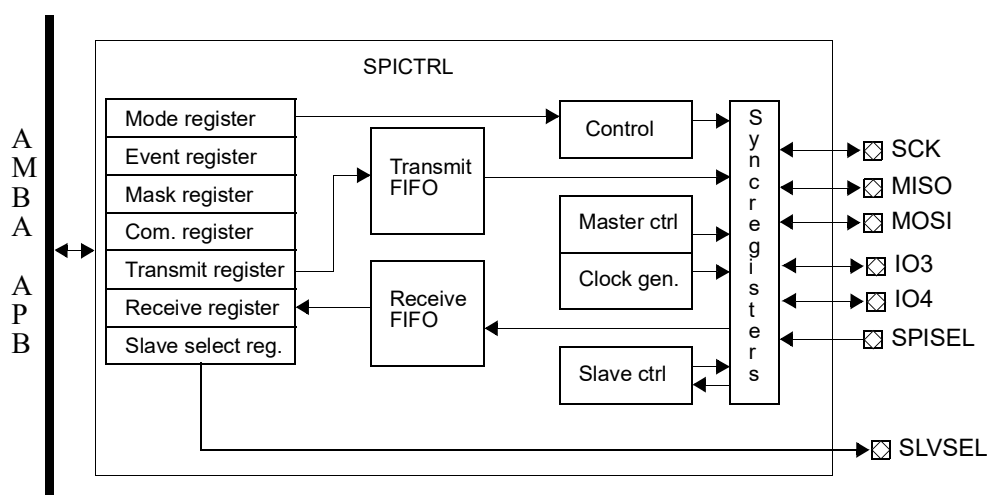
The core provides a link between the AMBA APB bus and the Serial Peripheral Interface (SPI) bus and can be dynamically configured to function either as a SPI master or a slave. The SPI bus parameters are highly configurable via registers. Core features also include configurable word length, bit ordering, clock gap insertion, automatic slave select and automatic periodic transfers of a specified length. All SPI modes are supported and optionally also dual SPI, quad SPI, and a 3-wire protocol where one bidirectional data line is used. In slave mode the core synchronizes the incoming clock and can operate in systems where other SPI devices are driven by asynchronous clocks.


Figure 306. Block diagram

120.2   Operation

120.2.1 SPI transmission protocol

The SPI bus is a full-duplex synchronous serial bus. Transmission starts when a master selects a slave through the slave's Slave Select (SLVSEL) signal and the clock line SCK transitions from its idle state. Data is transferred from the master through the Master-Output-Slave-Input (MOSI) signal and from the slave through the Master-Input-Slave-Output (MISO) signal. In a system with only one master and one slave, the Slave Select input of the slave may be always active and the master does not need to have a slave select output. If the core is configured as a master it will monitor the SPISEL signal to detect collisions with other masters, if SPISEL is activated the master will be disabled.

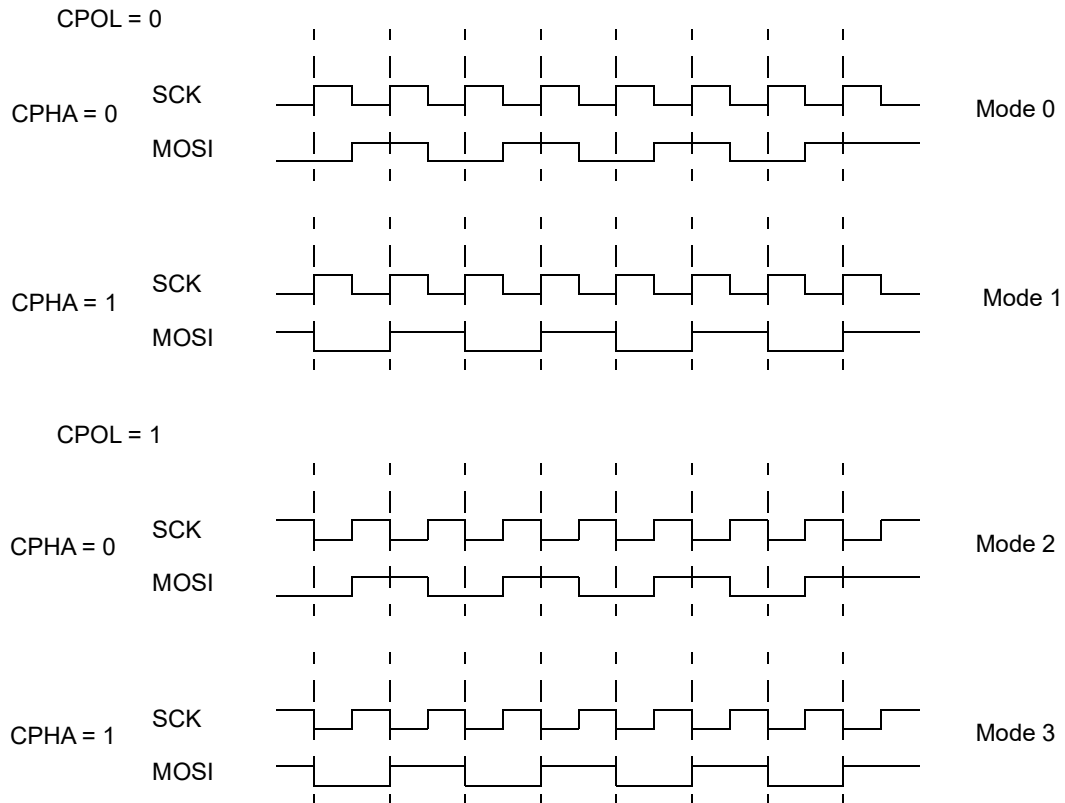
During a transmission on the SPI bus data is either changed or read at a transition of SCK. If data has been read at edge n, data is changed at edge n+1. If data is read at the first transition of SCK the bus is said to have clock phase 0, and if data is changed at the first transition of SCK the bus has clock phase 1. The idle state of SCK may be either high or low. If the idle state of SCK is low, the bus has clock polarity 0 and if the idle state is high the clock polarity is 1. The combined values of clock polarity (CPOL) and clock phase (CPHA) determine the mode of the SPI bus. Figure 307 shows one byte (0x55) being transferred MSb first over the SPI bus under the four different modes. Note that the idle state of the MOSI line is '1' and that CPHA = 0 means that the devices must have data ready before the first transition of SCK. The figure does not include the MISO signal, the behavior of this line is the same as for the MOSI signal. However, due to synchronization issues the MISO signal will be delayed when the core is operating in slave mode, please see section 120.2.6 for details.


Figure 307. SPI transfer of byte 0x55 in all modes

120.2.2 3-wire transmission protocol

The core can be configured to use a 3-wire protocol if the TWEN field in the core's Capability register 0 is set to '1', where the controller uses a bidirectional dataline instead of separate data lines for input and output data. In 3-wire protocol the bus is thus a half-duplex synchronous serial bus. Transmission starts when a master selects a slave through the slave's Slave Select (SLVSEL) signal and the clock line SCK transitions from its idle state. Only the Master-Output-Slave-Input (MOSI) signal is used for data transfer in the 3-wire protocol. The MISO signal is not used.

The direction of the first data transfer is determined by the value of the 3-wire Transfer Order (TTO) field in the core's Mode register. If TTO is '0', data is first transferred from the master (through the MOSI signal). After a word has been transferred, the slave uses the same data line to transfer a word back to the master. If TTO is '1' data is first transferred from the slave to the master. After a word has been transferred, the master uses the MOSI line to transfer a word back to the slave.

The data line transitions depending on the clock polarity and clock phase in the same manner as in SPI mode. The aforementioned slave delay of the MISO signal in SPI mode will affect the MOSI signal when using 3-wire protocol, when the core operates as a slave.

120.2.3 Dual and quad transmission protocols

The core can be configured to use dual and quad SPI protocols if support for these protocols is indicated in the PROT field of the core's Capability register 1. The SPROT field of the core's Command register determines the protocol to use.

In standard SPI mode, a master always transmits on the MOSI line and receives on the MISO line and vice-versa for a slave. With dual SPI protocol the slave or master may use both of MISO and MOSI for reception or transmission. In quad SPI mode the slave or master will use MISO, MOSI, IO2 and IO3 for either transmission or reception. Since this all traffic in this controller is driven via the trans-

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

mit queue it becomes necessary to mark the words to be transmitted so that the controller knows which direction that should be used for the MISO, MOSI, IO2 and IO3 lines in the corresponding transfer. The direction associated with the transfer is determined by the setting of the DIR field in the core's Command register.

120.2.4 Receive and transmit queues

The core's transmit queue consists of the transmit register and the transmit FIFO. The receive queue consists of the receive register and the receive FIFO. The total number of words that can exist in each queue is thus the FIFO depth plus one. When the core has one or more free slots in the transmit queue it will assert the Not full (NF) bit in the event register. Software may only write to the transmit register when this bit is asserted. When the core has received a word, as defined by word length (LEN) in the Mode register, it will place the data in the receive queue. When the receive queue has one or more elements stored the Event register bit Not empty (NE) will be asserted. The receive register will only contain valid data if the Not empty bit is asserted and software should not access the receive register unless this bit is set. If the receive queue is full and the core receives a new word, an overrun condition will occur. The received data will be discarded and the Overrun (OV) bit in the Event register will be set.

The core will also detect underrun conditions. An underrun condition occurs when the core is selected, via SPISEL, and the SCK clock transitions while the transmit queue is empty. In this scenario the core will respond with all bits set to '1' and set the Underrun (UN) bit in the Event register. An underrun condition will never occur in master mode. When the master has an empty transmit queue the bus will go into an idle state.

120.2.5 Clock generation

The core only generates the clock in master mode, the generated frequency depends on the system clock frequency and the Mode register fields DIV16, FACT, and PM. Without DIV16 the SCK frequency is:

$$SCKFrequency = \frac{AMBAclockfrequency}{(4 - (2 \cdot FACT)) \cdot (PM + 1)}$$

With DIV16 enabled the frequency of SCK is derived through:

$$SCKFrequency = \frac{AMBAclockfrequency}{16 \cdot (4 - (2 \cdot FACT)) \cdot (PM + 1)}$$

Note that the fields of the Mode register, which includes DIV16, FACT and PM, should not be changed when the core is enabled. If the FACT field is set to 0 the core's register interface is compatible with the register interface found in MPC83xx SoCs. If the FACT field is set to 1, the core can generate an SCK clock with higher frequency.

120.2.6 Slave operation

When the core is configured for slave operation it does not drive any SPI signal until the core is selected, via the SPISEL input, by a master. If the core operates in SPI mode when SPISEL goes low the core configures MISO as an output and drives the value of the first bit scheduled for transfer. If the core is configured to use 3-wire protocol then the core will first listen to the MOSI line and when a word has been transferred drive the response on the MOSI line. If the core is selected when the transmit queue is empty it will transfer a word with all bits set to '1' and the core will report an underflow.

Since the core synchronizes the incoming clock it will not react to transitions on SCK until two system clock cycles have passed. This leads to a delay of three system clock cycles when the data output line should change as the result of a SCK transition. This constrains the maximum input SCK frequency of the slave to (system clock) / 8 or less. The controlling master must also allow the decreased setup time on the slave data out line.

The core can also filter the SCK input. The value of the PM field in the Mode register defines for how many system clock cycles the SCK input must be stable before the core accepts the new value. If the PM field is set to zero, then the maximum SCK frequency of the slave is, as stated above, (system clock) / 8 or less. For each increment of the PM field the clock period of SCK must be prolonged by two times the system clock period as the core will require longer time discover and respond to SCK transitions.

120.2.7 Master operation

When the core is configured for master operation it will transmit a word when there is data available in the transmit queue. When the transmit queue is empty the core will drive SCK to its idle state. If the SPISEL input goes low during master operation the core will abort any active transmission and the Multiple-master error (MME) bit will be asserted in the Event register. If a Multiple-master error occurs the core will be disabled. Note that the core will react to changes on SPISEL even if the core is operating in loop mode and that the core can be configured to ignore SPISEL by setting the IGSEL field in the Mode register.

120.2.8 Automated periodic transfers

The core supports automated periodic transfers if the AMODE field in the core's Capability register is '1'. In this mode the core will perform transfers with a specified period and length. The steps below outline how to set up automated transfers:

1. Configure the core's Mode register as a master and set the AMEN field (bit 31) to '1'. Possibly also configure the automatic slave select settings.

2. Write to the AM Mask registers to configure which parts of the AM transmit queue that will be used. The number of bits in the AM Mask registers that are set to one together with the word length (set in the Mode register) defines how long the transfer should be.

3. Write data to the AM transmit queue (AM Transmit registers). Only those registers that correspond to a bit that is set to one in the AM Mask registers need to be written.

4. Set the transfer period in the AM Period register.

5. Set the options for the automated transfers in the AM Configuration register

6. Set the ACT or EACT field in the AM Configuration register.

7. Wait for the Not Empty field to be set in the Event register

8. Read out the AM Receive queue (AM Receive registers). If lock bit (LOCK) in AM Configuration register is set then all registers which have a bit in the AM Mask registers set must be read. If the lock bit is not set software does not need to read out any data, the core can write new data to the AM Receive registers anyway.

9. Go back to step 7.

When an automated transfer is performed, data is not immediately placed in AM receive queue. Instead the data is placed in a temporary queue to ensure that a full transfer can be read out atomically without interference from incoming data.

The AM receive queue is filled with the data from the temporary queue if the AM receive queue is empty, or if it is full and Sequential transfers (SEQ) is disabled in the AM Configuration register. It is possible to configure the core not to place new data in the AM receive queue while software is reading

out data from the queue. This is done by setting the lock bit (LOCK) in the AM Configuration register.

If the AM Configuration register's SEQ bit is set the core will not move data from the temporary queue until the AM receive queue has been cleared. Demanding Sequential transfers means that the AM receive queue's data will never be overwritten. However, data may still be lost, depending on the settings that determine how the temporary queue handles overflow conditions.

The controller will attempt to place data into the temporary receive queue when the automated transfer period counter reaches zero. If the temporary queue is filled, which can occur if the controller is prevented from moving the data to the receive queue, the core's behavior will depend on the setting of the Strict Period (STRICT) field in the AM Configuration register:

If the value of STRICT is '0' the core will delay the transfer and wait until the temporary queue has been cleared.

If the value of STRICT is '1', and the contents of the temporary queue can not be moved to the AM receive queue, there will be an overflow condition in the temporary queue. The core's behavior on a temporary queue overflow is defined by the AM Configuration register fields Overflow Transfer Behavior (OVTB) and Overflow Data Behavior (OVDB). If there is a temporary queue overflow and OVTB is set, the transfer will be skipped and the core's internal period counter will be reloaded. If the OVTB bit is not set the transfer will be performed. If the transfer is performed and the OVDB bit is set the data will be disregarded. If the OVDB bit is not set the data will be placed in the temporary receive queue and the previous data will be overwritten.

A series of automated transfers can be started by an external event. If the AM Configuration register field EACT is set, the core will activate Automated transfers when its internal ASTART input signal goes high. When the core detects that EACT and ASTART are both set, it will set the AM Configuration register ACT bit and reset the EACT bit. Note that subsequent automated transfers will be started when the period counter reaches zero, if ERPT field of the AM Configuration register is set to zero. If the ERPT field is set to one then the ASTART input is used to start subsequent transfers instead.

When automated transfers are enabled by setting the AM Configuration register ACT bit, the core will send a pulse on its internal ASTART output signal. This means that several cores can be connected together and have their start event synchronized. To synchronize a start event, set the EACT bit in all cores, except in the last core which is activated by setting the AM Configuration register ACT field. The last core will then pulse its ASTART output and trigger the start event in all the other connected cores. When this has been done the cores' transfers will be synchronized. However this synchronization may be lost if a core's receive queues are filled and STRICT transfers are disabled, since this will lead to a delay in the start of the core's next transfer.

When the core operates in AM mode, the Receive and Transmit registers should not be accessed. Nor should the AM transmit registers be updated when automatic transfers are enabled.

	FDEPTH		SR	FT		REV	
	*		*	*		5	
	r		r	r		r	

31 : 24	Slave Select register size (SSSZ) - If the core has been configured with slave select signals this field contains the number of available signals. This field is only valid is the SSEN bit (bit 16) is '1
23 : 20	Maximum word Length (MAXWLEN) - The maximum word length supported by the core: 0b0000 - 4-16, and 32-bit word length 0b0011-0b1111 - Word length is MAXWLEN+1, allows words of length 4-16 bits. The core must not be configured to use a word length greater than what is defined by this register.
19	3-wire Protocol Enable (TWEN) - If this bit is '1' the core supports 3-wire protocol. See also the PROT field in Capability register 1.
18	Auto mode (AMODE) - If this bit is '1' the core supports Automated transfers.
17	Automatic slave select available (ASELA) - If this bit is set, the core has support for setting slave select signals automatically.
16	Slave Select Enable (SSEN) - If the core has a slave select register, and corresponding slave select lines, the value of this field is one. Otherwise the value of this field is zero.
15 : 8	FIFO depth (FDEPTH) - This field contains the depth of the core's internal FIFOs. The number of words the core can store in each queue is FDEPTH+1, since the transmit and receive registers can contain one word each.
7	SYNCRAM (SR) - If this field is '1' the core has buffers implemented with SYNCRAM components.
6 : 5	Fault-tolerance (FT) - This field signals if the core has any fault-tolerant capabilities. "00" - No fault-tolerance. "01" - Parity DMR, "10" - TMR.
4 : 0	Core revision (REV) - This manual applies to core revision 5.

rw*	rw*	rw	rw*	rw				rw*		rw	rw	rw	rw	r

31   Auto mode enable (AMEN) - When this bit is set to '1' the core will be able to perform automated periodic transfers. See the AM registers below. The core supports this mode if the AMODE field in the capability register is set to '1'. Otherwise writes to this field has no effect. When this bit is set to '1' the core can only perform automated transfers. Software is allowed to initialize the transmit queue and to read out the receive queue but no transfers except the automated periodic transfers may be performed. The core must be configured to act as a master (MS field set to '1') when performing automated transfers.

30   Loop mode (LOOP) - When this bit is set, and the core is enabled, the core's transmitter and receiver are interconnected and the core will operate in loopback mode. The core will still detect, and will be disabled, on Multiple-master errors.

29   Clock polarity (CPOL) - Determines the polarity (idle state) of the SCK clock.

28   Clock phase (CPHA) - When CPHA is '0' data will be read on the first transition of SCK. When CPHA is '1' data will be read on the second transition of SCK.

27   Divide by 16 (DIV16) - Divide system clock by 16, see description of PM field below and see section 120.2.5 on clock generation. This bit has no significance in slave mode.

26   Reverse data (REV) - When this bit is '0' data is transmitted LSB first, when this bit is '1' data is transmitted MSB first. This bit affects the layout of the transmit and receive registers.

25   Master/Slave (MS) - When this bit is set to '1' the core will act as a master, when this bit is set to '0' the core will operate in slave mode.

24   Enable core (EN) - When this bit is set to '1' the core is enabled. No fields in the mode register should be changed while the core is enabled. This can bit can be set to '0' by software, or by the core if a multiple-master error occurs.

23 : 20   Word length (LEN) - The value of this field determines the length in bits of a transfer on the SPI bus. Values are interpreted as:

     0b0000 - 32-bit word length

     0b0001-0b0010 - Illegal values

     0b0011-0b1111 - Word length is LEN+1, allows words of length 4-16 bits.

     The value of this field must never specify a word length that is greater than the maximum allowed word length specified by the MAXWLEN field in the Capability register.

19 : 16   Prescale modulus (PM) - This value is used in master mode to divide the system clock and generate the SPI SCK clock. The value in this field depends on the value of the FACT bit.

     If bit 13 (FACT) is '0':The system clock is divided by 4*(PM+1) if the DIV16 field is '0' and 16*4*(PM+1) if the DIV16 field is set to '1'. The highest SCK frequency is attained when PM is set to 0b0000 and DIV16 to '0', this configuration will give a SCK frequency that is (system clock)/4. With this setting the core is compatible with the SPI register interface found in MPC83xx SoCs.

     If bit 13 (FACT) is '1': The system clock is divided by 2*(PM+1) if the DIV16 field is '0' and 16*2*(PM+1) if the DIV16 field is set to '1'. The highest SCK frequency is attained when PM is set to 0b0000 and DIV16 to '0', this configuration will give a SCK frequency that is (system clock)/2.

     In slave mode the value of this field defines the number of system clock cycles that the SCK input must be stable for the core to accept the state of the signal. See section 120.2.6.

15   3-wire protocol (TW) - If this bit is set to '1' the core will operate using 3-wire protocol. This bit can only be set if the TWEN field of the Capability register is set to '1'.

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 2235.*0x20 - MODE - SPI controller Mode register

14	Automatic slave select (ASEL) - If this bit is set to '1' the core will swap the contents in the Slave select register with the contents of the Automatic slave select register when a transfer is started and the core is in master mode. When the transmit queue is empty, the slave select register will be swapped back. Note that if the core is disabled (by writing to the core enable bit or due to a multiple-master-error (MME)) when a transfer is in progress, the registers may still be swapped when the core goes idle. This bit can only be set if the ASELA field of the Capability register is set to '1'. Also see the ASELDEL field which can be set to insert a delay between the slave select register swap and the start of a transfer.
13	PM factor (FACT) - If this bit is 1 the core's register interface is no longer compatible with the MPC83xx register interface. The value of this bit affects how the PM field is utilized to scale the SPI clock. See the description of the PM field.
12	Open drain mode (OD) - If this bit is set to '0', all pins are configured for operation in normal mode. If this bit is set to '1' all pins are set to open drain mode. The implementation of the core may or may not support open drain mode. If this bit can be set to '1' by writing to this location, the core supports open drain mode. The pins driven from the slave select register are not affected by the value of this bit.
11 : 7	Clock gap (CG) - The value of this field is only significant in master mode. The core will insert CG SCK clock cycles between each consecutive word. This only applies when the transmit queue is kept non-empty. After the last word of the transmit queue has been sent the core will go into an idle state and will continue to transmit data as soon as a new word is written to the transmit register, regardless of the value in CG. A value of 0b00000 in this field enables back-to-back transfers.
6 : 5	Automatic Slave Select Delay (ASELDEL) - If the core is configured to use automatic slave select (ASEL field set to '1') the core will insert a delay corresponding to ASELDEL*(SPI SCK cycle time)/2 between the swap of the slave select registers and the first toggle of the SCK clock. As an example, if this field is set to "10" the core will insert a delay corresponding to one SCK cycle between assigning the Automatic slave select register to the Slave select register and toggling SCK for the first time in the transfer. This field can only be set if the ASELA field of the Capability register is set to '1'.
4	Toggle Automatic slave select during Clock Gap (TAC) - If this bit is set, and the ASEL field is set, the core will perform the swap of the slave select registers at the start and end of each clock gap. The clock gap is defined by the CG field and must be set to a value >= 2 if this field is set. This field can only be set if the ASELA field of the Capability register is set to '1'.
3	3-wire Transfer Order (TTO) - This bit controls if the master or slave transmits a word first in 3-wire protocol. If this bit is '0', data is first transferred from the master to the slave. If this bit is '1', data is first transferred from the slave to the master. This bit can only be set if the TWEN field of the Capability register is set to '1'.
2	Ignore SPISEL input (IGSEL) - If this bit is set to '1' then the core will ignore the value of the SPISEL input.
1	Require Clock Idle for Transfer End (CITE) - If this bit is '0' the core will regard the transfer of a word as completed when the last bit has been sampled. If this bit is set to '1' the core will wait until it has set the SCK clock to its idle level (see CI field) before regarding a transfer as completed. This setting only affects the behavior of the TIP status bit, and automatic slave select toggling at the end of a transfer, when the clock phase (CP field) is '0'.
0	RESERVED (R) - Read as zero and should be written as zero to ensure forward compatibility.

120.3.4 SPI Controller Event Register

Table 2236. 0x24 - EVENT - SPI controller Event register

31	30 16	15	14	13	12	11	10	9	8	7 0
TIP	R	AT	LT	R	OV	UN	MME	NE	NF	R
0	0	0	0	0	0	0	0	0	0	0
r	r	r	wc	r	wc	wc	wc	r	r	r

31	Transfer in progress (TIP) - This bit is '1' when the core has a transfer in progress. Writes have no effect. This bit is set when the core starts a transfer and is reset to '0' once the core considers the transfer to be finished. Behavior affected by setting of CITE field in Mode register.
30 : 16	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
15	Automated transfers (AT) - This bit is '1' when the core has an automated transfer in progress. This bit is cleared automatically by the core. Writes have no effect.
14	Last character (LT) - This bit is set when a transfer completes if the transmit queue is empty and the LST bit in the Command register has been written. This bit is cleared by writing '1', writes of '0' have no effect.
13	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
12	Overrun (OV) - This bit gets set when the receive queue is full and the core receives new data. The core continues communicating over the SPI bus but discards the new data. This bit is cleared by writing '1', writes of '0' have no effect.
11	Underrun (UN) - This bit is only set when the core is operating in slave mode. The bit is set if the core's transmit queue is empty when a master initiates a transfer. When this happens the core will respond with a word where all bits are set to '1'. This bit is cleared by writing '1', writes of '0' have no effect.
10	Multiple-master error (MME) - This bit is set when the core is operating in master mode and the SPI-SEL input goes active. In addition to setting this bit the core will be disabled. This bit is cleared by writing '1', writes of '0' have no effect.
9	Not empty (NE) - This bit is set when the receive queue contains one or more elements. It is cleared automatically by the core, writes have no effect.
8	Not full (NF) - This bit is set when the transmit queue has room for one or more words. It is cleared automatically by the core when the queue is full, writes have no effect. This bit is only updated when the core is enabled (EN field of Mode register is set to '1').
7 : 0	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.

120.3.5 SPI Controller Mask Register

*Table 2237.*0x28 - MASK - SPI controller Mask register

31	30 16	15	14	13	12	11	10	9	8	7 0
TIPE	R	AT	LTE	R	OVE	UNE	MMEE	NEE	NFE	R
0	0	0	0	0	0	0	0	0	0	0
rw	r	rw	rw	rw	rw	rw	rw	rw	rw	r

31	Transfer in progress enable (TIPE) - When this bit is set the core will generate an interrupt when the TIP bit in the Event register transitions from '0' to '1'.
30 : 16	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
15	Automated transfers (AT) - When this bit is set, the core will generate an interrupt when an automated transfer is completed.
14	Last character enable (LTE) - When this bit is set the core will generate an interrupt when the LT bit in the Event register transitions from '0' to '1'.
13	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
12	Overrun enable (OVE) - When this bit is set the core will generate an interrupt when the OV bit in the Event register transitions from '0' to '1'.
11	Underrun enable (UNE) - When this bit is set the core will generate an interrupt when the UN bit in the Event register transitions from '0' to '1'.
10	Multiple-master error enable (MMEE) - When this bit is set the core will generate an interrupt when the MME bit in the Event register transitions from '0' to '1'.
9	Not empty enable (NEE) - When this bit is set the core will generate an interrupt when the NE bit in the Event register transitions from '0' to '1'.
8	Not full enable (NFE) - When this bit is set the core will generate an interrupt when the NF bit in the Event register transitions from '0' to '1'.
7 : 0	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.

GRIP

120.3.6 SPI Controller Command Register

*Table 2238.*0x2C - CMD - SPI controller Command register

31		23	22	21			4	3	2	1	0
R			LST	R				PGRD	DIR	SPROT	
0			0	0				0	0	0	
r			w*	r				w*	rw*	rw*	

31 : 23   RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.

22   Last (LST) - After this bit has been written to '1' the core will set the Event register bit LT when a character has been transmitted and the transmit queue is empty. If the core uses the 3-wire protocol then the Event register bit is set when the whole transfer has completed. This bit is automatically cleared when the Event register bit has been set and is always read as zero.

As of revision 6 of this SPI controller the LST bit can only be set to '1'. Previous revisions of the core allowed the LST bit to be set to '0' by writing to this bit. As of revision 6, writes of zero do not affect the core's internal state of the LST bit.

21 : 4   RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.

3   Protocol guard (PGRD) - This field must be set to '1' to modify the IO and SPROT fields. If the value of this field is 0 for a write operation then no change will be made to IO and SPROT.

2   Direction (DIR) - This field determines the direction for transfers when the SPROT field is non-zero.
0 - Output
1 - Input
This field can only be modified when the PGRD field is set in the write data.

1 : 0   SPI protocol (SPROT) - This field selects between standard, dual and quad SPI mode. The settings are:

0b00 - Standard SPI mode
0bx1 - Dual SPI mode
0b10 - Quad SPI mode

Dual and quad SPI modes can only be enabled if they are supported by the implementation as indicated by the PROT field in Capability register 1. This field must not be changed while the core is transmitting or receiving data. The same protocol is also used for the words received while transmitting.

This field must be set to 0 when using 3-wire protocol (controlled via Mode register).

This field can only be modified when the PGRD field is set in the write data.

120.3.7 SPI Controller Transmit Register

*Table 2239.*0x30 - TX - SPI controller Transmit register

31	0
TDATA	
0	
w	

31 : 0   Transmit data (TDATA) - Writing a word into this register places the word in the transmit queue. This register will only react to writes if the Not full (NF) bit in the Event register is set. The layout of this register depends on the value of the REV field in the Mode register:

Rev = '0': The word to transmit should be written with its least significant bit at bit 0.

Rev = '1': The word to transmit should be written with its most significant bit at bit 31.

120.3.8 SPI Controller Receive Register

*Table 2240.*0x34 - RXC - SPI controller Receive register

31		0
	RDATA	
	0	
	r	

31 : 0	Receive data (RDATA) - This register contains valid receive data when the Not empty (NE) bit of the Event register is set. The placement of the received word depends on the Mode register fields LEN and REV:
	For LEN = 0b0000 - The data is placed with its MSb in bit 31 and its LSb in bit 0.
	For other lengths and REV = '0' - The data is placed with its MSB in bit 15.
	For other lengths and REV = '1' - The data is placed with its LSB in bit 16.
	To illustrate this, a transfer of a word with eight bits (LEN = 7) that are all set to one will have the following placement:
	REV = '0' - 0x0000FF00
	REV = '1' - 0x00FF0000

120.3.9 SPI Slave Select Register (optional)

*Table 2241.*0x38 - SLVSEL - SPI Slave select register (optional)

31	SSSZ	SSSZ-1	0
R		SLVSEL	
0		all 1	
r		rw	

31 : SSSZ	RESERVED (R) - The lower bound of this register is determined by the Capability register field SSSZ if the SSEN field is set to 1. If SSEN is zero bits 31:0 are reserved.
(SSSZ-1) : 0	Slave select (SLVSEL) - If SSEN in the Capability register is 1 the core's slave select signals are mapped to this register on bits (SSSZ-1):0. Software is solely responsible for activating the correct slave select signals, the core does not assert or deassert any slave select signal automatically.

120.3.10 SPI Controller Automatic Slave Select Register

*Table 2242.*0x3C - ASLVSEL - SPI controller Automatic slave select register

31	SSSZ	SSSZ-1	0
R		ASLVSEL	
0		0	
r		rw	

31 : SSSZ	RESERVED (R) - The lower bound of this register is determined by the Capability register field SSSZ if the SSEN field is set to 1. If SSEN is zero bits 31:0 are reserved.
(SSSZ-1) : 0	Automatic Slave select (ASLVSEL) - If SSEN and ASELA in the Capability register are both '1' the core's slave select signals are assigned from this register when the core is about to perform a transfer and the ASEL field in the Mode register is set to '1'. After a transfer has been completed the core's slave select signals are assigned the original value in the slave select register.

Note: This register is only available if ASELA (bit 17) in the SPI controller Capability register is set

120.3.11SPI Controller AM Configuration Register

*Table 2243.*0x40 - AMCFG - SPI controller AM configuration register

31	30														16
RESERVED															
0															
r															

15						9	8	7	6	5	4	3	2	1	0
RESERVED							ECGC	LOCK	ERPT	SEQ	STRICT	OVTB	OVDB	ACT	EACT
0							0	0	0	0	0	0	0	0	0
r							rw	rw	rw	rw	rw	rw	rw	rw	rw

31 : 9	RESERVED - This field is reserved for future use and should always be written as zero.
8	External clock gap control (ECGC) - If software sets this bit to '1' then the clock gap between individual transfers in a set of automated transfers is controller by the core's CSTART input instead of the CG field in the Mode registers. Note that the requirement that the CG field must be set to a value >= 2 if the TAC bit is set still applies even if this bit is set. Reset value '0'.
7	Lock bit (LOCK) - If software sets this bit to '1' then the core will not place new data in the AM Receive registers while software is reading out new data.
6	External repeat (ERPT) - When this bit is set the core will use the input signal astart to start a new periodic transfer. If this bit is cleared, the period counter will be used instead.
5	Sequential transfers (SEQ) - When this bit is set the core will not update the receive queue unless the queue has been emptied by reading out its contents. Note that the contents in the temporary FIFO may still be overwritten with incoming data, depending on the setting of the other fields in this register.
4	Strict period (STRICT) - When this bit is set the core will always try to perform a transfer when the period counter reaches zero, if this bit is not set the core will wait until the receive FIFO is empty before it tries to perform a new transfer.
3	Overflow Transfer Behavior (OVTB) - If this bit is set to '1' the core will skip transfers that would result in data being overwritten in the temporary receive queue. Note that this bit only decides if the transfer is performed. If this bit is set to '0' a transfer will be performed and the setting of the Overflow Data Behavior bit (OVDB) will decide if data is actually overwritten.
2	Overflow Data Behavior (OVDB) - If this bit is set to '1' the core will skip incoming data that would overwrite data in the receive queues. If this bit is '0' the core will overwrite data in the temporary queue.
1	Activate automated transfers (ACT) - When this bit is set to '1' the core will start to decrement the AM period register and perform automated transfers. The system clock cycle after this bit has been written to '1' there will be a pulse on the core's ASTART output.
	Automated transfers can be deactivated by writing this bit to '0'. The core will wait until any ongoing transfer has finished before deactivating automated transfers. Software should not perform any operation on the core before this bit has been read back as '0'. The data in the last transfer(s) will be lost if there is a transfer in progress when this bit is written to '0'. All words present in the transmit queue will also be dropped.
0	External activation of automated transfers (EACT) - When this bit is set to '1' the core will activate automated transfers when the core's ASTART input goes HIGH. When the core has been activated by the external signal this bit will be reset and the ACT field (bit 1 will be set).

Note: This register is only available if AMODE (bit 18) in the SPI controller Capability register is set

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

120.3.12 SPI Controller AM Period Register

Table 2244. 0x44 - AMPER - SPI controller AM period register

31	0
AMPER	
0	
rw	

31 : 0   AM Period (AMPER) - This field contains the period, in system clock cycles, of the automated transfers. The core has an internal counter that is decremented each system clock cycle. When the counter reaches zero the core will begin to transmit all data in the transmit queue and reload the internal counter, which will immediately begin to start count down again. If the core has a transfer in progress when the counter reaches zero, the core will stall and not start a new transfer, or reload the internal counter, before the ongoing transfer has completed.

     The number of bits in this register is implementation dependent. Software should write this register with 0xFFFFFFFF and read back the value to see how many bits that are available.

Note: This register is only available if AMODE (bit 18) in the SPI controller Capability register is set

120.3.13 SPI Controller AM Mask Register(s)

Table 2245. 0x50-0x5C - AMMASK - SPI controller AM Mask register(s)

31	0
AM MASK	
0	
rw	

31 : 0   AM Mask - This field is used as a bit mask to determine which words in the AM Transmit / Receive queues to read from / write to. Bit 0 of the first mask register corresponds to the first position in the queues, bit 1 of the first mask register to the second position, bit 0 of the second mask register corresponds to the 33:d position, etc. The total number of bits implemented equals FDEPTH (bit 15:8) in the SPI controller Capability register. If a bit is set to one then the core will read / write the corresponding position in the queue, otherwise it will be skipped. Software can write these registers at all times. However if a automated transfer is in progress when the write occurs, then the core will save the new value in a temporary register until the transfer is complete. The reset value is all ones.

Note: This register is only available if AMODE (bit 18) in the SPI controller Capability register is set

120.3.14 SPI Controller AM Transmit Register(s)

Table 2246. 0x200-0x3FC - AMTX - SPI controller AM Transmit register(s)

31	0
TDATA	
0	
rw	

31 : 0   Transmit data (TDATA) - Writing a word into these register places the word in the AM Transmit queue. The address of the register determines the position in the queue. Address offset 0x200 corresponds to the first position, offset 0x204 to the second position etc.

     The layout of the registers during write depends on the value of the REV field in the Mode register:
Rev = '0': The word to transmit should be written with its least significant bit at bit 0.
Rev = '1': The word to transmit should be written with its most significant bit at bit 31.

     The layout of the registers during read is fixed, the word is read with its least significant bit at bit 0.

Note: This register is only available if AMODE (bit 18) in the SPI controller Capability register is set

GRIP
Apr 2024, Version 2024.1

1956

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

120.3.15 SPI Controller AM Receive Register

*Table 2247.*0x400-0x5FC - SPI controller AM Receive register(s)

31	0
RDATA	
0	
rw	

31 : 0   Receive data (RDATA) - The address of the register determines the position in the queue. Address offset 0x200 corresponds to the first position, offset 0x204 to the second position etc. The placement of the received word depends on the Mode register fields LEN and REV.

For LEN = 0b0000 - The data is placed with its MSb in bit 31 and its LSb in bit 0.

For other lengths and REV = '0' - The data is placed with its MSB in bit 15.

For other lengths and REV = '1' - The data is placed with its LSB in bit 16.

To illustrate this, a transfer of a word with eight bits (LEN = 7) that are all set to one will have the following placement:

REV = '0' - 0x0000FF00

REV = '1' - 0x00FF0000

Note: This register is only available if AMODE (bit 18) in the SPI controller Capability register is set

120.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x02D. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

120.5 Implementation

120.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

See also the documentation for the *syncrst* VHDL generic.

120.6 Configuration options

Table 2248 shows the configuration options of the core (VHDL generics).

*Table 2248.*Configuration options

Generic name	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by SPI controller	0 - NAHBIRQ-1	0

*Table 2248.*Configuration options

Generic name	Function	Allowed range	Default
fdepth	FIFO depth. The FIFO depth in the core is 2^{fdepth}. Note that the depth of the transmit and receive queues is FIFO depth + 1 since the Transmit and Receive registers can hold one word. The number of AM Transmit / Receive registers are however 2^{fdepth}.	1 - 7	1
slvselen	Enable Slave Select register. When this value is set to 1 the core will include a slave select register that controls slvselsz slave select signals.	0 - 1	0
slvselsz	Number of Slave Select (slvsel) signals that the core will generate. These signals can be controlled via the Slave select register if the generic slvselen has been set to 1, otherwise they are driven to '1'.	1 - 32	1
oepol	Selects output enable polarity	0 - 1	0
odmode	Open drain mode. If this generic is set to 1, the OD bit in the mode register can be set to 1 and the core must be connected to I/O or OD pads.	0 - 1	0
automode	Enable automated transfers. If this generic is set to 1 the core will include support to automatically perform periodic transfers. The core's receive and transmit queues must not contain more than 128 words if automode is enabled.	0 - 1	0
acntbits	Selects the number of bits used in the AM period counter. This generic is only of importance if the auto-mode generic is set to 1.	1 - 32	32
aslvsel	Enable automatic slave select. If this generic is set to 1 the core will include support for automatically setting the slave select register from the automatic slave select register before a transfer, or queue of transfers, starts. This generic is only significant of the slvselen generic is set to 1.	0 - 1	0
twen	Enable 3-wire protocol. If this generic is set to 1 the core will include support for 3-wire protocol.	0 - 1	1
maxwlen	Determines the maximum supported word length. Values are defined as: 0 - Core will support lengths up to 32-bit words 0-3 - Illegal values 4-15 - Maximum word length is maxlen+1, allows words of length 4-16 bits. This generic sets the size of the slots in the transmit and receive queues. If the core will be used in an application that will never need to perform transfers with words as long as 32-bits, this setting can be used to save area.	0 - 15	0
netlist	If this generic is set to 0 (default) then the RTL version of the core will be used. If this generic is non-zero, the netlist version of the core will be used (if available) and the value of *netlist* will specify the target technology.	0 - NTECH	0
syncram	When this generic is set to 1 the core will instantiate SYNCRAM_2P components for the receive and transmit queues. The use of SYNCRAM_2P components can reduce area requirements, particularly when automode is enabled.	0 - 1	1
memtech	Selects memory technology for SYNCRAM_2P components.	0 - NTECH	0 (inferred)

121 SPIMCTRL - SPI Memory Controller

121.1 Overview

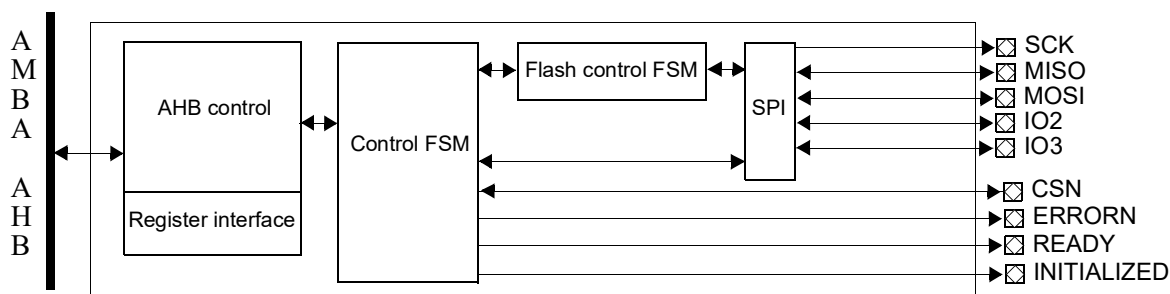
The core maps a memory device connected via the Serial Peripheral Interface (SPI) into AMBA address space. Read accesses are performed by performing normal AMBA read operations in the mapped memory area. For certain memory devices, the core can be configured to handle AMBA write operations in the same way, but in most cases writes are instead handled by directly sending SPI commands to the memory device via the core's register interface. The core is highly configurable and supports most SPI Flash memory devices.


Figure 309. Block diagram

121.2 Operation

121.2.1 Operational model

The core has two memory areas that can be accessed via the AMBA bus; the I/O area and the ROM area. The ROM area maps the memory device into AMBA address space and the I/O area is utilized for status reporting and to issue user commands to the memory device.

When transmitting SPI commands directly to the device the ROM area should be left untouched. The core will issue an AMBA ERROR response if the ROM area is accessed when the core is busy performing an operation initiated via I/O registers.

Depending on the type of device attached the core may need to perform an initialization sequence. Accesses to the ROM area during the initialization sequence receive AMBA error responses. The core has successfully performed all necessary initialization when the Initialized bit in the core's status register is set, the value of this bit is also propagated to the core's output signal *spio.initialized*.

121.2.2 I/O area

The I/O area contains registers that are used when issuing commands directly to the memory device. By default, the core operates in System mode where it will perform read operations on the memory device when the core's ROM area is accessed. Before attempting to issue commands directly to the memory device, the core must be put into User mode. This is done by setting the User Control (USRC) bit in the core's Control register. Care should be taken to not enter User mode while the core is busy, as indicated by the bits in the Status register. The core should also have performed a successful initialization sequence before User mode accesses (INIT bit in the Status register should be set).

Note that a memory device may need to be clocked when there has been a change in the state of the chip select signal. It is recommended that software transmits a byte with the memory device deselected after entering and before leaving User mode.

The following steps are performed to issue a command to the memory device after the core has been put into User mode:

GRIP
Apr 2024, Version 2024.1

1963

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

1. Check Status register and verify that the BUSY and DONE bits are cleared. Also verify that the core is initialized and not in error mode.
2. Optionally enable DONE interrupt by setting the Control register bit IEN.
3. Write command to Transmit register.
4. Wait for interrupt (if enabled) or poll DONE bit in Status register.
5. When the DONE bit is set the core has transferred the command.
6. Clear the Status register's DONE bit by writing one to its position.

To receive data from the device the same process as above need to be done, but instead writing to the Receive register at step 3. The data written will not be used by the controller, the write only signals to the core that it should clock the memory device until one byte has been received. The received data is then stored in the Receive register.

The core should not be brought out of User mode until the transfer completes. Accesses to ROM address space will receive an AMBA ERROR response when the core is in User mode and when an operation initiated under User mode is active.

121.2.3 ROM area

The ROM area supports both AMBA read and write operations. If the VHDL generic *allow_writes* is set to 0, then write operations will be ignored and a AMBA ERROR response will be returned. When a read or write access is made to the ROM area the core will perform an operation of the same type on the memory device. If the system has support for AMBA SPLIT responses the core will SPLIT the master until the access on the memory device has finished unless the operation is a locked access. A locked access never receives a SPLIT response, and the core inserts wait states instead. If the system lacks AMBA SPLIT support the core will always insert wait states until the read operation on the memory device has finished. The core uses the value of the VHDL generic *spliten* to determine if the system has AMBA SPLIT support.

The ROM area is marked as cacheable and prefetchable. This must be taken into account if the data in the ROM area is modified via the I/O area.

121.2.4 SPI memory device address offset

An offset can be specified at implementation via the core's *offset* VHDL generic. This offset will be added to all accesses to the ROM area before the address is propagated to the SPI memory device. Specifying an offset can be useful when the SPI memory device contains, as an example, FPGA configuration data at the lower addresses. By specifying an offset, the top of the SPI memory device can be used to hold user data. The AMBA system is unaware of the offset being added. An access to address *n* in the ROM area will be automatically translated to an access to address *offset + n* on the SPI memory device.

The offset must be accounted for when accessing the SPI memory device via the core's register interface. If data is programmed to the SPI memory device through the register interface, then the data must be written starting at the offset specified by the VHDL generic *offset*.

121.2.5 Supported memory devices

The core supports a wide range of memory devices due to its configuration options of read and write instruction, dummy cycles insertions and choice of input and output mode. These values are at reset set to the values as defined by the VHDL generic and, if the *reconf* VHDL generic is set, can be changed during runtime by writing to a configuration register.

The core is configured to issue the instruction defined by the *readcmd* and *writecmd* values. Following an access to the ROM area, the core will issue the instruction followed by 24 address bits. If the *extaddr* bit is set, 32 bits of address are sent instead. For reads operations, an optional number of dummy cycles can be transmitted to the device, as configured by the *dummybyte* and *dummycycles* values. If the *dummybyte* bit is set, 8 cycles will always be used. Otherwise, the value specified by

GRIP
Apr 2024, Version 2024.1

1964

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

dummycycles is utilized. In the case of write operations, no dummy cycles are sent, regardless of the values of *dummybyte* or *dummycycles*. After the possible dummy cycles, the core expects to either receive data from or send data to the device, depending on whether the access was a read or write operation.

For memory writes to many SPI memory devices there is often some prerequisite conditions that needs to be met before a write can occur by default, such as sending a write enable command. The core adopts a straightforward approach to handling writes and lacks logic to manage these conditions autonomously. It is the user's responsibility to configure the memory device in a manner that eliminates the need for these prerequisite conditions before a write. If configuring the memory device in such a way is not possible then writing to the ROM area of the core is discouraged as the prerequisite conditions would need to be set up using the I/O area before every write. In these cases, it is instead better to handle all writing of data completely through the I/O interface.

121.2.6 Supported SPI protocols

The SPIMCTRL can be configured to support a wide range of SPI instruction types/protocols through the *Quadinput*, *Dualinput*, *Quadoutput*, *Dualoutput*, *DSPI* and *QSPI* bits.

A typical SPI instruction consists of three phases: command, address and data. To easily describe the number of data lines used for each phase a three number representation is used, where each number represent a phase (command-address-data). For example, 1-1-4 means one data line is used during both the command and address phase while four are used during the data phase. For each phase, when one data line is selected MISO is used to receive data and MOSI to transmit data, when two data lines are selected both MISO and MOSI are used simultaneously to either transmit or receive data and when four data lines are selected MISO, MOSI, IO2 and IO3 are used simultaneously to either transmit or receive data.

There are three main modes you can set the controller to be in: Extended SPI (ESPI, 1-x-x), Dual SPI (DSPI, 2-2-2) or Quad SPI (QSPI, 4-4-4). The current selected mode is determined by the *DSPI* and *QSPI* bits; if neither of the two bits are set then the default ESPI mode is used and if both are set QSPI mode is used.

When in ESPI mode, the command phase of a read and also all communication through the I/O area will be sent using one data line (1-x-x).The behavior during the address phase is determined by the *[Dual/Quad]input* bits and the data phase is determined by the *[Dual/Quad]output* bits. If neither bit is set for a phase then one data lines is used, if the dual bit is set then two data lines are used and if the quad bit is set four data lines are used. If both dual and quad bits are set then quad mode is used.

When in DSPI mode, all communication with the memory happens using two data lines (2-2-2). When in the QSPI mode, all communication with the memory happens using four data lines (4-4-4). When in DSPI or QSPI mode the *Quadinput*, *Dualinput*, *Quadoutput* and *Dualoutput* bits are **ignored**.

Many memory devices support communication using more than one SPI protocol. When moving between ESPI modes it is often enough to only change the *readcmd* and one, or several, of the *Quadinput*, *Dualinput*, *Quadoutput*, *Dualoutput* bits. When changing configuration between the three main modes (ESPI, DSPI, QSPI) the memory first needs to be set to work in that mode, often through a device specific command or a write to a configuration register on the memory device (this is done using writes to the I/O area). After that is done, the SPIMCTRL needs to be configured to match the new mode the memory was set to use. If there is a mismatch between the mode the memory device and the controller are in, no meaningful communication can happen between the two devices.

In the table below it is described which configuration values need to be modified, assuming the controller is currently using the default values set in the VHDL generic, to work with some common SPI

instruction types / protocols. For all configurations the device specific values *readcmd, writecmd* and *dummycycles* also needs to be set.

TABLE 2253. SPIMCTRL configurations for some common SPI protocols

Mode	1-1-1 (ESPI)	1-1-2 (ESPI)	1-2-2 (ESPI)	2-2-2 (DSPI)	1-1-4 (ESPI)	1-4-4 (ESPI)	4-4-4 (QSPI)
Configuration		*Dualoutput*=1	*Dualoutput*=1 *Dualinput*=1	*DSPI*=1	*Quadoutput*=1	*Quadoutput*=1 *Quadinput*=1	*QSPI*=1

121.2.7 eXecute-In-Place

Some SPI memories have support for commands using eXecute-In-Place (XIP). XIP allows several consecutive commands of the same type to be sent, where only the first access needs to specify the command code. For XIP compatible commands, there is an activation byte or bit that should be sent directly after the address phase to the memory controller, determining whether XIP should be enabled or disabled. For some memories, the activation code is sent during the dummy cycles phase, while for others, additional cycles are added just for the XIP activation code. For example, in the Avalanche AS1001204 memory, one additional byte needs to be sent after the address phase and before the dummy cycles. If 'Axh' is sent then XIP is enabled, while 'Fxh' disabled it. Once XIP has been enabled, subsequent commands will not require sending any command code but can immediately send their address.

The core does not have the capability to efficiently use XIP mode. If possible, XIP compatible commands should be avoided. However, for some memories, especially when trying to utilize more advanced features like QSPI, there might be no choice but to use commands that also require XIP. In these cases, the goal from the user should be to configure the SPIMCTRL so a XIP disable code is sent for every access made. Some settings exist in the core specifically for this purpose, namely *xip_byte* and *xip_polarity*. The *xip_byte* settings make it so one byte of data is sent immediately after the address phase, using the same number of bits/cycle as was used during the address phase. The *xip_polarity* setting determines the bit polarity of the data shifted into the memory device during the XIP-byte and dummy cycles phase. With these settings, the core can be configured to work seamlessly with many commands which require XIP.

121.2.8 Bursts

The SPIMCTRL is designed to efficiently manage read and write bursts request from the AMBA AHB bus. When an access is recognized as a burst, the core does not release the chip select signal after handling the access. Instead, it awaits the next access and continues servicing that request without the need to resend the command or address bytes. The core identifies a burst based on the first AMBA AHB HBURST bit, meaning that only incrementing bursts are efficiently handled. Wrapping bursts are supported but will be treated by the core individually as regular non-burst accesses.

121.2.9 Clock generation and power-up timing

The core generates the device clock by scaling the system clock. The VHDL generic *scaler* selects the divisor to use for the device clock that is used when issuing read instructions.

The alternate clock can be used for all communication by setting the Enable Alternate Scaler (EAS) bit in the Control register. When configuring the core for communication with a device in a system where the target frequency may change it is recommended to set the VHDL generic *scaler* to a conservative value and configure the alternate scaler to produce a faster clock. A boot loader can then set the Enable Alternate Scaler (EAS) bit early in the boot process when it has been determined that the system can use the memory device at a higher frequency.

If the external device needs power-up time before being accessed then this needs to be handled at the system level or by waiting to access the SPI memory controller until the power up time has passed.

121.3.1 Configuration Register

*Table 2255.*0x00 - CONF - Configuration register

31 24	23-21	20	19	18	17	16	15	14	13	12	11 8	7 0
WRITECMD	RES	XIP	QIN	DIN	QOUT	DOUT	DBYTE	ADDR	QSPI	DSPI	DCYCLES	READCMD
-	0	-	-	-	-	-	-	-	-	-	-	-
r/rw*	r	r/rw*	r/rw*	r/rw*	r/rw*	r/rw*	r/rw*	r/rw*	r/rw*	r/rw*	r/rw*	r/rw*

31 :24	Write instruction (WRITECMD) - Write instruction that the core will use for writing to the memory device.
23 :21	RESERVED
20	XIP Byte (XIP) - Send one additional byte of data after the address phase containing either 0x00 or 0xFF depending on the value of *xip:_polarity*.
19	Quad input (QIN) - Use quad mode during the address phase for memory accesses when in ESP I mode.
18	Dual input (DIN) - Use dual mode during the address phase for memory accesses when in ESP I mode.
17	Quad output (QOUT) - Use quad mode during the data phase for memory accesses when in ESP I mode.
16	Dual output (DOUT) - Use dual mode during the data phase for memory accesses when in ESP I mode.
15	Dummy byte (DBYTE) - Output 8 dummy cycles after the address phase.
14	Extended Address (ADDR) - Use 32b address mode for memory accesses. When this bit is set to '0', then the default 24b address is used instead.
13	Enable QSPI (QSPI) - Enables QSPI mode. All communication to the memory device is done using quad mode. If both the QSPI and DSPI bits are '1', then QSPI mode will be used.
12	Enable DSPI (DSPI) - Enables DSPI mode. All communication to the memory device is done using dual mode. If both the QSPI and DSPI bits are '1', then QSPI mode will be used.
11:8	Dummy cycles (DCYCLES) - Determines the amount of dummy cycles used after the address phase. If the DBYTE bit is set to '1' then this value won't be used and the amount of dummy cycles will always be 8.
7:0	Read instruction (READCMD) - Read instruction that the core will use for reading from the memory device.

* Writing to the configuration register is only enabled when the *reconf* VHDL generic is set.

121.3.2 Control Register

*Table 2256.*0x04 - CTRL - Control register

31 5	4	3	2	1	0
RESERVED	RST	CSN	EAS	IEN	USRC
0	0	1	0	0	0
r	rw	rw	rw	rw	rw

31 :5	RESERVED
4	Reset core (RST) - By writing '1' to this bit the user can reset the core. This bit is automatically cleared when the core has been reset. Reset core should be used with care. Writing this bit has the same effect as system reset. Any ongoing transactions, both on AMBA and to the SPI device will be aborted.
3	Chip select (CSN) - Controls core chip select signal. This field always shows the level of the core's internal chip select signal. This bit is always automatically set to '1' when leaving User mode by writing USRC to '0'.
2	Enable Alternate Scaler (EAS) - When this bit is set the SPI clock is divided by using the alternate scaler.

121.5 Implementation

121.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

121.5.2 Technology mapping

The core does not instantiate any technology specific primitives.

121.5.3 RAM usage

The core does not use any RAM components.

121.5.4 Endianness

The core automatically changes its endianness behavior depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for both big-endian and little-endian systems.

121.6 Configuration options

Table 2260 shows the configuration options of the core (VHDL generics).

Table 2260. Configuration options

Generic name	Function	Allowed range	Default
hindex	AHB slave index	0 - (NAHBSLV-1)	0
hirq	Interrupt line	0 - (NAHBIRQ-1)	0
faddr	ADDR field of the AHB BAR1 defining ROM address space.	0 - 16#FFF#	16#000#
fmask	MASK field of the AHB BAR1 defining ROM address space.	0 - 16#FFF#	16#FFF#
ioaddr	ADDR field of the AHB BAR0 defining register address space.	0 - 16#FFF#	16#000#
iomask	MASK field of the AHB BAR0 defining register space.	0 - 16#FFF#	16#FFF#
spliten	If this generic is set to 1 the core will issue AMBA SPLIT responses when it is busy performing an operation on the memory device. Otherwise the core will insert wait states until the operation completes.	0 - 1	0
oepol	Select polarity of output enable signals. 0 = active low.	0 - 1	0
sdcard	Set to 0	0 - 0	0
readcmd	Read instruction of memory device	0 - 16#FF#	16#0B#
dummybyte	Use 8 dummy cycles after the address phase.	0 - 1	0
dualoutput	Use dual mode during the data phase for memory accesses in ESPI mode.	0 - 1	0
scaler	Clock divisor used when generating device clock is 2^{scaler}	1 - 512	1

*Table 2260.*Configuration options

Generic name	Function	Allowed range	Default
altscaler	Clock divisor used when generating alternate device clock is $2^{altscaler}$	1 - 512	1
pwrupcnt	Unused	N/A	0
maxahbaccsz	Maximum supported AHB access size. The core will support accesses ranging from 8-bit (BYTE) to the size set by maxahbaccsz. The maximum access size is 256 bits (8WORD).	32, 64, 128, 256	AHBDW
offset	Specifies offset that will be added to incoming AMBA address before address is propagated to SPI flash device. An access to memory position *n* in the core's ROM area will be translated to an access to SPI memory device address *n + offset*. Note that this only applies to accesses to the ROM area, accesses via the core's register interface are unaffected.	-	0
quadoutput	Use quad mode during the data phase for memory accesses in ESPI mode.	0 - 1	0
dualinput	Use dual mode during the address phase for memory accesses in ESPI mode.	0 - 1	0
quadinput	Use quad mode during the address phase for memory accesses in ESPI mode.	0 - 1	0
dummycycles	Number of dummy cycles to be used after address phase. If *dummybyte* is set, then 8 cycles will always be used instead.	0 - 15	0
dspi	Enables DSPI mode, all communication to the memory device is done using dual mode. If both the QSPI and DSPI bits are '1', then QSPI mode will be used.	0 - 1	0
qspi	Enables QSPI mode, all communication to the memory device is done using quad mode. If both the QSPI and DSPI bits are '1', then QSPI mode will be used.	0 - 1	0
extaddr	Use extended address mode, using 32 bit address instead of 24 for memory reads.	0 - 1	0
reconf	Enables writing to configuration register. Setting this bit to '1' roughly doubles the area required for the core.	0 - 1	0
writecmd	Write instruction of memory device	0 - 16#FF#	16#02#
allow_writes	If set, writes to the ROM area will be handled and sent to the memory device. When not set, all writes will be ignored and a AHB ERROR response will be returned.	0 - 1	0
xip_byte	Send one additional byte of data after the address phase containing either 0x00 or 0xFF, depending on the value of *xip:_polarity*.	0 - 1	0
xip_polarity	Determines the bit value sent to the memory device during the dummy-cycles and xip-byte phase. Either all '0's or '1's.	0 - 1	1

121.8 Signal definitions and reset values

The signals and their reset values are described in table 2262.

Table 2262. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
miso	Inout	Data into the master, can also serve as bi-directional signal if the core is configured to function with dual or quad memory devices.	-	Logical 1
mosi	Inout	Data out of the master, can also serve as bi-directional signal if the core is configured to function with dual or quad memory devices.	-	Logical 1
io2	Inout	Bi-directional signal used if the core is configured to work with quad memory devices.*	-	Logical 1
io3	Inout	Bi-directional signal used if the core is configured to work with quad memory devices.*	-	Logical 1
sck	Output	SPI clock	Logical 1	Logical 0
csn	Output	Chip select, can also be used as a card detect signal in which case the signal is bi-directinal.	Logical 0	Logical 1
ready	Output	Core ready	Logial 1	Logical 0
initialized	Output	Memory device initialized	Logical 1	Logical 0

* IO2&3 ports on the memory device often has other functionality triggered by an active low signal when they are not used for data transfers. To not accidentally trigger any of these functions the controller always outputs a '1' on these signals in those cases.

121.9 Library dependencies

Table 2263 shows the libraries used when instantiating the core (VHDL libraries).

Table 2263. Library dependencies

122 SPIMASTER - SPI Master Device

122.1 Overview

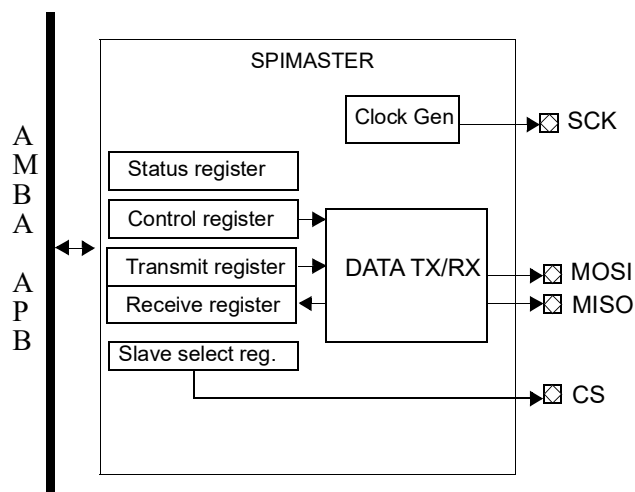
The core provides a link between the AMBA APB bus and the Serial Peripheral Interface (SPI) bus and function as a SPI master. Core features include configurable word length (4, 5, 6... 32 bits), bit ordering and all four SPI modes are supported. This IP is developed as part of ESA activity: Prototyping of space protocol(s) for SPI (Contract: 4000114112/15/NL/LF).


Figure 310. Block diagram

122.2 Transmission

The SPI bus is a full-duplex synchronous serial bus. Transmission starts when a master selects a slave through the slave's Slave Select (CS) signal and the clock line SCK transitions from its idle state. The clock line transition occurs when the EN bit in the Transmit Enable register is set to "high", the data need to be transferred must be written into the Transmit register before writing the transmit enable register. Data is transferred from the master through the Master-Output-Slave-Input (MOSI) signal and from the slave through the Master-Input-Slave-Output (MISO) signal. The SCK is only available during the data transfer and return to idle state after the transmission is completed.

During a transmission on the SPI bus data is either changed or read at a transition of SCK. If data has been read at edge n, data is changed at edge n+1. If data is read at the first transition of SCK the bus is said to have clock phase 0, and if data is changed at the first transition of SCK the bus has clock phase 1. The idle state of SCK may be either high or low. If the idle state of SCK is low, the bus has clock polarity 0 and if the idle state is high the clock polarity is 1. The combined values of clock polarity (CPOL) and clock phase (CPHA) determine the mode of the SPI bus. Figure below shows one byte (0x55) being transferred MSb first over the SPI bus under the four different modes. Note that the idle state of the MOSI line is '1' and that CPHA = 0 means that the devices must have data ready before the first transition of SCK. The figure does not include the MISO signal, the behavior of this line is the same as for the MOSI signal.

Figure 311. SPI transfer of byte 0x55 in all modes

122.3 Operation

The data transfer between this master and a slave device is performed using the registers mapped into APB address space. The data need to be transferred must be written into the Transmit register and the EN bit in the Transmit Enable register must be set "high" inorder to send and receive, the receive data is available when the transmission is completed. The EN bit will be set by the core to "low" when all the transmission is completed. It is also possible to generate an interrupt when all the transmission is completed using Transmission Done interrupt. The core's control, polarity, chip select, clock registers must be appropriately set as per the requirements of the slave device. The SCK is only available during the data transfer and return to idle state after the transmission is completed.

The core can hold a data in addition to the one currently in transfer. The BC field in Status register specify the number of data available. If two words are written into the Transmit register the BC field show a value of 2, after the first transfer the value will be 1and finally when the transfer is completed the BC field will have value 0. The purpose of the hold register is to continuously transfer data to a slave device. In order to transfer continuously the software should perform the following, write two data to be transferred into the Transmit register and enable the transfer, after the first data is transferred (the software can learn about the data transfer either by polling the BC in Status register or using the RX Received data interrupt) the software can write the consecutive data into the Transmit register.

In order to receive a data the master should transmit a data. The Software should take care of clearing (reading) the data available in the received register before transmitting (receiving) an another data. The transmit buffer is maximum 32 bit (WLEN in Control register defines the Word length bit count), note also a transmit hold register is available which is also maximum 32 bit (also depends on the WLEN bit count). The Software controlling the master should take into account the response time of the slave (or by polling the EN bit in the Transmit Enable register, or by using the interrupt triggered

RX Received data interrupt) to determine when a transmission is completed, and also make sure the received data is read back before the next data is set to be transfered.

It is possible an overrun condition could occur if a received data is not read before the arrival of next data. If new data arrived before the Software could read the previously received data overrun condition is triggered. An Overrun interrupt is generated when overrun condition occurs for data reception.

122.4 Registers

The core is programmed through registers mapped into APB address space.

*Table 2264.*APB registers

APB address offset	Register

122.4.1 Control Register

*Table 2265.*0x00 - CTRL - Control register

31	24	23-17	16	15-13	12	8	7	6	5	4	3	2	1	0
Key		R	OD	R	WLEN		IAMBA	CPHA	CPOL	REV	LOOP	RESET	R	R
0		0	0	0	0x0F		0	0	0	1	0	0	0	0
w		r	rw	r	rw		rw	rw	rw	rw	rw	rw	r	r

31	Safety code (KEY) - Must be 0x94 when writing, otherwise register write is ignored
23 : 17	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
16	Overrun detect (OD) - To detect overrun condition (also to trigger overrun interrupt) this bit must be enabled.
15 : 13	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
12 : 8	Word length (WLEN) - The value of this field determines the length in bits of a transfer on the SPI bus. Valid values are 0x03 to 0x1F
	Word length is WLEN+1, allows words of length 4-32 bits.
7	AMBA Interrupt enable (IAMBA) - If set, AMBA interrupt generation is enabled for the events that are individually maskable by the Interrupt enable (INTE) register
6	Clock phase (CPHA) - When CPHA is '0' data will be read on the first transition of SCK. When CPHA is '1' data will be read on the second transition of SCK.
5	Clock polarity (CPOL) - Determines the polarity (idle state) of the SCK clock.
4	Reverse data (REV) - When this bit is '0' data is transmitted LSB first, when this bit is '1' data is transmitted MSB first.
3	Loop mode (LOOP) - When this bit is set, the core's transmitter and receiver are interconnected and the core will operate in loopback mode.
2	Reset (RESET) - Resets all the registers in the core.
1	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
0	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.

122.4.2 Status Register

*Table 2266.*0x00 - CTRL - Control register

31	2	1	0
R			BC
			0
			r

31: 2	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
1:0	Buffer count BC - Transmit buffer count (maximum 2)

122.4.3 Clock Divide Register

31	24	23	0
Key		CD	
0		0	
w		rw	

*Table 2267.*0x08 - CDR - Clock divide register

31	Safety code (KEY) - Must be 0x94 when writing, otherwise register write is ignored
23 : 0	Clock divide (CD) - This value is used to divide the system clock and generate the SPI SCK clock. If the value is '0' then the system clock is divided by two and the SCK frequency is half the system clock. Similarly
	if the value is '1' the SCK frequency is 1/4 the system clock.
	if the value is '2' the SCK frequency is 1/6 the system clock.
	if the value is '3' the SCK frequency is 1/8 the system clock.
	if the value is '4' the SCK frequency is 1/10 the system clock.

122.4.4 Chip Select Polarity Register

*Table 2268.*0x0C - CSP - Chip select polarity register

31 24	23 8	7 0
Key	R	CSP
0	0	0
w	r	rw

31 : 24	Safety code (KEY) - Must be 0x94 when writing, otherwise register write is ignored
23 : 8	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
7 : 0	Chip select polarity (CSP) - This register is provided in order to be able to communicate with devices having an active high chip select polarity. By default the polarity is active low.

122.4.5 Chip Select Register

*Table 2269.*0x10 - CS - Chip select register

31 24	23 8	7 0
Key	R	CS
0	0	0xFFFFFF
w	r	rw

31 : 24	Safety code (KEY) - Must be 0x94 when writing, otherwise register write is ignored
23 : 8	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
7 : 0	Chip select (CS) - The slave device must be selected before starting communication. Software is solely responsible for activating the correct chip select signal, the core does not assert or deassert any chip select signal automatically.

31 : 24	Safety code (KEY) - Must be 0x94 when writing, otherwise register write is ignored.
23 : 1	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
2	Overrun interrupt (OVR) - An interrupt is generated when overrun condition occurs for data reception. (a received data must be read before the arrival of next data, if new data arrived before the Software could read the previously received data overrun condition is triggered)
1	Received data (RX) - An interrupt is generated when a data is received.
0	Transmission done (TXD) - Data Transmission completed (when the transmit and hold buffer is empty after a transmission).

122.5 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0A6. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

122.6 Implementation

122.6.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

122.7 Configuration options

Table 2275 shows the configuration options of the core (VHDL generics).

*Table 2275.*Configuration options

Generic name	Function	Allowed range	Default
gSLVSEL	Number of slave select signals that the core will generate.	1 - 24	1
gPINDEX	APB slave index	0 - NAPBSLV-1	0
gHINDEX	Unused	0	0
gPADDR	ADDR field of the APB BAR	0 - 16#FFF#	0
gPMASK	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#
gPIRQ	Interrupt line driven by APB interface.	0 - NAHBIRQ-1	1

123 SPISLAVE - Dual Port SPI Slave

123.1 Overview

This core is a Dual Port SPI Slave device that provides link between SPI and AMBA AHB and APB ports. Core features include configurable word length (4, 5, 6 ... 32 bits), bit ordering and all four SPI modes are supported. This core also has redundant SPI ports which can be interfaced using two different masters. The slave takes two sets of SPI interfaces (nominal and redundant each consists of two data signals, one clock signal and one chip select signal). This IP is developed as part of ESA activity: Prototyping of space protocol(s) for SPI (Contract: 4000114112/15/NL/LF).

123.2 Implementation of SPI protocols

This slave device is based on the protocols developed for SPI4SPACE activity. The following text explains the different protocols supported.

In order to support the SPI 0 protocol the slave provides configurable word length of 4, 5, 6 ... 32 bits transmission and reception. The Word bit ordering can be MSB first or LSB first transferred.

For SPI 1 protocol the word length of the transfer can be 8, 16 or 24 bits. The word bit ordering MSB transferred first and LSB transferred last is supported. The parity bit can be appended at the end of every word, the parity bit is not included by the SPI slave device, since the implementation supports 9, 17 and 25 bits of word transfer the parity bit can be appended by the software.

All control and data transfer for SPI protocol 0 and 1 are supported only through the APB registers.

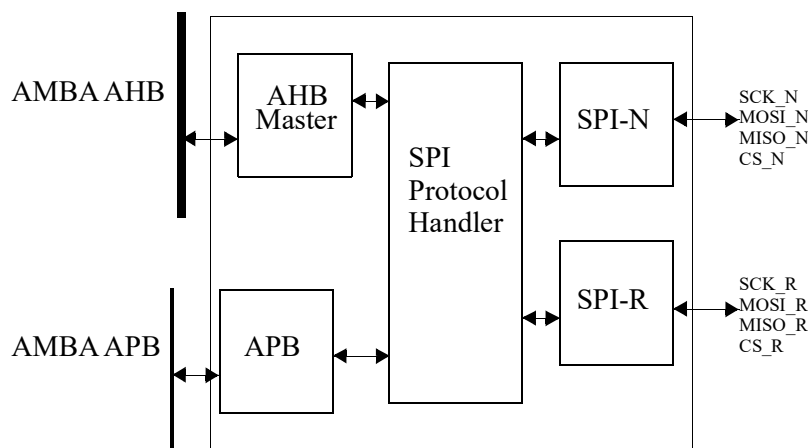
The SPI protocol 2 uses a fixed word length of 16 bits. The word bit ordering is MSB transferred first and LSB transferred last. Also this core implements the network layer of the SPI protocol 2, the slave hardware itself can process the SPI protocol 2 commands and provide responses. The APB interface is only for control and status, all the data transfer to the AMBA is performed using the AHB Master.


Figure 312. Block diagram

123.3 Transmission

The SPI bus is a full-duplex synchronous serial bus. Transmission starts when a master selects a slave through the slave's Slave Select (CS) signal and the clock line SCK transitions from its idle state. Data is transferred from the master through the Master-Output-Slave-Input (MOSI) signal and from the slave through the Master-Input-Slave-Output (MISO) signal. In some systems with only one master and one slave, the Slave Select input of the slave may be always active and the master does not

GRIP
Apr 2024, Version 2024.1

1984

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

need to have a slave select output. This does not apply to this device, the slave select signal must be used to mark the start and end of an operation.

During a transmission on the SPI bus data is either changed or read at a transition of SCK. If data has been read at edge n, data is changed at edge n+1. If data is read at the first transition of SCK the bus is said to have clock phase 0, and if data is changed at the first transition of SCK the bus has clock phase 1. The idle state of SCK may be either high or low. If the idle state of SCK is low, the bus has clock polarity 0 and if the idle state is high the clock polarity is 1. The combined values of clock polarity (CPOL) and clock phase (CPHA) determine the mode of the SPI bus. Figure below shows one byte (0x55) being transferred MSb first over the SPI bus under the four different modes. Note that the idle state of the MOSI line is '1' and that CPHA = 0 means that the devices must have data ready before the first transition of SCK. The figure does not include the MISO signal, the behavior of this line is the same as for the MOSI signal.

Figure 313. SPI transfer of byte 0x55 in all modes

123.4 Operation

The data transfer between the master and the slave is through APB registers or through command transfer from a master is determined by the EN bit in the SPI2 control register. When APB registers are used the data transferred by a master is available at receive registers (NRDATA or RRDATA depending on the port used) while during the same reception period the contents of the transmit registers (TDATA) are transferred to the master. When appropriate commands are transferred by a master SPI device and EN bit in the SPI2 control register is enabled then the commands are processed by the SPI 2 protocol handler available in this core. The SPI protocol 2 implementation is explained in detail in the following section.

123.5 SPI 2 Protocol Handler

The core is capable of handling the commands (based on SPI protocol 2) transferred by a SPI master and provide response. The message format transferred between a SPI master and SPI slave device is defined below.

*Table 2278.*Example message format (write data)

Signal	Message Header		Payload	Payload CRC
MOSI	Command #1	Command #2	Data	CRC-16
MISO	Response #1	Response #2	0x0000	0x0000

*Table 2279.*Example message format (read data)

Signal	Message Header		Payload	Payload CRC
MOSI	Command #1	Command #2	0x0000	0x0000
MISO	Response #1	Response #2	Data	CRC-16

The message header is composed of a Command token from the master and a Response token from the slave. The message also contains optional data words and CRC checksum appended at the end that are calculated for the data words transferred. The CRC is mandatory, if the message contains payload data then the message is always appended with one word of CRC. The received messages are processed by the SPI slave device and response and data are transferred as per the received command. Also note some of the status bits in the response token are status for the previously received command.

The SPI slave has the possibility to address incoming data with clock gaps (splitted) fashion. If the SPI master transfers the data with a clock gap the slave can accept the data and provide proper response. For example if the SPI master is software controlled and has a SPI controller with a word-width that is less than the full message then software needs to keep at least one word in the transmit queue at all times to avoid breaking the protocol. In order to provide a relaxed requirement on software, the SPI2 protocol allow gaps between clock periods (equivalent to stretching a clock period). The gaps must be at word level (16 bits) i.e. the clock gap can be between Command #1 and Command #2 not within the Command #1 16 bits.

123.5.1 Message Header - Command Token

The master transmits a message header that specifies the action need to be performed in slave. The command token sent by the master device consist of two 16 bit words. The message header content details are explained below.

*Table 2280.*Command word 1

MSB	Command Token Word #1														LSB
Prefix		Command Code						Spare		Message Length					
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
'0'	'1'	C5	C4	C3	C2	C1	C0	'1'	'1'	L5	L4	L3	L2	L1	L0

*Table 2281.*Command word 2

MSB	Command Token Word #2														LSB
Prefix		Sub-address								Spare		CRC-4			
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16

GRIP
Apr 2024, Version 2024.1

1986

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

'0'	'1'	SA7	SA6	SA5	SA4	SA3	SA2	SA1	SA0	'I'	'I'	CRC3	CRC2	CRC1	CRC0

- Prefix and spare

The prefix bits are transmitted initially. In the command word#1 and #2 the prefix and spare bits have fixed value in the current implementation, these are reserved bits. The spislave receives them and use it for validating the token. If an invalid prefix and spare bits are received then Status illegal command (SIC) status bit is enabled and also transmitted to master as part of the next response token.

- Message Length

The number of payload words that will be transmitted in the current message. The number should not include the command token and the CRC checksum appended at the end of the message.

- Sub-address

This field provide additional sub-address location for write and read commands.

- CRC-4

The final four bits of the command token consist of a checksum for all the previous command token bits transmitted in this message. The CRC-4 should be computed for the following 28 bits, Command word #1 (16bits, MSB first sent to the CRC generator) and Command word #2 (excluding this CRC-4 field) (12bits, MSB first sent to the CRC generator). The Prefix and Spare fields are included in the CRC calculation. The generator polynomial used is $X^4 + X + 1$. In this SPI slave receiving end the CRC-4 is calculated internally for the received command token, if the calculated CRC-4 does not match the expected value (this field) the corresponding command token is discarded and message error status is enabled and transmitted to master as part of the next response token.

- Payload data

The payload consist of the data need to be transferred from the master to slave. Depending on the command executed the master must include valid data or dummy information in the form of string of zeros. For example the write command have the data to be written as the payload but the read command have dummy information in the form of string of zeros.

- Payload CRC

When a valid payload is delivered in the payload data section of the message a Payload CRC (CRC-16) must be included at the end of the message. The generator polynomial used is $x^{16} + x^{15} + x^2 + 1$. When dummy information in the form of string of zeros is included then no Payload CRC need to be attached then the payload CRC field must be all zero (0X0000). In the SPI slave receiving end the CRC-16 is calculated internally for the received payload data, if the calculated CRC-16 does not match the expected value (this field) the corresponding operation with respect to the command is not performed and message error status is enabled and transmitted to master as part of the next response token.

123.5.2 Command Code

The command code specify the operating instruction for the receiving slave. The detailed explanation of each command code and its implementation are explained in the table below.

- Reset command

Code	Command	Length	Sub-address	Payload	Description
0x00	RESET_SPI	0x00	0x00	None	This command will reset all the spi slave device registers to the default value except the time registers (TIME1, TIME2) and core enable registers (ENN and ENR).

GRIP

Apr 2024, Version 2024.1

1987

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The RESET_SPI command resets the SPI slave device to a power up initialized state. The SPI slave resets the system only if it received a valid command. If the prefix and spare bits does not match or if the calculated CRC-4 does not match the expected value then the RESET_SPI command is discarded.

- Time synchronization command

Code	Command	Length	Sub-address	Payload	Description
0x07	SYNCH	0x04	0x00	MOSI:\<SYNC1>\<SYNC2>\<SYNC3>\<SYNC4>\<CRC-16> MISO: \<all zeros>	The master must transmit the SYNC command token followed by payload words containing synchronization information for it. These words are copied inside dedicated registers implemented in the SPI slave device after validation.

The time register is of 64 bit in width, the most significant time is transferred first in SYNC1 followed by SYNC2, SYNC3 and SYNC4. The time register roll over when its maximum count is reached. The time is synchronised only when all the words are received and also the command token CRC-4 and data CRC-16 must be valid. All bits are zero at reset. The RESET_SPI does not reset the time register.

- Time increment command

Code	Command	Length	Sub-address	Payload	Description
0x08	TICK	0x00	Used as index for increment.	None	This command is used to advance the timing synchronization register available in the SPI slave device (same register used for the SYNC command).

A valid command increments the implemented time register. The sub address field specify from which bit the time register must increment.

- Read back sent command

Code	Command	Length	Sub-address	Payload	Description
0x0A	READBACK_CMD	0x02	0x00	MOSI: \<all zeros> MISO:\<CMDTOKEN>\<CRC-16>	The command can be used to verify the correct reception of the previous command. Upon reception of the command the slave respond with the previous command token.

The SPI slave device after receiving the READBACK_CMD send the previous command token transmitted by the SPI master. This command is useful only when some other command (other than RESET_SPI) was previously transmitted. If the previous command is RESET_SPI, the SPI master only receives zeros in the payload section of this command.

GRIP
Apr 2024, Version 2024.1

1988

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Write command

Code	Command	Length	Sub-address	Payload	Description
0x0D	WRITE_SA	Number of words to be written, N	SA	MOSI:<DW1> <DW2> ...<DWN> <CRC-16> MISO: <all zeros>	The command is used to write a certain number of data words into a slave specific Sub Address. Dedicated field of the command token select the payload length and the target SA.

When a valid WRITE_SA command is received the payload data is stored at the address specified. The address for writing the data is calculated by using the write address register (CONFIG_WRITE), and sub-address. The CRC-16 is calculated for received words and compared with the received payload CRC, if a data CRC error is detected then message error status is enabled and transmitted to master as part of the next response token.

- Read command

Code	Command	Length	Sub-address	Payload	Description
0x0E	READ_SA	Number of words to be read, N	SA	MOSI: <all zeros> MISO:<DW1> <DW2> ...<DWN> <CRC-16>	The command is used to read a certain number of data words into a slave specific Sub Address. Dedicated field of the command token select the payload length and the target SA.

When a valid READ_SA command is received the payload data is transferred from the address specified. The address for reading the data is calculated by using the read address register (CONFIG_READ), and sub-address. The CRC-16 is calculated for transmitted words and sent as payload CRC by the slave device.

- Configure address commands

Code	Command	Length	Sub-address	Payload	Description
0x20	CONFIGWRITE_ADDR	0x02	0x00	MOSI:<CW1><CW2> <CRC-16> MISO: <all zeros>	The command can be used to notify the slave about the address to which the data from the master is written, used for WRITE_SA command.
0x21	CONFIG READ_ADDR	0x02	0x00	MOSI:<CR1><CR2> <CRC-16> MISO: <all zeros>	The command can be used to notify the slave about the address from which the data to the master is read, used for READ_SA command.

Dedicated registers for write address and read address is implemented, these registers takes value from this command. The purpose of this register is to access upto 32 bits of address space. The most significant word CW1 (or CR1) contains the most significant bytes of the target address.

- Redundancy commands

GRIP

Apr 2024, Version 2024.1

1989

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler
Figure 314. Redundant system

Code	Command	Length	Sub-address	Payload	Description
0x24	ACTIVATE	0x00	0x00	None	The command is used to activate the other slave interface. This command cannot activate the interface in which it is receiving this command.

Code	Command	Length	Sub-address	Payload	Description
0x25	DEACTIVATE	0x00	0x00	None	The command is used to deactivate the other slave interface. This command cannot deactivate the interface in which it is receiving this command.

The SPI Slave device has two dedicated interfaces for two masters. The masters can send to its corresponding slave interface to activate or deactivate the other SPI interface. The master device cannot activate or deactivate the same ports on which it is connected, it can only activate or deactivate the other ports.

Initially both the SPI port interfaces are enabled to receive commands, when the communication between the nominal master and slave interface fails then the redundant master can deactivate the nominal interface using its dedicated redundant interface. The redundant master can also activate the nominal interface.

An example switchover scenario from nominal to redundant interface is described in the following text.

The nominal master communicates with its dedicated interface to a slave device, a fault occurred can be detected by the master using several options,

The status received by the master have invalid values (using the response token),

The Read back command sent does not provide appropriate values in the received payload,

Error bits are enabled in the status received by the master (using the response token),

GRIP
Apr 2024, Version 2024.1

1990

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Based on any of the above mentioned fault detection methods the master can send deactivate command in the redundant interface to deactivate the nominal interface of the slave. The master can send Read back sent commands (using redundant) to check if the previous deactivate command was received by the slave and can check the status of the response token as well. After conforming a proper communication has been established the master can use the redundant interface to perform its normal operations.

- Others

Code	Command	Length	Sub-address	Payload	Description
All others	*N/A*	*0x00*			*These command codes are currently not implemented and their use is reserved for future. Upon reception of one of these codes the slave discard the incoming data.*

Any other commands which are not implemented is received then the command token is discarded and Status illegal command (SIC) bit is enabled and also transmitted to master as part of the next response token.

123.5.3 Message Header -Response Token

The slave transmits a message header which consist of status of module and details of error occurred. The message header sent by SPI slave device is called response token which consist of two 16 bit words. The message header content details are explained below.

MSB				Response Token Word #1											LSB
Prefix		*Status*					*Spare*					*Module State*			
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
'1'	'0'	STF	ME	AR	IC	'0'	'0'	'0'	'0'	'0'	'0'	MS3	MS2	MS1	MS0

*Table 2282.*Response word #1

MSB					Response Token Word #2										LSB
Prefix		*Data*	*Spare*									*CRC-4*			
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
'1'	'0'	DNA	'0'	'0'	'1'	'1'	'1 '	'1'	'0'	'0'	'0'	CRC3	CRC2	CRC1	CRC0

*Table 2283.*Response word #2

- Status bits

Bit	Identifier	Type	Value	Description	Clear Condition
13	*SPI_TERMINAL_FAULT*	*Error*	*'0'=no fault* *'1'=fault*	*The bit flag a SPI terminal fault condition.*	*According to the module current state.*

In SPI slave device this bit is enabled or disabled by SPI2 control register (STF) using APB.

GRIP

Apr 2024, Version 2024.1

1991

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

Bit	Identifier	Type	Value	Description	Clear Condition
12	*MESSAGE_ERROR*	*Error*	*'0'=no fault* *'1'=fault*	*This bit is utilized to indicate that the previous message received from the bus master has failed to pass the validity tests.*	*Always related to the previous command. Reception of a valid command will clear it (with a delay of one command).*

This status bit is enabled when the received message fails to pass the command token and payload data CRC checks. The next valid command clears this status bit.

Bit	Identifier	Type	Value	Description	Clear Condition
11	*ADDRESS_ERROR*	*Error*	*'0'=no fault* *'1'=fault*	*This bit flag an AMBA error occured while performing the previous command.*	*Always related to the previous command. Reception of a valid command will clear it (with a delay of one command)*

The SPI slave device uses an AHB master to perform the memory read and write, this bit is enabled when an AHB error is reported.

Bit	Identifier	Type	Value	Description	Clear Condition
10	*ILLEGAL_COMMAND*	*Error*	*'0'=no fault* *'1'=fault*	*This bit flag that the previous received command was not compatible with the SPI slave device.*	*Always related to the previous command. Reception of a valid command will clear it (with a delay of one command)*

When the prefix and spare bits in the received command token do not match the intended value or an unimplemented command is received this status bit is enabled. The next valid command clears this status bit.

- Module state:

In the SPI slave device these bits are enabled or disabled by SPI2 control register (MODSTAT) using APB. These bits can be used by Software controlling the slave device to provide additional status to the master.

123.6 Redundancy

The SPI slave has a two SPI ports which can be interfaced using two different masters. Two SPI master capable of communicating individually to the respective port must be available inorder to achieve redundancy using this Dual-port SPI slave.The slave takes two sets of SPI interfaces (nominal and

redundant). The configuration registers available in the device is used to enable which interface to communicate and it is possible to use dedicated commands (using SPI 2 protocol) to activate and deactivate ports.

While using configuration registers to activate or deactivate ports, the complete control of activation and deactivation must be performed by the external unit, only one port must active at any time. If both enabled then both the SPI ports are open for communication which is not supported while using external configuration for redundancy. The system which initiates the communication should take responsibility for which lane to take (there must be dedicated SPI Masters available in the system to communicate with the respective slave). If both are disabled then no communication is possible. The Master (driver) must have two dedicated SPI Master to perform communication on each lane of the SPI bus.

When commands are used to control the ports, the device can receive commands from both the interfaces. By receiving from both the interfaces the slave device can deactivate a non-working interface. The intention is to keep only one bus active for normal operation but using the redundant bus to achieve switchover. The SPI protocol 2 implementation supports dedicated commands to achieve the activation and deactivation of interfaces.

In normal working case the SPI masters Nominal and redundant (using HW or SW) should make sure not to write at the same time to both lanes of dual-port SPI Slave (for example to make a transfer). The SW or HW can command the Redundant master only when it detects problem with the Nominal communication. For worst case lets say, the SPI masters Nominal (in error state babelling some command repeatedly), using the redundant port the Nominal lane can be switched off (switch over command using redundant port or external configuration), the slave takes the redundant port input, the SPI slave is designed to take the redundant port inputs when it is available rather than nominal input.

123.7   Registers

The core is programmed through registers mapped into APB address space.

Table 2284. APB registers

APB address offset	Register
0x00	Control register
0x04	Status register
0x08	Transmit register
0x0C	Nominal receive register
0x10	Redundant receive register
0x14	Interrupt enable register
0x18	Interrupt register
0x1C	Reserved
0x20	SPI2 control register
0x24	SPI2 time1 register
0x28	SPI2 time2 register
0x2C	SPI2 config address write register
0x30	SPI2 config address read register

123.7.1 Control Register

*Table 2285.*0x00 - CTRL - Control register

31	24	23-17	16	15-13	12	8	7	6	5	4	3	2	1	0
Key		R	OD	R	WLEN		IAMBA	CPHA	CPOL	REV	R	RESET	ENR	ENN
0		0	0	0	0x0F		0	0	0	1	0	0	1	1
w		r	rw	r	rw		rw	rw	rw	rw	r	rw	rw	rw

31	Safety code (KEY) - Must be 0x68 when writing, otherwise register write is ignored
23 : 17	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
16	Overrun detect (OD) - To detect overrun condition (also to trigger overrun interrupt) this bit must be enabled. Valid only for SPI protocol 0 and 1.
15 : 13	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
12 : 8	Word length (WLEN) - The value of this field determines the length in bits of a transfer on the SPI bus. Valid values are 0x03 to 0x1F.
	Word length is WLEN+1, allows words of length 4-32 bits.
7	AMBA Interrupt enable (IAMBA) - If set, AMBA interrupt generation is enabled for the events that are individually maskable by the Interrupt enable (INTE) register
6	Clock phase (CPHA) - When CPHA is '0' data will be read on the first transition of SCK. When CPHA is '1' data will be read on the second transition of SCK.
5	Clock polarity (CPOL) - Determines the polarity (idle state) of the SCK clock.
4	Reverse data (REV) - When this bit is '0' data is transmitted LSB first, when this bit is '1' data is transmitted MSB first.
3	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
2	Reset (RESET) - Resets all the registers in the core except time registers (TIME1, TIME2) and core enable registers (ENN and ENR).
1	Enable redundant port transfer (ENR) - Enable bit for redundant port transfer. See section 5.6 for more information.
0	Enable nominal port transfer (ENN)- Enable bit for nominal port transfer. See section 5.6 for more information.

123.7.2 Status Register

*Table 2286.*0x04 - STAT - Status register

31			8	7	6	5	4	3	2	1	0
	RESERVED			ATR	ATN	SAR	SIC	R		RR	RN
	0			0	1	0	0	0		0	0
	r			r	r	r	r	r		r	r

31 : 3	RESERVED
7	Active transmission in redundant port (ATR) - This bit provides the status of the redundant transmission port. Set based on the incoming activate and deactivate commands (active '1' else '0'). Valid only for SPI protocol 2 implementation.
6	Active transmission in nominal port (ATN) - This bit provides the status of the nominal transmission port. Set based on the incoming activate and deactivate commands (active '1' else '0'). Valid only for SPI protocol 2 implementation.
5	Status address error (SAR) - This bit gets set to '1' when an AMBA write or read access resulted in a error. A valid new command clears this status bit. Valid only for SPI protocol 2 implementation.
4	Status illegal command (SIC) - This bit gets set to '1' when an illegal command is received. A valid new command clears this status bit. Valid only for SPI protocol 2 implementation.
3 : 2	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
1	Received data nominal (RR) - This bit gets set to '1' each time a data is received in the redundant port. The bit gets set to '0' when the Redundant receive register is read.
0	Received data nominal (RN) - This bit gets set to '1' each time a data is received in the nominal port. The bit gets set to '0' when the Nominal receive register is read.

123.7.3 Transmit Register

*Table 2287.*0x08 - TDATA - Transmit register

31	0
TDATA	
0	
rw	

31 : 0	Transmit data (TDATA) - The written data is transferred to the master device when appropriate conditions for CS and SCK are satisfied. The word to transmit should be written with its least significant bit at bit 0. Also note that only the number of bits need to be transferred from this register should match the word length register (WLEN). Valid only for SPI protocol 0 and 1.

123.7.4 Nominal Receive Register

*Table 2288.*0x0C - NRDATA - Nominal receive register

31	0
NRDATA	
0	
r	

31 : 0	Nominal Receive data (NRDATA) - This register contains received data from the nominal port. Valid only for SPI protocol 0 and 1.

123.7.5 Redundant Receive Register

31 : 24	Safety code (KEY) - Must be 0x68 when writing, otherwise register write is ignored.
23 : 9	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
8	Overrun interrupt (OVR) - An interrupt is generated when overrun condition occurs for data reception. (a received data must be read before the arrival of next data, if new data arrived before the Software could read the previously received data overrun condition is triggered). Valid only for SPI protocol 0 and 1.
7	Write data interrupt (WD). Valid only for SPI protocol 2.
6	AMBA access error interrupt (AI). Valid only for SPI protocol 2.
5	Change in config read address interrupt (CR). Valid only for SPI protocol 2.
4	Change in config write address interrupt (CW). Valid only for SPI protocol 2.
3	Tick command received interrupt (TICK). Valid only for SPI protocol 2.
2	Sync command received interrupt (SYNC). Valid only for SPI protocol 2.
1	Data received in redundant port interrupt (RXR).Valid only for SPI protocol 0 and 1.
0	Data received in nominal port interrupt (RXN). Valid only for SPI protocol 0 and 1.

123.7.8 SPI2 Control Register

*Table 2292.*0x20- SPI2C- SPI2 control register

31 24	23 8	7	6	5	4	3	2	1	0
Key	RESERVED	MODSTAT				RESERVED		STF	EN
0	0	0	0	0	0	0	0	0	1
w	r	rw	rw	rw	rw	r	r	rw	rw

31 : 24	Safety code (KEY) - Must be 0x68 when writing, otherwise register write is ignored.
23 : 8	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
7: 4	Module state (MODSTAT). The values in these bits are sent to the master via the response token. These are user configurable registers which can be set to '1' or '0'. Valid only for SPI protocol 2.
3: 2	RESERVED (R) - Read as zero and should be written to zero to ensure forward compatibility.
1	SPI terminal failure (STF). This value in this bit is sent to the master via the response token. In order to intimate a terminal failure this bit can be written to '1' through software. Valid only for SPI protocol 2.
0	Enable (EN). SPI protocol 2 enable bit. If set to '1' the commands received from master are handled by the SPI 2 protocol handler in the core. If set to '0' the data received and transfered are using the APB registers.

123.7.9 SPI2 Time1 Register

*Table 2293.*0x24 - TIME1 - SPI2 time1 register

31   0
TIME1
0x00000000
r

31 : 0	Time 1 register (TIME1) - Provides the most significant 32 bits of the time register. This is a status (read only) register, the contents of this register is a reflection of the time modified/incremented using the sync and tick command respectively.

31 : 0   Configuration read address (CONFR) - Defines the base address for the memory area where the core is allowed to make accesses. This is a status (read only) register, the contents of this register can be modified by the configuration read address command.

123.8 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0A7. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

123.9 Implementation

123.9.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

123.9.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

124   SRCTRL- 8/32-bit PROM/SRAM Controller

124.1   Overview

SRCTRL is an 8/32-bit PROM/SRAM/IO controller that interfaces external asynchronous SRAM, PROM and I/O to the AMBA AHB bus. The controller can handle 32-bit wide SRAM and I/O, and either 8- or 32-bit PROM.
Figure 315. 8/32-bit PROM/SRAM/IO controller

The controller is configured through VHDL-generics to decode three address ranges: PROM, SRAM and I/O area. By default PROM area is mapped into address range 0x0 - 0x00FFFFFF, the SRAM area is mapped into address range 0x40000000 - 0x40FFFFFF, and the I/O area is mapped to 0x20000000 - 0x20FFFFFF.

One chip select is decoded for the I/O area, while SRAM and PROM can have up to four and two select signals respectively. The controller generates both a common write-enable signal (WRITEN) as well as four byte-write enable signals (WREN). If the SRAM uses a common write enable signal the controller can be configured to perform read-modify-write cycles for byte and half-word write accesses. Number of waitstates is separately configurable for the three address ranges.

A single write-enable signal is generated for the PROM area (WRITEN), while four byte-write enable signals (RWEN[3:0]) are provided for the SRAM area. If the external SRAM uses common write enable signal, the controller can be configured to perform read-modify-write cycles for byte and half-word write accesses.

Number of waitstates is configurable through VHDL generics for both PROM and SRAM areas.

A signal (BDRIVE) is provided for enabling the bidirectional pads to which the data signals are connected. The oepol generic is used for selecting the polarity of these enable signals. If output delay is an issue, a vectored output enable signal (VBDRIVE) can be used instead. In this case, each pad has

its own enable signal driven by a separate register. A directive is placed on these registers so that they will not be removed during synthesis (if the output they drive is used in the design).

124.1.1 Endianness

The core is designed for big-endian systems.

124.2 8-bit PROM access

The SRCTRL controller can be configured to access a 8-bit wide PROM. The data bus of external PROM should be connected to the upper byte of the 32-bit data bus, i.e. D[31:24]. The 8-bit mode is enabled with the prom8en VHDL generic. When enabled, read accesses to the PROM area will be done in four-byte bursts. The whole 32-bit word is then presented on the AHB data bus. Writes should be done one byte at a time and the byte should always be driven on bit 31-24 on the AHB data bus independent of the byte address.

It is possible to dynamically switch between 8- and 32-bit PROM mode using the BWIDTH[1:0] input signal. When BWIDTH is "00" then 8-bit mode is selected. If BWIDTH is "10" then 32-bit mode is selected. Other BWIDTH values are reserved for future use.

SRAM access is not affected by the 8-bit PROM mode.

124.3 PROM/SRAM waveform

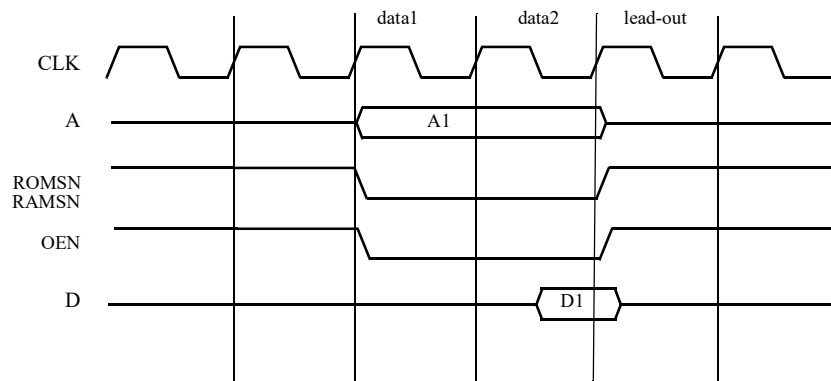
Read accesses to 32-bit PROM and SRAM has the same timing, see figure below.


Figure 316. 32-bit PROM/SRAM/IO read cycle

The write access for 32-bit PROM and SRAM can be seen below.
Figure 317. 32-bit PROM/SRAM/IO write cycle

If waitstates are configured through the VHDL generics, one extra data cycle will be inserted for each waitstate in both read and write cycles.

124.4 Burst cycles

To improve the bandwidth of the memory bus, accesses to consecutive addresses can be performed in burst mode. Burst transfers will be generated when the memory controller is accessed using an AHB burst request. These includes instruction cache-line fills and burst from DMA masters. The timing of a burst cycle is identical to the programmed basic cycle with the exception that during read cycles, the lead-out cycle will only occurs after the last transfer.

124.5 Registers

The core does not implement any user programmable registers.

All configuration is done through the VHDL generics.

124.6 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x008. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

124.7 Implementation

124.7.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers. The registers driving external chip select, output enable and output enables for the data bus have asynchronous reset.

124.7.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

124.8 Configuration options

Table 2301 shows the configuration options of the core (VHDL generics).

*Table 2300.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	1 - NAHBSLV-1	0
romaddr	ADDR field of the AHB BAR0 defining PROM address space. Default PROM area is 0x0 - 0xFFFFFF.	0 - 16#FFF#	16#000#
rommask	MASK field of the AHB BAR0 defining PROM address space.	0 - 16#FFF#	16#FF0#
ramaddr	ADDR field of the AHB BAR1 defining SRAM address space. Default SRAM area is 0x40000000-0x40FFFFFF.	0 - 16#FFF#	16#400#
rammask	MASK field of the AHB BAR1 defining SRAM address space.	0 -16#FFF#	16#FF0#
ioaddr	ADDR field of the AHB BAR2 defining IO address space. Default IO area is 0x20000000-0x20FFFFFF.	0 - 16#FFF#	16#200#
iomask	MASK field of the AHB BAR2 defining IO address space.	0 -16#FFF#	16#FF0#
ramws	Number of waitstates during access to SRAM area	0 - 15	0
romws	Number of waitstates during access to PROM area	0 - 15	2
iows	Number of waitstates during access to IO area	0 - 15	2
rmw	Enable read-modify-write cycles.	0 - 1	0
prom8en	Enable 8 - bit PROM accesses	0 - 1	0
oepol	Polarity of bdrive and vbdrive signals. 0=active low, 1=active high	0 - 1	0
srbanks	Set the number of SRAM banks	1 - 5	1
banksz	Set the size of bank 1 - 4. 0 = 8 Kbyte, 1 = 16 Kbyte, ... , 13 = 64Mbyte.	0 - 13	13
romasel	address bit used for PROM chip select.	0 - 27	19

124.9 Signal description

Table 2300 shows the interface signals of the core (VHDL ports).

*Table 2301.*Signal descriptions

Signal name	Field	Type	Function	Polarity
CLK	N/A	Input	Clock	-
RST	N/A	Input	Reset	Low

124.10 Library dependencies

Table 2302 shows libraries used when instantiating the core (VHDL libraries).

Table 2302. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AHB signal definitions
GAISLER	MEMCTRL	Signals, component	Memory bus signals definitions, component declaration

124.11 Component declaration

The core has the following component declaration.

```
component srctrl
  generic (
    hindex  : integer := 0;
    romaddr : integer := 0;
    rommask : integer := 16#ff0#;
    ramaddr : integer := 16#400#;
    rammask : integer := 16#ff0#;;
    ioaddr  : integer := 16#200#;
    iomask  : integer := 16#ff0#;
    ramws   : integer := 0;
    romws   : integer := 2;
    iows    : integer := 2;
    rmw     : integer := 0;-- read-modify-write enable
    prom8en : integer := 0;
    oepol   : integer := 0;
    srbanks : integer range 1 to 5 := 1;
    banksz  : integer range 0 to 13:= 13;
    romasel : integer range 0 to 27:= 19
  );
  port (
    rst     : in  std_ulogic;
    clk     : in  std_ulogic;
    ahbsi   : in  ahb_slv_in_type;
    ahbso   : out ahb_slv_out_type;
    sri     : in  memory_in_type;
    sro     : out memory_out_type;
    sdo     : out sdctrl_out_type
  );
end component;
```

124.12 Instantiation

This example shows how the core can be instantiated.

The example design contains an AMBA bus with a number of AHB components connected to it including the memory controller. The external memory bus is defined on the example designs port map and connected to the memory controller. System clock and reset are generated by GR Clock Generator and Reset Generator.

Memory controller decodes default memory areas: PROM area is 0x0 - 0xFFFFFF and SRAM area is 0x40000000 - 0x40FFFFFF. The 8-bit PROM mode is disabled. Two SRAM banks of size 64 Mbyte are used and the fifth chip select is disabled.

125   SSRCTRL- 32-bit SSRAM/PROM Controller

125.1   Overview

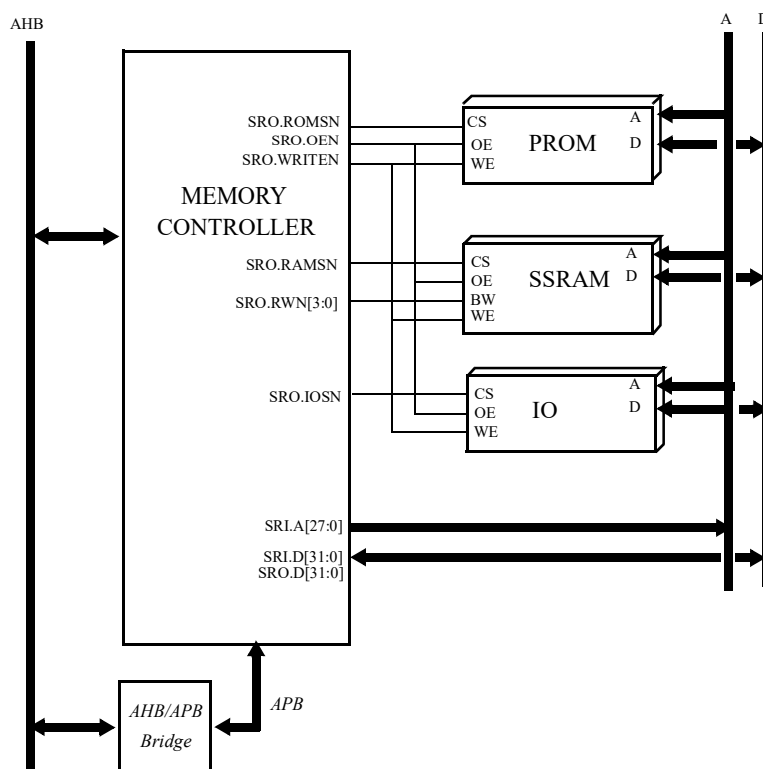
The memory controller (SSRCTRL) is an 32-bit SSRAM/PROM/IO controller that interfaces external Synchronous pipelined SRAM, PROM, and I/O to the AMBA AHB bus. The controller acts as a slave on the AHB bus and has a configuration register accessible through an APB slave interface. Figure 318 illustrates the connection between the different devices.


Figure 318. 32-bit SSRAM/PROM/IO controller

The controller is configured by VHDL-generics to decode three address ranges: PROM, SSRAM and I/O area. By default PROM area is mapped into address range 0x0 - 0x00FFFFFF; the SSRAM area is mapped into address range 0x40000000 - 0x40FFFFFF; and the I/O area is mapped to 0x20000000 - 0x20FFFFFF.

One chip select is generated for each of the address areas. The controller generates both a common write-enable signal (WRITEN) as well as four byte-write enable signals (WRN). The byte-write enable signal enables byte and half-word write access to the SSRAM.

A signal (BDRIVE) is provided for enabling the bidirectional pads to which the data signals are connected. The oepol generic is used to select the polarity of these enable signals. If output delay is an issue, a vectored output enable signal (VBDRIVE) can be used instead. In this case, each pad has its own enable signal driven by a separate register. A directive is placed on these registers so that they will not be removed during synthesis (in case the output they drive is used in the design).

The SSRCTRL conteoller can optionally support 16-bit PROM/IO devices. This is enabled through the BUS16 generic. A 32-bit access to the PROM or IO area will be translated into two 16-bit accesses with incrementing address.

125.1.1 Endianness

The core is designed for big-endian systems.

125.2 SSRAM/PROM waveform

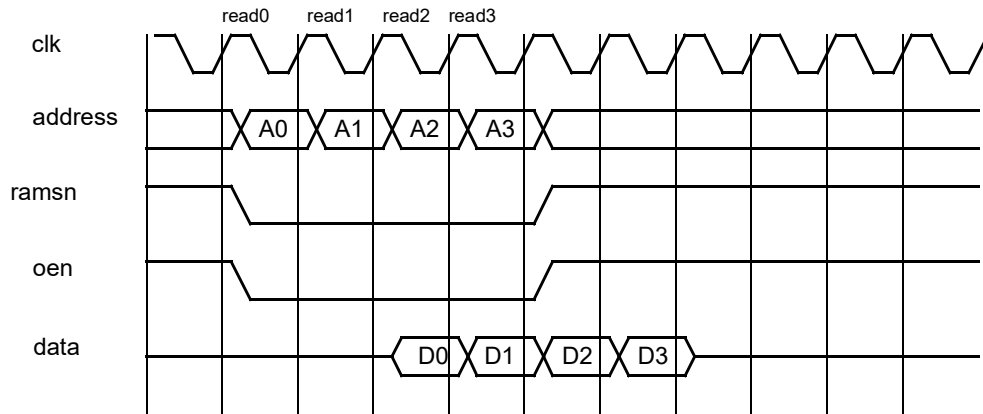
Because the SSRAM (Synchronous pipelined SRAM) has a pipelined structure, the data output has a latency of three clock cycles. The pipelined structure enables a new memory operation to be issued each clock cycle. Figure 318 and figure 319 show timing diagrams for the SSRAM read and write accesses.


Figure 319. 32-bit SSRAM read cycle

As shown in the figure above, the controller always perform a burst read access to the memory. This eliminates all data output latency except for the first word when a burst read operation is executed.
Figure 320. 32-bit SSRAM write cycle

A write operation takes three clock cycles. On the rising edge of the first clock cycle, the address and control signals are latched into the memory. On the next rising edge, the memory puts the data bus in high-impedance mode. On the third rising edge the data on the bus is latched into the memory and the write is complete. The controller can start a new memory (read or write) operation in the second clock cycle. In figure 320 this is illustrated by a read operation following the write operation.

Due to the memory automatically putting the data bus in high-impedance mode when a write operation is performed, the output-enable signal (OEN) is held active low during all SSRAM accesses (including write operations).

125.2.1 PROM and IO access

For the PROM and I/O operations, a number of waitstates can be inserted to increase the read and write cycle. The number of waitstates can be configured separately for the I/O and PROM address ranges, through a programmable register mapped into the APB address space. After a reset the wait-states for PROM area is set to its maximum (15). Figure 321 and figure 322 show timing diagrams for the PROM read and write accesses.

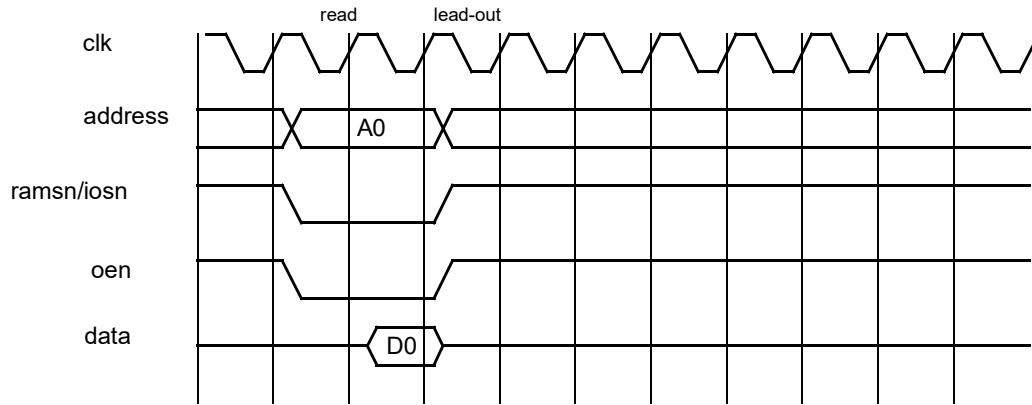
Read accesses to 32-bit PROM and I/O has the same timing, see figure 321


Figure 321. 32-bit PROM/IO read cycle

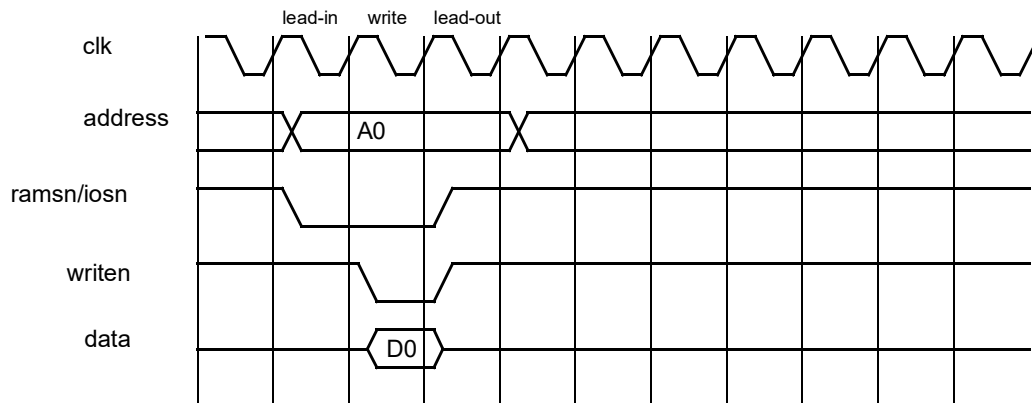
The write access for 32-bit PROM and I/O can be seen in figure 322


Figure 322. 32-bit PROM/IO write cycle

The SSRCTRL conteoller can optionally support 16-bit PROM/IO devices. This is enabled through the BUS16 generic. A 32-bit access to the PROM or IO area will be translated into two 16-bit accesses with incrementing address. A 16-bit access will result in one bus access only. 8-bit accesses are not allowed.

16-bit PROM/IO operation is enabled by writing "01" to the romwidth field in SSRAM control register. At reset, the romwidth field is set by the MEMI.BWIDTH input signal.

125.3 Registers

The core is programmed through registers mapped into APB address space.

Table 2303. SSRAM controller registers

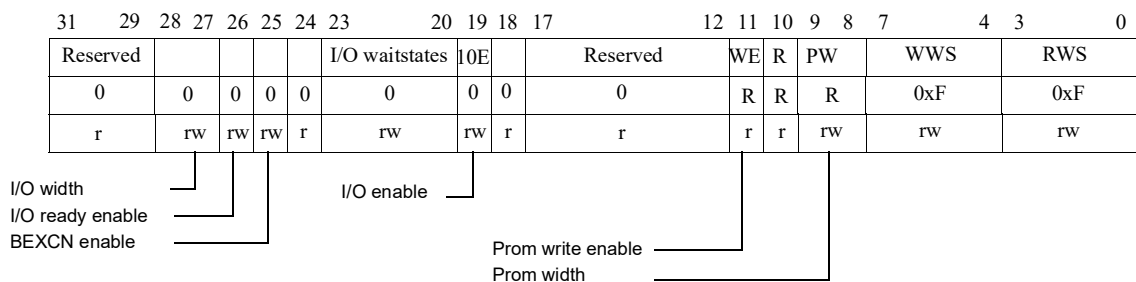
APB address offset	Register
0x00	Memory configuration register


Figure 325. Memory configuration register

[3:0]: Prom read waitstates. Defines the number of waitstates during prom read cycles ("0000"=0, "0001"=1,... "1111"=15).

[7:4]: Prom write waitstates. Defines the number of waitstates during prom write cycles ("0000"=0, "0001"=1,... "1111"=15).

[9:8]: Prom width. Defines the data with of the prom area ("01"=16, "10"=32).

[10]: Reserved

[11]: Prom write enable. If set, enables write cycles to the prom area. NOT USED.

[17:12]: Reserved

[19]: I/O enable. If set, the access to the memory bus I/O area are enabled. NOT USED.

[23:20]: I/O waitstates. Defines the number of waitstates during I/O accesses ("0000"=0, "0001"=1, "0010"=2,..., "1111"=15).

[25]: Bus error (BEXCN) enable. NOT USED.

[26]: Bus ready (BRDYN) enable. NOT USED.

[28:27]: I/O bus width. Defines the data with of the I/O area ("01"=16, "10"=32).

During power-up (reset), the PROM waitstates fields are set to 15 (maximum) and the PROM bus width is set to the value of MEMI.BWIDTH. All other fields are initialized to zero.

125.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x00A. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

125.5 Implementation

125.5.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

125.6 Configuration options

Table 2304 shows the configuration options of the core (VHDL generics).

Table 2304. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	1 - NAHBSLV-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
romaddr	ADDR field of the AHB BAR0 defining PROM address space. Default PROM area is 0x0 - 0xFFFFFF.	0 - 16#FFF#	16#000#
rommask	MASK field of the AHB BAR0 defining PROM address space.	0 - 16#FFF#	16#FF0#
ramaddr	ADDR field of the AHB BAR1 defining RAM address space. Default RAM area is 0x40000000-0x40FFFFFF.	0 - 16#FFF#	16#400#
rammask	MASK field of the AHB BAR1 defining RAM address space.	0 -16#FFF#	16#FF0#
ioaddr	ADDR field of the AHB BAR2 defining IO address space. Default IO area is 0x20000000-0x20FFFFFF.	0 - 16#FFF#	16#200#

125.8 Library dependencies

Table 2306 shows libraries used when instantiating the core (VHDL libraries).

Table 2306. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AHB signal definitions
GAISLER	MEMCTRL	Signals, component	Memory bus signals definitions, component declaration

125.9 Component declaration

The core has the following component declaration.

```
component ssrctrl
  generic (
    hindex  : integer := 0;
    pindex  : integer := 0;
    romaddr : integer := 0;
    rommask : integer := 16#ff0#;
    ramaddr : integer := 16#400#;
    rammask : integer := 16#ff0#;
    ioaddr  : integer := 16#200#;
    iomask  : integer := 16#ff0#;
    paddr   : integer := 0;
    pmask   : integer := 16#fff#;
    oepol   : integer := 0;
    bus16 : integer := 0
  );
  port (
    rst     : in  std_ulogic;
    clk     : in  std_ulogic;
    ahbsi   : in  ahb_slv_in_type;
    ahbso   : out ahb_slv_out_type;
    apbi    : in  apb_slv_in_type;
    apbo    : out apb_slv_out_type;
    sri     : in  memory_in_type;
    sro     : out memory_out_type

  );
end component;
```

125.10 Instantiation

This example shows how the core can be instantiated.

The example design contains an AMBA bus with a number of AHB components connected to it, including the memory controller. The external memory bus is defined in the example designs port map and connected to the memory controller. System clock and reset are generated by the Clk-gen_ml401 Clock Generator and GR Reset Generator.

The memory controller decodes default memory areas: PROM area is 0x0 - 0x00FFFFFF, I/O-area is 0x20000000-0x20FFFFFF and RAM area is 0x40000000 - 0x40FFFFFF.

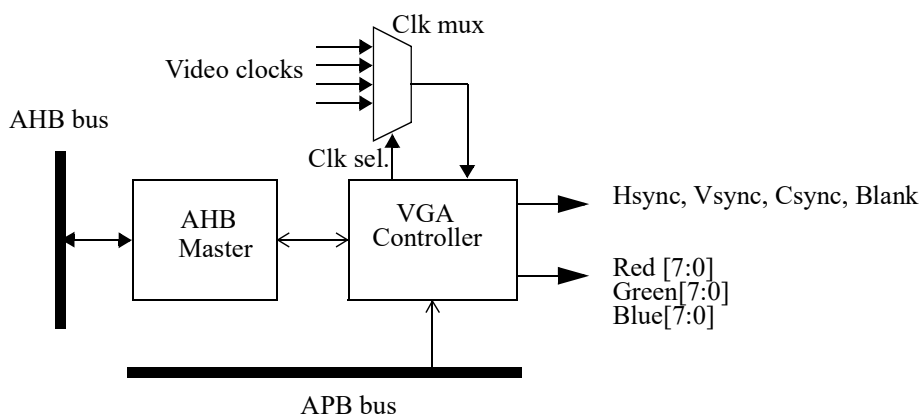
126   SVGACTRL - VGA Controller Core

126.1   Overview

The core is a pixel based video controller (frame buffer), capable of displaying standard and custom resolutions with variable bit depth and refresh rates. The video controller consists of a synchronization unit, main control unit, FIFO unit and an AHB master as shown in the figure below.


126.2   Operation

The core uses external frame buffer memory located in the AHB address space. A frame on the display is created by fetching the pixel data from memory and sending it to the screen through an external DAC using three 8-bit color vectors. To hide the AHB bus latency, the pixel data is buffered in a FIFO inside the core. The start address of the frame buffer is specified in the Frame buffer Memory Position register, and can be anywhere in the AHB address space. In addition to the color vectors the video controller also generates HSYNC, VSYNC, CSYNC and BLANK signals control signals.

The video timing is programmable through the Video Length, Front Porch, Sync Length and Line Length registers. The bit depth selection and enabling of the controller is done through the status register. These values make it possible to display a wide range of resolutions and refresh rates.

The pixel clock can be either static or dynamic multiplexed. The frequency of the pixel clock is calculated as *Horizontal Line Length * Vertical Line Length * refresh rate*. When using a dynamically multiplexed clock, bits [5:4] in the status register are used to control the clock selector. The dynamic pixel clocks should be defined in the core's VHDL generics to allow software to read out the available pixel clock frequencies.

The core can use bit depths of 8, 16 and 32 bits. When using 32 bits, bits[23:0] are used, when 16 bits a [5,6,5] color scheme is used and when using 8 bits a color lookup table "CLUT" is used. The CLUT has 256 positions, each 24 bits wide, and the 8 bit values read from memory are used to index the CLUT to obtain the actual color.

126.3   DVI support

In order to initialize a DVI transmitter, an additional core such as the I^{2}C master is normally required. Additional glue logic may also be required since the interfaces of DVI transmitters differ between manufacturers and product lines. Examples on how to interface the core to a DVI transmitter are available in the GRLIB IP Library's template designs.

126.4 Registers

The core is programmed through registers mapped into APB address space.

Table 2307. VGA controller registers

APB address offset	Register
0x00	Status register
0x04	Video length register

15:8   Green color data (GREEN) - Green color data to set in the specified register.

7:0   Blue color data (BLUE) - Blue color data to set in the specified register.

126.5 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x063. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

126.6 Implementation

126.6.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

See also the documentation for the *asyncrst* VHDL generic.

126.6.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). All accesses match the width of the AHB bus, defined by the *ahbaccsz* generic.

126.7 Configuration options

Table 2319 shows the configuration options of the core (VHDL generics).

*Table 2319.*Configuration options

Generic name	Function	Allowed range	Default
length	Size of the pixel FIFO	3 - 1008	384
part	Pixel FIFO part length	1 - 336	128
memtech	Memory technology	0 - NTECH	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	12-bit MSB APB address	0 - 16#FFF#	0
pmask	APB address mask	0 - 16#FFF#	16#FFF#
hindex	AHB master index	0 - NAHBMST-1	0
hirq	Interrupt line	0 - NAHBIRQ-1	0
clk0	Period of dynamic clock 0 in ps	0- 16#FFFFFFFF#	40000
clk1	Period of dynamic clock 1 in ps	0- 16#FFFFFFFF#	20000
clk2	Period of dynamic clock 2 in ps	0- 16#FFFFFFFF#	15385
clk3	Period of dynamic clock 3 in ps	0- 16#FFFFFFFF#	0
burstlen	AHB burst length. The core will burst $2^{burstlen}$ words.	2 - 8	8
ahbaccsz	Determines the size of the AMBA accesses that the core will use when fetching data from memory.	32 - AHBDW	32
asyncrst	Use asynchronous reset for the VGA clock domain. If this generic is set to 1 the core will use the *arst* input to reset part of the registers in the VGA domain. Asynchronous reset should be used if the VGA clock is not available during system reset. If this generic is 0 the *arst* input is not used.	0 - 1	0

127 SYNCIOTEST - Test block for synchronous I/O interfaces

127.1 Overview

This IP core is a helper block for instantiation into other IP cores, in order to simplify clock-to-out and setup/hold production testing on ASICs. It needs to be embedded into the IP in order to use the same registers as is used in the functional mode in order to get relevant timing measurement.

It currently has a few conditions on its use for implementation reasons:

- Number of inputs+bidirs needs to be 8 or more.
- Number of outputs needs to be at least 1

127.2 Operation

The modes are:

- Idle
- Output pseudo-random sequence on outputs and bidirs (pattern repeats after 255 cycles)
- Output toggle values between all-ones and all-zeros
- Output toggle between all-one, tristate, all-zero, tristate, ...
- Output toggle each bit in sequence "00101010" with other values first as all-one and then again with other outputs as all-zero.
- Input same pseudo-random sequence as in output mode above. If the wrong data is received on a byte lane, one of the outputs is set to flag an error. The PRNG is re-seeded with the input data every cycle to make the test mode self synchronizing with the input stream.

The tmodeact output controls when the test mode is activated, when high the surrounding IP core should mux in the dataout vector to the output registers and the tmodeoe signal to bidir output-enable registers.

A simple safety scheme is implemented. An inverted copy of the mode vector must be supplied on the top bits of the tmode input, if this is incorrect then no mode is activated. If the tmode signal is mapped to a register in the IP core, it can scrub the field for accidental bit-flips by clearing it when the tmodeact signal is low.

127.3 Implementation

127.3.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

127.4 Configuration options

Table 2322 shows the configuration options of the core (VHDL generics).

*Table 2322.*Configuration options

Generic name	Function	Allowed range	Default
ninputs	Number of inputs		1
noutputs	Number of outputs		1
nbidir	Number of bidirectional signals		1
dirmode	Direction mode. 0=both, 1=in-only, 2=out-only		1

127.5 Signal descriptions

Table 2323 shows the interface signals of the core (VHDL ports).

Table 2323. Signal descriptions

Signal name	Field	Type	Function	Active
CLK	N/A	Input	Clock	-
RSTN	N/A	Input	Reset	Low
DATAIN	N/A	Input	Data input	-
DATAOUT	N/A	Output	Data output	-
TMODE	N/A	Input	Test mode	High
TMODEACT	N/A	Output	Test mode activated	High
TMODEOE	N/A	Output	Test mode output enable	High

128   SYNCRAM - Single-port RAM generator

128.1   Overview

SYNCRAM is a single port RAM that maps on technology-specific RAM blocks. The core has a common address bus, and separate data-in and data-out buses. All inputs are latched on the on the rising edge of clk. The read data appears on dataout directly after the clk rising edge.

128.2   Configuration options

Table 2325 shows the configuration options of the core (VHDL generics).

*Table 2325.*Configuration options

Name	Function	Range	Default
tech	Technology selection	0 - NTECH	0
abits	Address bits. Depth of RAM is $2^{abits-1}$	see table below	-
dbits	Data width	see table below	-
testen	Enable bypass logic for scan testing	0 - 1	0
custombits	Bits used by custom interface		
pipeline	Adds pipeline register on data outputs. Adds one clock cycle latency	0 - 15	0

128.3   Scan test support

Scan test support will be enabled if the TESTEN generic is set to 1. This option will generate a register (flip-flops) connected between the DATAIN and DATAOUT of the syncram module. In test mode, DATAOUT is driven from the register rather then from the RAM outputs. This will allow both input and output paths around the syncram to be testable by scan. The address bus and control signals are xored with the DATAIN signal to also increase test coverage of those. Test mode is enabled by driving the TESTIN(3) signals to 1. This signal should typically be connected to the global test enable signals of the design.

129 SYNCRAMBW - Single-port RAM generator with byte enables

129.1 Overview

SYNCRAMBW implements a single port RAM with byte enables, using the GRLIB technology wrapping for different target technologies. The core operates identically to SYNCRAM, with the addition that each byte has a separate chip select (ENABLE) and write select (WRITE). The core is provided in a generic configuration and also in configurations of 128, 156 and 256 bits, and the corresponding entities are named SYNCRAMBW, SYNCRAM128BW, SYNCRAM156BW and SYN-CRAM256BW. In the simplest case, the IP cores just instantiate several eight bit wide SYNCRAM components. SYNCRAM128BW, SYNCRAM156BW and SYNCRAM256BW, used in GRLIB's Level-2 cache core, contain specialized maps for several technologies to more efficiently utilize device resources.

Note that some SYNCRAM components may be missing from the library depending on the type of GRLIB distribution.

129.2 Configuration options

Table 2329 shows the configuration options of the core (VHDL generics).

*Table 2329.*Configuration options

Name	Function	Range	Default
tech	Technology selection	0 - NTECH	0
abits	Address bits. Depth of RAM is $2^{abits-1}$	see table below	-
testen	Enable bypass logic for scan testing	0 - 1	0
custombits	Bits used by custom interface		
pipeline	Adds pipeline register on data outputs. Adds one clock cycle latency	0 - 15	0

129.3 Scan test support

Scan test support will be enabled if the TESTEN generic is set to 1. This option will generate a register (flip-flops) connected between the DATAIN and DATAOUT of the syncram module. In test mode, DATAOUT is driven from the register rather then from the RAM outputs. This will allow both input and output paths around the syncram to be testable by scan. The address bus and control signals are xored with the DATAIN signal to also increase test coverage of those. Test mode is enaled by driving the TESTIN(3) signals to 1. This signal should typically be connected to the global test enable signals of the design.

all others	-	syncram core with dwidth=8	tech depend.	tech depend.

To add support for a new technology, the following steps should be taken:

- Add technology-specific version for the RAM core in lib/techmap/TECH

- Instantiate the technology-specific RAM core in lib/techmap/maps/syncram256bw.vhd, and set the has_sram256bw() constant to 1 for the specific technology:

```
constant has_sram256bw : tech_ability_type := (
virtex2 => 1, virtex4 => 1, virtex5 => 1, spartan3 => 1,
spartan3e => 1, spartan6 => 1, virtex6 => 1,
altera => 1, cyclone3 => 1, stratix2 => 1, stratix3 => 1,
tm65gpl => 0, others => 0);
```

See also syncrambw.vhd, syncram128bw.vhd and syncram156bw.vhd under lib/techmap/maps/ for the corresponding SYNCRAM BW IP cores.

130   SYNCRAM_2P - Two-port RAM generator

130.1   Overview

The two-port RAM generator has a one read port and one write port. Each port has a separate address and data bus. All inputs are registered on the rising edge of clk. The read data appears on dataout directly after the clk rising edge. Address width, data width and target technology is parametrizable through generics.

130.2   Write-through operation

Write-through is supported if the function *syncram_2p_write_through(tech)* returns 1 for the target technology, or if the *wrfst* generic is set to 1. If *wrfst* = 1, additional logic will be generated to detect simultaneous read/write to the same memory location, and in that case bypass the written data to the data outputs.

130.3   Conflicts

Some technologies will produce unpredictable results when a read and write operation occurs simultaneously to the same memory location. The function *syncram_2p_dest_rw_collision(tech)* returns 1 for technologies that has this characteristic. If SYNCRAM_2P is implemented with *sepclk* = 0 then logic will be included that disables the read enable signal, if needed, when a collision is detected. If the core is implemented with *sepclk* = 1 (and *syncram_2p_dest_rw_collision(tech)* returns 1) then collision avoidance must be handled by external logic.

130.4   Scan test support

Scan test support will be enabled if the TESTEN generic is set to 1. This option will generate a register (flip-flops) connected between the DATAIN and DATAOUT of the syncram module. In test mode, DATAOUT is driven from the register rather then from the RAM outputs. This will allow both input and output paths around the syncram to be testable by scan. The address bus and control signals are xored with the DATAIN signal to also increase test coverage of those. Test mode is enaled by driving the TESTIN(3) signals to 1. This signal should typically be connected to the global test enable signals of the design.

131.4 Library dependencies

Table 2340 shows libraries used when instantiating the core (VHDL libraries).

Table 2340. Library dependencies

Library	Package	Imported unit(s)	Description
TECHMAP	GENCOMP	Constants	Technology contants

131.5 Component declaration

The core has the following component declaration.

```
library techmap;
use techmap.gencomp.all;

component syncram_dp
  generic (tech : integer := 0; abits : integer := 6; dbits : integer := 8);
  port (
    clk1     : in std_ulogic;
    address1 : in std_logic_vector((abits -1) downto 0);
    datain1  : in std_logic_vector((dbits -1) downto 0);
    dataout1 : out std_logic_vector((dbits -1) downto 0);
    enable1  : in std_ulogic;
    write1   : in std_ulogic;
    clk2     : in std_ulogic;
    address2 : in std_logic_vector((abits -1) downto 0);
    datain2  : in std_logic_vector((dbits -1) downto 0);
    dataout2 : out std_logic_vector((dbits -1) downto 0);
    enable2  : in std_ulogic;
    write2   : in std_ulogic);
  end component;
```

131.6 Instantiation

This example shows how the core can be instantiated.

```
library ieee;
use ieee.std_logic_1164.all;
library techmap;
use techmap.gencomp.all;

clk1     : in std_ulogic;
address1 : in std_logic_vector((abits -1) downto 0);
datain1  : in std_logic_vector((dbits -1) downto 0);
dataout1 : out std_logic_vector((dbits -1) downto 0);
enable1  : in std_ulogic;
write1   : in std_ulogic;
clk2     : in std_ulogic;
address2 : in std_logic_vector((abits -1) downto 0);
datain2  : in std_logic_vector((dbits -1) downto 0);
dataout2 : out std_logic_vector((dbits -1) downto 0);
enable2  : in std_ulogic;
write2   : in std_ulogic);

ram0 : syncram_dp generic map ( tech => tech, abits => addrbits, dbits => dbits)
      port map ( clk1, address1, datain1, dataout1, enable1, write1, clk2, address2, datain2,
dataout2, enable2, write2);
```

132   SYNCRAMFT - Single-port RAM generator with EDAC

132.1   Overview

SYNCRAMFT is a single port RAM that maps on technology-specific RAM blocks. The core has a common address bus, and separate data-in and data-out buses. All inputs are latched on the on the rising edge of clk. The read data appears on dataout directly after the clk rising edge. SYNCRAMFT can be configured to include logic for error detection or error detection and correction. This protection is added either as logic connected to an internal SYNCRAM instantiation or by mapping directly to technology specific memory resources with SECDED EDAC.

132.2   Configuration options

Table 2341 shows the configuration options of the core (VHDL generics).

*Table 2341.*Configuration options

Name	Function	Range	Default
tech	Technology selection	0 - NTECH	0
abits	Address bits. Depth of RAM is $2^{abits-1}$	-	-
dbits	Data width	-	-
ft	Fault-tolerance 0: Standard SYNCRAM, no FT 1: byte parity DMR 2: true TMR 3: byte-parity, no DMR (only error detection) 4: SECDED - BCH 5: SECDED - target technology specific Technology specific protection is further documented in the GRLIB-FT User's Manual (grlib-ft.pdf).	0 - 5	0
testen	Enable bypass logic for scan testing	0 - 1	0
custombits	Bits used by custom interface		
pipeline	Adds pipeline registers on data outputs. Bits 3:0 of is a field that adds registers to the data outputs of the RAM cell. This adds one additional clock cycle before the read data is available on the SYNCRAM data outputs. Bits 7:4 is a field that adds a register after the error correction logic. This adds one additional clock cycle before the read data is available on the data outputs. The error signals are delayed in the same way as the data. This has the following effect on data read latency Pipeline value: added latency 0 : 0 1 : 1 16: 1 17: 2	0 - 255	0

132.3   Scan test support

133 TAP - JTAG TAP Controller

133.1 Overview

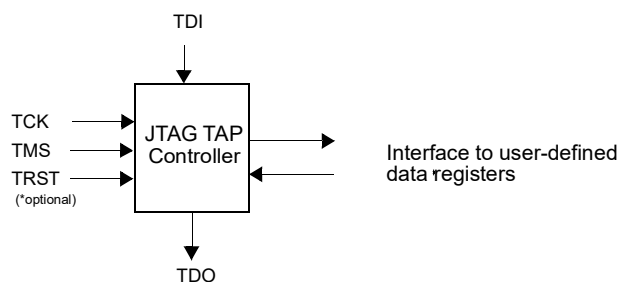
JTAG TAP Controller provides an Test Access Port according to IEEE-1149 (JTAG) Standard. The core implements the Test Access Port signals, the synchronous TAP state-machine, a number of JTAG data registers (depending on the target technology) and an interface to user-defined JTAG data registers.


Figure 329. TAP controller block diagram

133.2 Operation

133.2.1 Generic TAP Controller

The generic TAP Controller implements JTAG Test Access Point interface with signals TCK, TMS, TDI and TDO, a synchronous state-machine compliant to the IEEE-1149 standard, JTAG instruction register and two JTAG data registers: bypass and device identification code register. The core is capable of shifting and updating the JTAG instruction register, putting the device into bypass mode (BYPASS instruction) and shifting out the devices identification number (IDCODE instruction). User-defined JTAG test registers are accessed through user-defined data register interface.

The access to the user-define test data registers is provided through the user-defined data register interface. The instruction in the TAP controller instruction register appears on the interface as well as shift-in data and signals indicating that the TAP controller is in Capture-Data-Register, Shift-Data-Register or Update-Data-Register state. Logic controlling user-defined data registers should observe value in the instruction register and TAP controller state signals in order to capture data, shift data or update data-registers.

JTAG test registers such as boundary-scan register can be interfaced to the TAP controller through the user data register interface.

133.3 Technology specific TAP controllers

The core instantiates technology specific TAP controller for Altera and Xilinx devices.

133.4 Registers

The core implements three JTAG registers: instruction, bypass and device identification code register.

133.5 Vendor and device identifiers

The core does not have vendor and device identifiers since it does not have AMBA interfaces.

133.6 Implementation

133.6.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). If the VHDL generic trsten is non-zero then the corer makes use of asynchronous reset. Otherwise synchronous reset is used.

133.7 Configuration options

Table 2344 shows the configuration options of the core (VHDL generics).

*Table 2344.*Configuration options

Generic	Function	Allowed range	Default
tech	Target technology	0 - NTECH	0

134   GRTM - CCSDS/ECSS Telemetry Encoder

This IP core is only available as part of a design service.

134.1   Overview

The CCSDS/ECSS/PSS Telemetry Encoder implements part of the Data Link Layer, covering the Protocol Sub-layer and the Frame Synchronization and Coding Sub-layer and part of the Physical Layer of the packet telemetry encoder protocol.

The operation of the Telemetry Encoder is highly programmable by means of control registers. The design of the Telemetry Encoder is highly configurable by means of VHDL generics.

The Telemetry Encoder comprises several encoders and modulators implementing the Consultative Committee for Space Data Systems (CCSDS) recommendations, European Cooperation on Space Standardization (ECSS) and the European Space Agency (ESA) Procedures, Standards and Specifications (PSS) for telemetry and channel coding. The Telemetry Encoder comprises the following:

- Packet Telemetry and/or Advanced Orbiting Systems (AOS) Encoder
- Reed-Solomon Encoder
- Turbo Encoder (future option)
- Pseudo-Randomiser (PSR)
- Non-Return-to-Zero Mark encoder (NRZ)
- Convolutional Encoder (CE)
- Split-Phase Level modulator (SP)
- Sub-Carrier modulator (SC)
- Clock Divider (CD)

134.3 Layers

134.3.1 Introduction

The Packet Telemetry (or simply Telemetry or TM) and Advanced Orbiting System (AOS) standards are similar in their format, with only some minor variations. The AOS part covered here is the downlink or transmitter, not the uplink or receiver.

The relationship between these standards and the Open Systems Interconnection (OSI) reference model is such that the OSI Data Link Layer corresponds to two separate layer, namely the Data Link Protocol Sub-layer and Synchronization and Channel Coding Sub-Layer. The OSI Data Link Layer is covered here.

The OSI Physical Layer is also covered here to some extended, as specified in [ECSS-E-ST-50-05C] and [PSS-04-105].

The OSI Network Layer or higher layers are not covered here.

134.3.2 Data Link Protocol Sub-layer

The Data Link Protocol Sub-layer differs somewhat between TM and AOS. Differences are pointed out where needed in the subsequent descriptions.

The following functionality is not implemented in the core:

• Packet Processing

• Bitstream Processing (applies to AOS only)

The following functionality is implemented in the core:

• Virtual Channel Generation (for Idle Frame generation only)

• Virtual Channel Multiplexing (for Idle Frame generation only)

• Master Channel Generation (applies to Packet Telemetry only)

• Master Channel Multiplexing (including Idle Frame generation)

• All Frame Generation

134.3.3 Synchronization and Channel Coding Sub-Layer

The Synchronization and Channel Coding Sub-Layer does not differ between TM and AOS.

The following functionality is implemented in the core:

• Attached Synchronization Marker

• Reed-Solomon coding

• Turbo coding (future option)

• Pseudo-Randomiser

• Convolutional coding

134.3.4 Physical Layer

The Physical Layer does not differ between TM and AOS.

The following functionality is implemented in the core:

• Non-Return-to-Zero modulation

• Split-Phase modulation

• Sub-Carrier modulation

134.4 Data Link Protocol Sub-Layer

134.4.1 Physical Channel

The configuration of a Physical Channel covers the following parameters:

- Transfer Frame Length (in number of octets)
- Transfer Frame Version Number

Note that there are other parameters that need to be configured for a Physical Channel, as listed in section 134.4.8, covering the All Frame Generation functionality.

The Transfer Frame Length can be programmed by means of the DMA length register.

The Transfer Frame Version Number can be programmed by means of a register, and can take one of two legal values: 00b for Telemetry and 01b for AOS.

134.4.2 Virtual Channel Frame Service

The Virtual Channel Frame Service is implemented by means of a DMA interface, providing the user with a means for inserting Transfer Frames into the Telemetry Encoder. Transfer Frames are automatically fetched from memory, for which the user configures a descriptor table with descriptors that point to each individual Transfer Frame. For each individual Transfer Frame the descriptor also provides means for bypassing functions in the Telemetry Encoder. This includes the following:

- Virtual Channel Counter generation can be enabled in the Virtual Channel Generation function (this function is normally only used for Idle Frame generation but can be used for the Virtual Channel Frame Service when sharing a Virtual Channel)
- Master Channel Counter generation can be bypassed in the Master Channel Generation function (TM only)
- Frame Secondary Header (FSH) generation can be bypassed in the Master Channel Generation function (TM only)
- Operational Control Field (OCF) generation can be bypassed in the Master Channel Generation function (TM only)
- Frame Error Header Control (FECH) generation can be bypassed in the All Frame Generation function (AOS only)
- Insert Zone (IZ) generation can be bypassed in the All Frame Generation function (AOS only)
- Frame Error Control Field (FECF) generation can be bypassed in the All Frame Generation function
- A Time Strobe can be generated for the Transfer Frame.

Note that the above features can only be bypassed for each Transfer Frame, the overall enabling of the features is done for the corresponding functions in the Telemetry Encoder, as described in the subsequent sections.

The detailed operation of the DMA interface is described in section 134.8.

134.4.3 Virtual Channel Generation

The Virtual Channel Generation function is used to generate the Virtual Channel Counter for Idle Frames as described hereafter. The function can however also be enabled for any Transfer Frame inserted via the Virtual Channel Frame Service described above, allowing a Virtual Channel to be shared between the two services. In this case the Virtual Channel Counter, the Extended Virtual Channel Counter (only for TM, as defined for ECSS and PSS, including the complete Transfer Frame Secondary Header) and the Virtual Channel Counter Cycle (only for AOS) fields will be inserted and incremented automatically when enabled as described hereafter.

GRIP

2055

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

134.4.4 Virtual Channel Multiplexing

The Virtual Channel Multiplexing Function is used to multiplex Transfer Frames of different Virtual Channels of a Master Channel. Virtual Channel Multiplexing in the core is performed between two sources: Transfer Frames provided through the Virtual Channel Frame Service and Idle Frames. Note that multiplexing between different Virtual Channels is assumed to be done as part of the Virtual Channel Frame Service outside the core.

The Virtual Channel Frame Service user interface is described above. The Idle Frame generation is described hereafter.

Idle Frame generation can be enabled and disabled by means of a register. The Spacecraft ID to be used for Idle Frames is programmable by means of a register. The Virtual Channel ID to be used for Idle Frames is programmable by means of a register.

Master Channel Counter generation for Idle Frames can be enabled and disabled by means of a register (only for TM). Note that it is also possible to generate the Master Channel Counter field as part of the Master Channel Generation function described in the next section. When Master Channel Counter generation is enabled for Idle Frames, then the generation in the Master Channel Generation function is bypassed.

The Virtual Channel Counter generation for Idle Frames is always enabled (both for TM and AOS) and generated in the Virtual Channel Generation function described above.

Extended Virtual Channel Counter generation for Idle Frames can be enabled and disabled by means of a register (only for TM, as defined for ECSS and PSS). This includes the complete Transfer Frame Secondary Header.

Virtual Channel Counter Cycle generation for Idle Frames can be enabled and disabled by means of a register (only for AOS).

If Frame Secondary Header generation is enabled in the Master Channel Generation function described in the next section, it can be bypassed for Idle Frames, programmable by means of a register. This allows VC_FSH or MC_FSH realization.

If Operation Control Field generation is enabled in the Master Channel Generation function described in the next section, it can be bypassed for Idle Frames, programmable by means of a register. This allows VC_OCF or MC_OCF realization.

134.4.5 Master Channel Generation

The Master Channel Counter can be generated for all frames on a master channel (only for TM). It can be can be enabled and disabled by means of a register. The generation can also be bypassed for Idle Frames or Transfer Frames provided via the DMA interface.

The Frame Secondary Header (FSH) can be generated from a 128-bit register (only for TM). This can be done for all frames on an master channel (MC_FSH) or be bypassed for Idle Frames or Transfer Frames provided via the DMA interface, effectively implementing FSH on a per virtual channel basis (VC_FSH). The FSH length is programmable by means of a register.

The Operational Control Field (OCF) can be generated from a 32-bit register. This can be done for all frames on an master channel (MC_OCF) or be bypassed for Idle Frames or Transfer Frames provided via the DMA interface, effectively implementing OCF on a per virtual channel basis (VC_OCF).

134.4.6 Master Channel Frame Service

The Master Channel Frame Service user interface is equivalent to the previously described Virtual Channel Frame Service user interface, using the same DMA interface. The interface can thus be used for inserting both Master Channel Transfer Frame and Virtual Channel Transfer Frames.

134.4.7 Master Channel Multiplexing

The Master Channel Multiplexing Function is used to multiplex Transfer Frames of different Master Channels of a Physical Channel. Master Channel Multiplexing is performed between three sources: Master Channel Generation Service, Master Channel Frame Service and Idle Frames.

Bypassing all the functionality of the Master Channel Generation functionality described above effectively establishes the master channel frame service. The same holds for the Idle Frame generation described above, allowing the core to generate Idle Frame on the level of the Physical Channel.

134.4.8 All Frame Generation

The All Frame Generation functionality operates on all transfer frames of a Physical Channel. Each of the individual functions can be bypassed for each frame coming from the DMA interface or idle frame generation functionality.

The Frame Header Error Control (FHEC) generation can be enabled and disabled by means of a register (AOS only).

The Insert Zone can be generated from a 128-bit register (only for AOS). This can be done for all frames on an physical channel (MC_FSH) or be bypassed for Idle Frames or Transfer Frames provided via the DMA interface. The Insert Zone length is programmable by means of a register. Note that the Insert Zone and Frame Secondary Header functionality share the same resources, since they cannot be used simultaneously for a Physical Channel.

Frame Error Control Field (FECF) generation can be enabled and disabled by means of a register.

134.5 Synchronization and Channel Coding Sub-Layer

134.5.1 Attached Synchronization Marker

The 32-bit Attached Synchronization Marker is placed in front of each Transfer Frame as per [CCSDS-131.0-B-2] and [ECSS-E-ST-50-03C].

An alternative Attached Synchronization Marker for embedded data streams can also be used, its enabling and bit pattern being programmable via a configuration register.

134.5.2 Reed-Solomon Encoder

The CCSDS recommendation [CCSDS-131.0-B-2] and ECSS standard [ECSS-E-ST-50-03C] specify Reed-Solomon codes, one (255, 223) code and one (255, 239) code. The ESA PSS standard [PSS013] only specifies the former code. Although the definition style differs between the documents, the (255, 223) code is the same in all three documents. The definition used in this document is based on the PSS standard [PSS013].

The Reed-Solomon Encoder implements both codes.

The Reed-Solomon encoder is compliant with the coding algorithms in [CCSDS-131.0-B-2] and [ECSS-E-ST-50-03C]:

- there are 8 bits per symbol;
- there are 255 symbols per codeword;
- the encoding is systematic:
- for E=8 or (255, 239), the first 239 symbols transmitted are information symbols, and the last 16 symbols transmitted are check symbols;
- for E=16 or (255, 223), the first 223 symbols transmitted are information symbols, and the last 32 symbols transmitted are check symbols;
- the E=8 code can correct up to 8 symbol errors per codeword;

GRIP

+46 31 7758650 | frontgrade.com/gaisler

- the E=16 code can correct up to 16 symbol errors per codeword;

- the field polynomial is

$$f_{esa}(x) = x^8 + x^6 + x^4 + x^3 + x^2 + x + 1$$

- the code generator polynomial for E=8 is

$$g_{esa}(x) = \prod_{i=120}^{135} (x + \alpha^i) = \sum_{j=0}^{16} g_j \cdot x^j$$

for which the highest power of x is transmitted first;

- the code generator polynomial for E=16 is

$$g_{esa}(x) = \prod_{i=112}^{143} (x + \alpha^i) = \sum_{j=0}^{32} g_j \cdot x^j$$

for which the highest power of x is transmitted first;

- interleaving is supported for depth $I = \{1 \text{ to } 8\}$, where information symbols are encoded as I codewords with symbol numbers $i + j*I$ belonging to codeword i {where $0 \le i < I$ and $0 \le j < 255$};

- shortened codeword lengths are supported;

- the input and output data from the encoder are in the representation specified by the following transformation matrix T_{esa}, where i_0 is transferred first

$$\begin{bmatrix} \iota_0 & \iota_1 & \iota_2 & \iota_3 & \iota_4 & \iota_5 & \iota_6 & \iota_7 \end{bmatrix} = \begin{bmatrix} \alpha_7 & \alpha_6 & \alpha_5 & \alpha_4 & \alpha_3 & \alpha_2 & \alpha_1 & \alpha_0 \end{bmatrix} \times \begin{bmatrix} 0 & 0 & 1 & 1 & 0 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 & 1 & 1 \\ 0 & 1 & 1 & 1 & 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 1 & 1 & 0 & 1 & 1 \end{bmatrix}$$

- the following matrix T^{-1}_{esa} specifying the reverse transformation

$$\begin{bmatrix} \alpha_7 & \alpha_6 & \alpha_5 & \alpha_4 & \alpha_3 & \alpha_2 & \alpha_1 & \alpha_0 \end{bmatrix} = \begin{bmatrix} \iota_0 & \iota_1 & \iota_2 & \iota_3 & \iota_4 & \iota_5 & \iota_6 & \iota_7 \end{bmatrix} \times \begin{bmatrix} 1 & 1 & 1 & 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \end{bmatrix}$$

- the Reed-Solomon output is non-return-to-zero level encoded.

The Reed-Solomon Encoder encodes a bit stream from preceding encoders and the resulting symbol stream is output to subsequent encoder and modulators. The encoder generates codeblocks by receiving information symbols from the preceding encoders which are transmitted unmodified while calculating the corresponding check symbols which in turn are transmitted after the information symbols. The check symbol calculation is disabled during reception and transmission of unmodified data not

GRIP

2058
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

related to the encoding. The calculation is independent of any previous codeblock and is perform correctly on the reception of the first information symbol after a reset.

Each information symbol corresponds to an 8 bit symbol. The symbol is fed to a binary network in which parallel multiplication with the coefficients of a generator polynomial is performed. The products are added to the values contained in the check symbol memory and the sum is then fed back to the check symbol memory while shifted one step. This addition is performed octet wise per symbol. This cycle is repeated until all information symbols have been received. The contents of the check symbol memory are then output from the encoder. The encoder is based on a parallel architecture, including parallel multiplier and adder.

The encoder can be configured at compile time to support only the E=16 (255, 223) code, only the E=8 (255, 239) code, or both. This is done with the *reed* VHDL generic. Only the selected coding schemes are implemented. The choice between the E=16 and E=8 coding can be performed during operation by means of a configuration register.

The maximum number of supported interleave depths I_{max} is selected at compile time with the *reed-depth* VHDL generic, the range being 1 to 8. For a specific instantiation of the encoder, the choice of any interleave depth ranging from 1 to the chosen I_{max} is supported during operation. The area of the encoder is minimized, i.e. logic required for a greater interleave depth than I_{max} is not unnecessarily included.

The interleave depth is chosen during operation by means of a configuration register.

134.5.3 Pseudo-Randomiser

The Pseudo-Randomiser (PSR) generates a bit sequence according to [CCSDS-131.0-B-2] and [ECSS-E-ST-50-03C] which is xor-ed with the data output of preceding encoders. This function allows the required bit transition density to be obtained on a channel in order to permit the receiver on ground to maintain bit synchronization.

The polynomial for the Pseudo-Randomiser is $h(x) = x^8 + x^7 + x^5 + x^3 + 1$ and is implemented as a Fibonacci version (many-to-one implementation) of a Linear Feedback Shift Register (LFSR). The registers of the LFSR are initialized to all ones between Transfer Frames. The Attached Synchronization Marker (ASM) is not effected by the encoding.
Figure 331. Pseudo-randomiser

134.5.4 Convolutional Encoder

The Convolutional Encoder (CE) implements two convolutional encoding schemes. The ESA PSS standard [PSS-04-103] specifies a basic convolutional code without puncturing. This basic convolutional code is also specified in the CCSDS recommendation [CCSDS-131.0-B-2] and ECSS standard [ECSS-E-ST-50-03C], which in addition specifies a punctured convolutional code.

The basic convolutional code has a code rate of 1/2, a constraint length of 7, and the connection vectors G1 = 1111001_b (171 octal) and G2 = 1011011_b (133 octal) with symbol inversion on output path, where G1 is associated with the first symbol output.

The punctured convolutional code has a code rate of 1/2 which is punctured to 2/3, 3/4, 5/6 or 7/8, a constraint length of 7, and the connection vectors G1 = 1111001_b (171 octal) and G2 = 1011011_b (133 octal) without any symbol inversion. The puncturing and output sequences are defined in [CCSDS-

131.0-B-2]. The encoder also supports rate 1/2 unpunctured coding with aforementioned connection vectors and no symbol inversion.
Figure 332. Unpuctured convolutional encoder
Figure 333. Punctured convolutional encoder

134.6 Physical Layer

134.6.1 Non-Return-to-Zero Mark encoder

The Non-Return-to-Zero Mark encoder (NRZ) encodes differentially a bit stream from preceding encoders according to [ECSS-E-ST-50-05C]. The waveform is shown in figure 334

Both data and the Attached Synchronization Marker (ASM) are affected by the coding. When the encoder is not enabled, the bit stream is by default non-return-to-zero level encoded.
Figure 334. NRZ-L and NRZ-M waveform

134.6.2 Split-Phase Level modulator

The Split-Phase Level modulator (SP) modulates a bit stream (output symbols) from preceding encoders according (input symbols) to [ECSS-E-ST-50-05C]. The waveform is shown in figure 335.

Both data and the Attached Synchronization Marker (ASM) are effected by the modulator. The modulator will increase the output bit rate with a factor of two.

Figure 335. SP-L waveform

134.6.3 Sub-Carrier modulator

The Sub-Carrier modulator (SC) modulates a bit stream (output symbols) from preceding encoders according (input symbols) to [ECSS-E-ST-50-05C], which is Binary Phase Shift Key modulation (BPSK) or Phase Shift Key Square.

The sub-carrier modulation frequency is programmable. The symbol rate clock be divided to a degree 2^{15}. The divider can be configured during operation to divide the symbol rate clock frequency from $1/2$ to $1/2^{15}$. The phase of the sub-carrier is programmable, selecting which phase 0º or 180º should correspond to a logical one on the input.

134.6.4 Clock Divider

The Clock Divider (CD) provides clock enable signals for the telemetry and channel encoding chain. The clock enable signals are used for controlling the bit rates of the different encoder and modulators.

The source for the bit rate frequency is the dedicated bit rate clock input. The bit rate clock input can be divided to a degree 2^{15}. The divider can be configured during operation to divide the bit rate clock frequency from $1/1$ to $1/2^{15}$. In addition, the Sub-Carrier modulator can divide the above resulting clock frequency from $1/2$ to $1/2^{15}$. The divider in the sub-carrier modulator can be used without enabling actual sub-carrier modulation, allowing division up to $1/2^{30}$.

The bit rate frequency is based on the output frequency of the last encoder in a coding chain, except for the sub-carrier modulator. No actual clock division is performed, since clock enable signals are used. No clock multiplexing is performed in the core.

The Clock Divider (CD) supports clock rate increases for the following encoders and rates:

*   Convolutional Encoder (CE), 1/2, 2/3, 3/4, 5/6 and 7/8;

*   Split-Phase Level modulator (SP-L), rate 1/2;

*   Sub-Carrier modulator (SC), rate 1/2 to $1/2^{15}$.

The resulting symbol rate and telemetry rate are depended on what encoders and modulators are enabled. The following variables are used in the tables hereafter: f = input bit frequency, n = SYMBOLRATE+1 (GRTM physical layer register field +1), and m = SUBRATE+1 (physical layer register field +1), c = convolutional coding rate {1/2, 2/3, 3/4, 5/6, 7/8} (see CERATE field in GRTM coding sub-layer register).

Table 2347. Data rates without sub-carrier modulation (SUB=0)

Coding & Modulation	Telemetry rate	Convolutional rate	Split-Phase rate	Sub-carrier frequency	Output symbol rate	Output clock frequency
-	f / n / m	-	-	-	f / n / m	f / n / m
CE	(f / n / m) * c	f / n / m	-	-	f / n / m	f / n / m
SP-L	f / n / m / 2	-	f / n / m	-	f / n / m	f / n / m
CE + SP-L	(f / n / m / 2) * c	f / n / m / 2	f / n / m	-	f / n / m	f / n / m
For n = 1, no output symbol clock is generated, i.e. SYMBOLRATE register field equals 0. m should be an even number, i.e. SUBRATE register field should be uneven and > 0 to generate an output symbol clock with 50% duty cycle. If m > 1 then also n must be > 1, i.e. if SUBRATE register field is > 0 then SYMBOLRATE register field must be > 0.

Table 2348. Data rates with sub-carrier modulation (SUB=1)

Coding & Modulation	Telemetry rate	Convolutional rate	Split-Phase rate	Sub-carrier frequency	Output symbol rate [1]	Output clock frequency
SC	f / n / m	-	-	f / n / 2	f / n	f / n
CE + SC	(f / n / m) * c	f / n / m	-	f / n / 2	f / n	f / n
SP-L+ SC	f / n / m / 2	-	f / n / m	f / n / 2	f / n	f / n
CE + SP-L + SC	(f / n / m / 2) * c	f / n / m / 2	f / n / m	f / n / 2	f / n	f / n

n = 1 or m = 1 are invalid settings for sub-carrier modulation, i.e SYMBOLRATE and SUBRATE register fields must be > 0.
m must be an even number, i.e. SUBRATE register field must be uneven and > 0.
m defines number of sub-carrier phases per input bit from preceding encoder or modulator.
Note 1: The output symbol rate for sub-carrier modulation corresponds to the rate of phases, not the frequency. Sub-carrier frequency is half the symbol rate.

134.7 Connectivity

The output from the Packet Telemetry and AOS encoder can be connected to:

•   Reed-Solomon encoder

•   Pseudo-Randomiser

•   Non-Return-to-Zero Mark encoder

•   Convolutional encoder

•   Split-Phase Level modulator

•   Sub-Carrier modulator

The input to the Reed-Solomon encoder can be connected to:

•   Packet Telemetry and AOS encoder

The output from the Reed-Solomon encoder can be connected to:

•   Pseudo-Randomiser

The input to the Split-Phase Level modulator (SP) can be connected to:

- Packet Telemetry and AOS encoder
- Reed-Solomon encoder
- Pseudo-Randomiser
- Non-Return-to-Zero Mark encoder
- Convolutional encoder

The output from the Split-Phase Level modulator (SP) can be connected to:

- Sub-Carrier modulator

The input to the Sub-Carrier modulator (SC) can be connected to:

- Packet Telemetry and AOS encoder
- Reed-Solomon encoder
- Pseudo-Randomiser
- Non-Return-to-Zero Mark encode
- Convolutional encoder
- Split-Phase Level modulator

134.8 Operation

134.8.1 Introduction

The DMA interface provides a means for the user to insert Transfer Frames in the Packet Telemetry and AOS Encoder. Depending on which functions are enabled in the encoder, the various fields of the Transfer Frame are overwritten by the encoder. It is also possible to bypass some of these functions for each Transfer Frame by means of the control bits in the descriptor associated to each Transfer Frame. The DMA interface allows the implementation of Virtual Channel Frame Service and Master Channel Frame Service, or a mixture of both, depending on what functions are enabled or bypassed.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

134.8.2 Descriptor setup

The transmitter DMA interface is used for transmitting transfer frames on the downlink. The transmission is done using descriptors located in memory.

A single descriptor is shown in table 2349 and 2350. The number of bytes to be sent is set globally for all transfer frames in the length field in register DMA length register. The address field of the descriptor should point to the start of the transfer frame. The address must be word-aligned. If the interrupt enable (IE) bit is set, an interrupt will be generated when the transfer frame has been sent (this requires that the transmitter interrupt enable bit in the control register is also set). The interrupt will be generated regardless of whether the transfer frame was transmitted successfully or not. The wrap (WR) bit is also a control bit that should be set before transmission and it will be explained later in this section.

*Table 2349.*GRTM transmit descriptor word 0 (address offset 0x0)

31 16	15	14	13 10	9	8	7	6	5	4	3	2	1	0
RESERVED	UE	TS	0000	VCE	MCB	FSHB	OCFB	FHECB	IZB	FECFB	IE	WR	EN

31: 16	RESERVED
15	Underrun Error (UE) - underrun occurred while transmitting frame (status bit only)
14	Time Strobe (TS) - generate a time strobe for this frame
13: 10	RESERVED
9	Virtual Channel Counter Enable (VCE) - enable virtual channel counter generation (using the Idle Frame virtual channel counter)
8	Master Channel Counter Bypass (MCB) - bypass master channel counter generation (TM only)
7	Frame Secondary Header Bypass (FSHB) - bypass frame secondary header generation (TM only)
6	Operational Control Field Bypass (OCFB) - bypass operational control field generation
5	Frame Error Header Control Bypass (FECHB) - bypass frame error header control generation (AOS)
4	Insert Zone Bypass (IZB) - bypass insert zone generation (AOS)
3	Frame Error Control Field Bypass (FECFB) - bypass frame error control field generation
2	Interrupt Enable (IE) - an interrupt will be generated when the frame from this descriptor has been sent provided that the transmitter interrupt enable bit in the control register is set. The interrupt is generated regardless if the frame was transmitted successfully or if it terminated with an error.
1	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 8. The pointer automatically wraps to zero when the 1 kB boundary of the descriptor table is reached.
0	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.

*Table 2350.*GRTM transmit descriptor word 1 (address offset 0x4)

31 2	1 0
ADDRESS	RES

31: 2	Address (ADDRESS) - Pointer to the buffer area from where the packet data will be loaded.
1: 0	RESERVED

To enable a descriptor the enable (EN) bit should be set and after this is done, the descriptor should not be touched until the enable bit has been cleared by the core.

134.8.3 Starting transmissions

Enabling a descriptor is not enough to start a transmission. A pointer to the memory area holding the descriptors must first be set in the core. This is done in the transmitter descriptor pointer register. The address must be aligned to a 1 kByte boundary. Bits 31 to 10 hold the base address of descriptor area while bits 9 to 3 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the core, the pointer field is incremented by 8 to point at

GRIP
Apr 2024, Version 2024.1

2064

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

the next descriptor. The pointer will automatically wrap back to zero when the next 1 kByte boundary has been reached (the descriptor at address offset 0x3F8 has been used). The WR bit in the descriptors can be set to make the pointer wrap back to zero before the 1 kByte boundary.

The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when a transmission is active.

The final step to activate the transmission is to set the transmit enable bit in the DMA control register. This tells the core that there are more active descriptors in the descriptor table. This bit should always be set when new descriptors are enabled, even if transmissions are already active. The descriptors must always be enabled before the transmit enable bit is set.

If external virtual channel generation is enabled the descriptors for this function are read from the area starting at the address defined by the externaladdr VHDL generic.

134.8.4 Descriptor handling after transmission

When a transmission of a frame has finished, status is written to the first word in the corresponding descriptor. The Underrun Error bit is set if the FIFO became empty before the frame was completely transmitted. The other bits in the first descriptor word are set to zero after transmission while the second word is left untouched. The enable bit should be used as the indicator when a descriptor can be used again, which is when it has been cleared by the core.

There are multiple bits in the DMA status register that hold transmission status.

The Transmitter Interrupt (TI) bit is set each time a DMA transmission of a transfer frame ended successfully. The Transmitter Error (TE) bit is set each time an DMA transmission of a transfer frame ended with an underrun error. For either event, an interrupt is generated for transfer frames for which the Interrupt Enable (IE) was set in the descriptor. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

The Transmitter AMBA error (TA) bit is set when an AMBA AHB error was encountered either when reading a descriptor or when reading transfer frame data. Any active transmissions were aborted and the DMA channel was disabled. It is recommended that the Telemetry Encoder is reset after an AMBA AHB error. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

The Transfer Frame Sent (TFS) bit is set whenever a transfer frame has been sent, independently if it was sent via the DMA interface or generated by the core. The interrupt is maskable with the Transfer Frame Interrupt Enable (TFIE) bit in the control register.

The Transfer Frame Failure (TFF) bit is set whenever a transfer frame has failed for other reasons, such as when Idle Frame generation is not enabled and no user Transfer Frame is ready for transmission, independently if it was sent via the DMA interface or generated by the core. The interrupt is maskable with the Transfer Frame Interrupt Enable (TFIE) bit in the control register.

The Transfer Frame Ongoing (TFO) bit is set when DMA transfers are enabled, and is not cleared until all DMA induced transfer frames have been transmitted after DMA transfers are disabled.

134.8.5 Interrupts

The Transfer Frame Sent (TFS) and Transfer Frame Failure (TFF) interrupts are maskable with the Transfer Frame Interrupt Enable (TFIE) bit in the DMA control register, and can be observed via the DMA status register.

The Transmitter Interrupt (TI), Transmitter Error (TE) and Transmitter AMBA Error (TA) interrupts are maskable with the Interrupt Enable (IE) bit in the DMA control register, and can be observed via the DMA status register.

The Time Strobe Interrupt (TSI) is maskable with the Transfer Frame Interrupt Enable (TFIE) bit in the DMA control register.

135   GRTM_DESC - CCSDS/ECSS Telemetry Encoder - Descriptor

This IP core is only available as part of a design service.

135.1   Overview

The CCSDS/ECSS/PSS Telemetry Encoder Descriptor implements an automatic descriptor handler for external Telemetry Virtual Channels implemented in hardware (Telemetry Encoder Virtual Channel Generation function), not requiring software support.

135.2   Operation

135.2.1 Introduction

Warning: software should not read or write the descriptor table. All interaction is performed automatically by hardware.

The bandwidth is allocated equally between the external Telemetry Virtual Channels. Note that the descriptor table will be continuously checked by the Telemetry Encoder, even when all descriptors have their Enable (EN) bit cleared. This will go on until the External Enable (XEN) bit in the Telemetry Encoder is cleared by software.

135.2.2 Descriptor definition

A single descriptor is shown in table 2378 and 2379.

Table 2378. Transmit descriptor word 0 (address offset 0x0)

31	16	15	14	13 10	9	8	7	6	5	4	3	2	1	0

8	Master Channel Counter Bypass (MCB) - bypass master channel counter generation (TM only) (static 0)
7	Frame Secondary Header Bypass (FSHB) - bypass frame secondary header generation (TM only) (static 0)
6	Operational Control Field Bypass (OCFB) - bypass operational control field generation (static 0)
5	Frame Error Header Control Bypass (FECHB) - bypass frame error header control generation (AOS) (static 0)
4	Insert Zone Bypass (IZB) - bypass insert zone generation (AOS) (static 0)
3	Frame Error Control Field Bypass (FECFB) - bypass frame error control field generation (static 0)
2	Interrupt Enable (IE) - an interrupt will be generated when the frame from this descriptor has been sent provided that the transmitter interrupt enable bit in the control register is set. (static 0)
1	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 8. The pointer automatically wraps to zero when the 1 kB boundary of the descriptor table is reached. (Set to 1 for last descriptor entry, otherwise static 0).
0	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields. (Automatically set an cleared by hardware)

31	2	1	0
ADDRESS		RES	

31: 2	Address (ADDRESS) - Pointer to the buffer area from where the packet data will be loaded.
1: 0	RESERVED

135.3 Registers

The core does not implement any memory mapped registers.

135.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x084. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

135.5 Implementation

135.5.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

135.6 Configuration options

Table 2380 shows the configuration options of the core (VHDL generics).

Table 2380. Configuration options

Generic name	Function	Allowed range	Default
hindex	Selects which AHB select signal (HSEL) will be used to access the memory.	0 to NAHBMAX-1	0

136   GRTM_VC - CCSDS/ECSS Telemetry Encoder - Virtual Channel Generation

This IP core is only available as part of a design service.

136.1   Overview

The CCSDS/ECSS/PSS Telemetry Encoder Virtual Channel Generation function implements:

- Transfer Frame Primary Header insertion
- Transfer Frame Data Field insertion (with support for different lengths due to OCF and FECF)
- First Header Pointer (FHP) handling and insertion

The function keeps track of the number of octets received and the packet boundaries in order to calculated the First Header Pointer (FHP). The data are stored in pre-allocated slots in the buffer memory comprising complete Transfer Frames. The module fully supports the FHP generation and does not require any alignment of the packets with the Transfer Frame Data Field boundary.

The data input format can be CCSDS Space Packet [CCSDS-133.0-B-1] or any user-defined datablock. Data is input via a separate Virtual Channel Generation function input interface.

The function communicates with the Telemetry Encoder Virtual Channel Frame Service by means of a buffer memory space. The buffer memory space allocated to the Virtual Channel is treated as a circular buffer. The buffer memory space is accessed by means of a AMBA AHB master interface.

136.2   Registers

The core does not implement any memory mapped registers.

136.3   Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x085. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

136.4   Implementation

136.4.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

137   GRTM_PAHB - CCSDS/ECSS Telemetry Encoder - Virtual Channel Generation Input - AMBA

This IP core is only available as part of a design service.

137.1   Overview

The Telemetry Encoder Virtual Channel Generation function input interface implements an interfaces towards the automatic Virtual Channel Generation function of the Telemetry Encoder (also called external Virtual Channels). Space Packets or any other user-defined data block can be input.

Data is transferred to the Virtual Channel Generation function by writing to the AMBA AHB slave interface, located in the AHB I/O area. Writing is only possible when the packet valid delimiter is asserted, else the access results in an AMBA access error. It is possible to transfer one, two or four bytes at a time, following the AMBA big-endian convention regarding send order. The last written data can be read back via the AMBA AHB slave interface. Data are output as octets to the Virtual Channel Generation function.

In the case the data from a previous write access has not been fully transferred over the interface, a new write access will result in an AMBA retry response. The progress of the interface can be monitored via the AMBA APB slave interface. An interrupt is generated when the data from the last write access has been transferred. An interrupt is also generated when the ready for input packet indicator is asserted.

The core incorporates status and monitoring functions accessible via the AMBA APB slave interface. This includes:

*   Busy and ready signaling from Virtual Channel Generation function

*   Interrupts on ready for new word, or ready for new packet (size 518 octets (set with *roomsize* VHDL generic))

137.2   Interrupts

Two interrupts are implemented by the interface:

Index:	Name:	Description:
0	NOT BUSY	Ready for a new data (word, half-word or byte)
1	READY	Ready for new packet

The interrupts are configured by means of the *pirq* VHDL generic.

137.3   Registers

The core is programmed through registers mapped into APB address space.

Table 2386. GRTM_PAHB registers

r		rw	rw	r		rw*	rw	rw

8: BUSYEN
9: READYENEnable ready for packet interrupt when 1
2: VALID Packet valid delimiter, packet valid when 1, in-between packets when 0 (read-only)
1: RST Reset complete core when 1
0: EN Enable interface when 1

All bits are cleared to 0 at reset. Note that RST is read back as 0.

137.4 AHB I/O area

Data to be transferred to the Virtual Channel Generation function is written to the AMBA AHB slave interface which implements a AHB I/O area. See [GRLIB] for details.

Note that the address is not decoded by the core. Address decoding is only done by the AMBA AHB controller, for which the I/O area location and size is configured by means of the *ioaddr* and *iomask* VHDL generics. It is possible to transfer one, two or four bytes at a time, following the AMBA big-endian convention regarding send order. The last written data can be read back via the AMBA AHB slave interface. Data are output as octets on the Virtual Channel Generation interface.

138 GRTM_PW - CCSDS/ECSS Telemetry Encoder - Virtual Channel Generation Input - PacketWire

This IP core is only available as part of a design service.

The PacketWire (PW) interface to a telemetry encoder is a simple bit synchronous protocol. There is one PacketWire interface for each telemetry Virtual Channel.

The data can be any CCSDS supported packets. The interface comprises three input signals; bit data, bit clock and packet delimiter. There is an additional discrete signal provided for busy signalling.

Data should consist of multiples of eight bits otherwise the last bits will be lost. The input packet delimiter signal is used to delimit packets. It should be asserted while a packet is being input, and de-asserted in between. In addition, the input packet delimiter signal should define the octet boundaries in the input data stream, the first octet explicitly and the following octets each subsequent eight bit clock cycles.

The interface is based on the de facto standard PacketWire interface used by the *European Space Agency* (ESA). At the time of writing there were no relevant documents available from the *European Cooperation for Space Standardization* (ECSS).

138.1 Operation

The PacketWire interface accepts and generates the waveform format shown in figure 337.
Figure 337. Synchronous bit serial waveform

The PacketWire protocol follows the CCSDS transmission convention, the most significant bit being sent first. Transmitted data should consist of multiples of eight bits otherwise the last bits will be lost. The input message delimiter port is used to delimit messages (packets). It should be asserted while a message is being input, and deasserted in between. In addition, the message delimiter port should define the octet boundaries in the data stream, the first octet explicitly and the following octets each subsequent eight bit clock cycles.

The maximum receiving input baud rate is defined as half the frequency of the system clock input. There is no lower limit for the input bit rate in the receiver.

The handshaking between the PacketWire links and the interface is implemented with a busy port. When a message is sent, the busy signal on the PacketWire input link will be asserted as soon as the input interface is not ready to receive more data, it will then be deasserted as soon as the interface is ready to receive the next octet. This gives the transmitter ample time to stop transmitting after the completion of an octet and wait for the busy signal deassertion before starting the transmission of the next octet. The handshaking is continued through out the message.

139   GRTM_UART - CCSDS/ECSS Telemetry Encoder - Virtual Channel Generation Input - UART

This IP core is only available as part of a design service.

The PacketAsynchronous (PA) interface to a telemetry encoder is a simple bit asynchronous protocol. There can be one bit asynchronous interface per telemetry Virtual Channel.

The protocol has a fixed or programmable baud rate, 1 start bit, 8 data bits, optional odd parity, 1 or 2 stop bits, with a BREAK command for message delimiting (sending 13 bits of logical zero).

The data can be any CCSDS supported packet. The interface comprises one input signal with bit asynchronous data. There are two additional discrete signals provided for busy signalling.

139.1   Asynchronous bit serial data format

The asynchronous bit serial interface complies to the data format defined in [EIA 232]. It also complies to the data format and waveform shown in table 2396 and figure 339. The interface is independent of the transmitted data contents. Positive logic is considered for the data bits. The number of stop bits can optionally be either one or two. The parity bit can be optionally included.

Asynchronous bit serial format	start	D0	D1	D2	D3	D4	D5	D6	D7	parity	stop	stop
first		*lsb*							*msb*			*last*
General data format $i = \{0, n\}$		$8*i+7$	$8*i+6$	$8*i+5$	$8*i+4$	$8*i+3$	$8*i+2$	$8*i+1$	$8*i$			
		last							*first*			

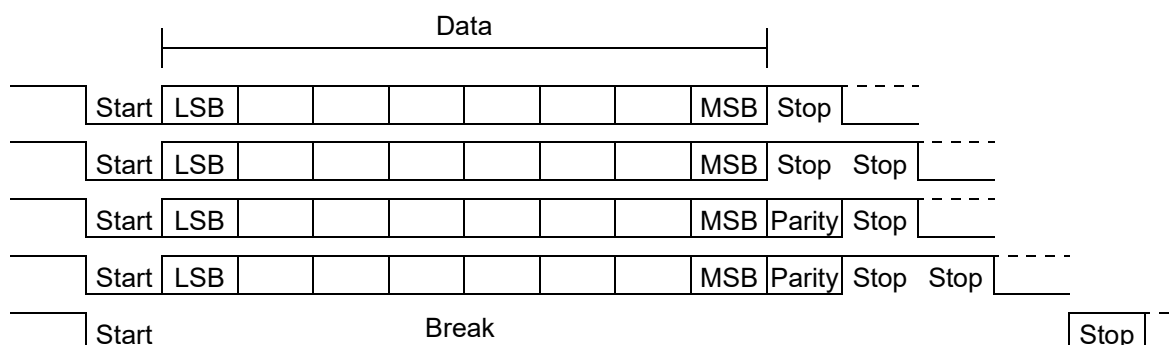
Table 2396. Asynchronous bit serial data format


Figure 339. Asynchronous bit serial protocol / waveform

The handshaking for the bit asynchronous links is implemented with a busy signal. When a message is sent, the busy signal on the input link will be asserted as soon as the input interface is not ready to receive more data, it will then be deasserted as soon as the interface is ready to receive the next octet. The handshaking is continued through out the packet.

139.2   Registers

The core has not user accessible registers.

139.3   Vendor and device identifiers

The core has has neither a vendor identifier nor a device identifier.

140   GEFFE - CCSDS/ECSS Telemetry Encoder - Geffe Generator

This IP core is only available as part of a design service.

140.1   Overview

The Geffe Generator implements a simple stream based cipher to encrypt Telemetry Transfer Frames.

The Geffe generator acts as a keystream generator. It uses three Linear Feed-back Shift Registers (LFSR) combined in a nonlinear manner. Two of the LFSRs (LFSR1 and LFSR2) are inputs into a multiplexer, and the third LFSR (LFSR0) controls the output of the multiplexer. Suppose LFSR0, LFSR1, and LFSR2 are the outputs of the three LFSRs, then the generator output is as follows:

```
b(x) = (LFSR0 and LFSR1) xor (not LFSR0 and LFSR2)
```

The generator is programmable, in terms of the power of the polynomials used (i.e. stages or states), the polynomials (POLY0, POLY1 and POLY2) and the initialization values (INIT0, INIT1 and INIT2), individually for each of the three LFSRs.

The Geffe Generator interfaces with the GRTM CCSDS Telemetry Encoder via its external encryption/cipher interface located between the Data Link Protocol Sub-Layer and the Synchronization and Channel Coding Sub-Layer. This corresponds to Link Layer Security Option A according CCSDS definitions (see CCSDS 350.0-G-2 *"The application of CCSDS protocols to secure systems"*). This corresponds to Link Layer Security Option A according to CCSDS 350.0-G-2, i.e. between Logical Link Sublayer and Coding Sublayer.

The implementation of security services is below the Transfer Frame level. The full Transfer Frame is encrypted after any other necessary security services are applied. The generated keystream is XOR-ed bit wise with the Transfer Frame bit stream, starting with first bit transmitted. The LFSRs are only shifted when there is data to be encrypted. The shift is made after each bit has been encrypted.

The three LFSRs are initialized once when the generator is enabled, with the contents of the programmable INIT0, INIT1 and INIT2 register fields, respectively.

The LFSRs initialization value can be optionally XOR-ed with the Transfer Frame Master Channel Counter (only supported for hardware implemented Master Channel Counter in telemetry encoder), according to the following formula:

```
LFSR(31:24) = INIT(31:24) xor MCC(0:7),  LFSR(23:16) = INIT(23:16) xor MCC(0:7)
LFSR(15: 8) = INIT(15: 8) xor MCC(0:7),  LFSR( 7: 0) = INIT( 7: 0) xor MCC(0:7)
```

where INIT(31:0) is the programmable register field (bit 31 being the most significant), and MCC(0:7) is the Transfer Frame Master Channel Counter (bit 0 being the most significant).

The keystream is optionally restarted for each Transfer Frame, i.e. the LFSRs are re-initialized.

The Attached Synchronization Marker remains in plaintext to enable the ground systems to delimit the Channel Access Service Data Units. Also the Reed-Solomon check symbols are in plaintext, i.e. error detection & correction before decrypting begins.

Encryption for Idle Transfer Frames can be optionally disabled (only supported for hardware implemented Idle Transfer Frame generation in telemetry encoder).

A Cyclic Redundancy Code (CRC) can be optionally calculated over the encrypted data according to CCSDS/ECSS algorithm and replace the Frame Error Control Field (FECF) when transmitted in a Transfer Frame (only supported for hardware implemented CRC calculation in telemetry encoder).

The Geffe generator provides support for the following programmable functions:

- Enable/disable encryption on Transfer Frame boundaries

- Initialize LFSRs in-between Transfer Frames

- Initialize LFSRs taking Master Channel Counter value into account

- Skip encryption for Idle Transfer Frames

- Recalculate Cyclic Redundancy Code (CRC) and replace Frame Error Control Field (FECF)

140.2 Linear Feed-back Shift Registers

The three Linear Feed-back Shift Registers (LFSR) are Many-to-One implementation, i.e. Fibonacci version of LFRS. The One-to-Many implementation, i.e. Galois version of LFSR is not supported.

There are two mathematical representations for Fibonacci LFSR:

- output has the highest power, h(x)

- output has the lowest power, l(x)

The implementation of the Geffe Generator supports both representations. Note that both representations generate the same keystream.

The LFSRs are always shifted to the left. The feedback is always entered to the right. The output bits corresponds to the leftmost set bits in the POLY fields in the polynomial configuration registers. The POLY field defined the feedback taps. The initialization values of the LFSRs is defined in the INIT fields in the polynomial initialization value configuration registers.

Note that the bit index of the configuration registers is not directly related to the polynomial powers. The interpretation of the bit index values depends on which of the above representations is assumed.

A first example of an LFSR configuration and the two possible interpretations is shown hereafter. The POLY field is set to 0x0000000B1. Since the leftmost bit set has index 7, the LFSR has 8 stages, and the output is taken from bit index 7, indicated with *out* in the figure.

Assuming that the output has the highest power, indicated with *High* and *h(x)*, the resulting polynomial is $h(x) = x^8 + x^6 + x^5 + x^1 + x^0$.

Assuming that the output has the highest power, indicated with *Low* and *l(x)*, the resulting polynomial is $l(x) = x^0 + x^2 + x^3 + x^7 + x^8$.

```

```
140.3 Connectivity

The connectivity of the Geffe Generator is tightly coupled to the functionality of the GRTM CCSDS Telemetry Encoder.

The input to the Geffe Generator can be connected to:

• Packet Telemetry and AOS encoder

The output from the Geffe Generator can be connected to:

• Reed-Solomon encoder

• Pseudo-Randomiser

• Non-Return-to-Zero Mark encoder

• Convolutional encoder

• Sub-Carrier modulator

140.4 Registers

The core is programmed through registers mapped into APB address space.

141 GRTMRX - CCSDS/ECSS Telemetry Receiver

This IP core is only available as part of a design service.

141.1 Overview

The CCSDS/ECSS/PSS Telemetry Receiver implements part of the Data Link Layer, covering the Protocol Sub-layer and the Frame Synchronization and Coding Sub-layer and part of the Physical Layer of the packet telemetry protocol.

The operation of the Telemetry Receiver is highly programmable by means of control registers.

The Telemetry Receiver comprises several decoders and modulators implementing the Consultative Committee for Space Data Systems (CCSDS) recommendations, European Cooperation on Space Standardization (ECSS) and the European Space Agency (ESA) Procedures, Standards and Specifications (PSS) for telemetry and channel coding. The Telemetry Receiver comprises the following:

- Operation Control Field (OCF)
- Frame Error Control Field (FECF)
- Pseudo-De-Randomiser (PSR)
- Attached Sync Marker search (ASM)
- Non-Return-to-Zero Mark decoder (NRZ)
- Convolutional Quick-Look Decoder (CE)
- Split-Phase Level de-modulator (SP)
- Sub-Carrier de-modulator (SC)

141.3   Layers

141.3.1 Introduction

The Packet Telemetry (or simply Telemetry or TM) and Advanced Orbiting System (AOS) standards are similar in their format, with only some minor variations. The AOS part covered here is the down-link or transmitter, not the uplink or receiver.

GRIP

Apr 2024, Version 2024.1

2101

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The relationship between these standards and the Open Systems Interconnection (OSI) reference model is such that the OSI Data Link Layer corresponds to two separate layer, namely the Data Link Protocol Sub-layer and Synchronization and Channel Coding Sub-Layer. The OSI Data Link Layer is covered here.

The OSI Physical Layer is also covered here to some extended, as specified in [ECSS05] and [PPS105].

The OSI Network Layer or higher layers are not covered here.

141.3.2 Data Link Protocol Sub-layer

The following functionality is implemented in the core:

- Master Channel Reception / Virtual Channel Reception
  - Operation Control Field (OCF) extraction
- All Frame Reception:
  - Frame Error Control Field (FECF) extraction and check
  - Frame filtering on the four first received octets (of the Transfer Frame after ASM)

141.3.3 Synchronization and Channel Coding Sub-Layer

The following functionality is implemented in the core:

- Attached Synchronization Marker (ASM) search
- Pseudo de-randomiser
- Convolutional quick-look decoding

141.3.4 Physical Layer

The following functionality is implemented in the core:

- Non-Return-to-Zero de-modulation
- Split-Phase de-modulation
- Sub-Carrier de-modulation

141.4 Operation

141.4.1 Introduction

The DMA interface provides a means for the user to receive blocks of data of arbitrary length, normally this is Telemetry Transfer Frames, with ASM and optional Reed-Solomon checkbits.

141.4.2 Descriptor setup

The receiver DMA interface is used for receiving data on the downlink. The reception is done using descriptors located in memory.

A single descriptor is shown in tables 2408 through 2411.

The number of bits to be received is set globally. The the address field of the descriptor should point to the start of the transfer frame. The address must be word-aligned. If the interrupt enable (IE) bit is set, an interrupt will be generated when the transfer frame has been received (this requires that the interrupt enable bit in the control register is also set). The interrupt will be generated regardless of whether the transfer frame was received successfully or not. The wrap (WR) bit is also a control bit that should be set before reception and it will be explained later in this section.

Table 2408. GRTMRX descriptor word 0 (address offset 0x0)

31			16	15		11	10	9	8	7	6		3	2	1	0
		LEN			RESERVED		ALOCK	INV	CERR	OV		RESERVED		WR	IE	EN

31: 16	(LEN) - received length in bytes (read only)
15: 11	RESERVED
10:	ASM Lock (ALOCK) - (read only) Set to one when ASM search is in lock.
9:	Inverted bit stream (INV) - (read only) Set to one when an inverted bit stream detected.
8:	CRC Error (CERR) - (read only) Set to one when a CRC error was detected (speculative, only useful if FECF present in frame)
7:	Overrun (OV) - (read only) Set to one when an overrun has occurred during reception.
6: 3	RESERVED
2:	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 16. The pointer automatically wraps to zero when the 16 kB boundary of the descriptor table is reached.
1:	Interrupt Enable (IE) - an interrupt will be generated when the frame from this descriptor has been sent provided that the receiver interrupt enable bit in the control register is set. The interrupt is generated regardless if the frame was received successfully or if it terminated with an error.
0:	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.

Table 2409. GRTMRX descriptor word 1 (address offset 0x4)

31		2	1	0
	ADDRESS			-

31: 2	Address (ADDRESS) - Pointer to the buffer area to where data will be stored.
1: 0	RESERVED

Table 2410. GRTMRX descriptor word 2 (address offset 0x8)

31	0
	STATUS0

31: 0	(STATUS0) - External status information

Table 2411. GRTMRX descriptor word 3 (address offset 0xC)

31	0
	STATUS1

31: 0	(STATUS1) - External status information

To enable a descriptor the enable (EN) bit should be set and after this is done, the descriptor should not be touched until the enable bit has been cleared by the core.

141.4.3 Starting reception

Enabling a descriptor is not enough to start reception. A pointer to the memory area holding the descriptors must first be set in the core. This is done in the descriptor pointer register. The address must be aligned to a 16 kByte boundary. Bits 31 to 14 hold the base address of descriptor area while

GRIP
Apr 2024, Version 2024.1
2103
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

bits 13 to 4 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the core, the pointer field is incremented by 16 to point at the next descriptor. The pointer will automatically wrap back to zero when the next 16 kByte boundary has been reached. The WR bit in the descriptors can be set to make the pointer wrap back to zero before the 16 kByte boundary.

The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when reception is active.

The final step to activate the reception is to set the enable bit in the DMA control register. This tells the core that there are more active descriptors in the descriptor table. This bit should always be set when new descriptors are enabled, even if reception is already active. The descriptors must always be enabled before the reception enable bit is set.

141.4.4 Descriptor handling after reception

When the reception of a frame has finished, status is written to the first word in the corresponding descriptor. The other bits in the first descriptor word are set to zero after reception. The enable bit should be used as the indicator when a descriptor can be used again, which is when it has been cleared by the core. Additionally, the last two words in the corresponding descriptor are written with external status information.

There are multiple bits in the DMA status register that hold status information.

The Receiver Interrupt (RI) bit is set each time a DMA reception ended successfully. The Receiver Error (RE) bit is set each time an DMA reception ended with an overrun error. For either event, an interrupt is generated for descriptor for which the Interrupt Enable (IE) was set. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

The Receiver AMBA error (RA) bit is set when an AMBA AHB error was encountered either when reading a descriptor or when writing data. Any active reception was aborted and the DMA channel was disabled. It is recommended that the receiver is reset after an AMBA AHB error. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

141.4.5 Demodulator clock recovery

Demodulators are provided, that support Split-Phase Level (SP) demodulation (SP), and Binary Phase Shift Key (BPSK) demodulation (or Phase Shift Key Square) as per [ECSS-E-ST-50-05C]. The demodulators can operate separately or in combination.

The demodulators can operate either with a bit serial clock input signal, or with just the bit serial data stream.

For the former, it is assumed that a bit serial clock input, which is synchronous with the bit serial data input, is provided. The demodulator can decode symbol rates up the system clock frequency.

For the latter, a bit serial clock signal can be re-generated locally for a bit serial data input that is Split-Phase-L (SP-L) and/or Sub-Carrier (SC) modulated. The clock recovery is enabled by setting the EN bit in the GRTMRX Demodulator register. With clock recovery, the demodulator can decode a bit serial data input where the symbol period has a duration of down to four times the system clock period. Note that when Sub Carrier (SC) modulation is used, a symbol corresponds to a single phase of the sub-carrier waveform, thus the sub-carrier frequency can be up to an eighth of the system clock frequency.

141.5.8 GRTMRX Physical Layer Register

Table 2420. 0x90 - PLR - physical layer register

31	30 16	15	14 0
SF	SYMBOLRATE	SCF	SUBRATE
0	0	0	0
rw	r	rw	r

31	Symbol Fall (SF) - symbol clock has a falling edge at start of symbol bit
30: 16	Symbol Rate (SYMBOLRATE) - symbol rate division factor -1 (read-only) (diagnostics)
	When Sub Carrier (SC) is disabled, this field corresponds to the lower 15 bits of the number of system clock periods -1 counted per incoming symbol clock period duration.
	When Sub Carrier (SC) is enabled, this field corresponds to the number of system clock periods -1 counted per incoming symbol clock period duration.
15	Sub Carrier Fall (SCF) -sub carrier output start with a falling edge for logical 1
14: 0	Sub Carrier Rate (SUBRATE) - sub carrier division factor - 1 (read only) (diagnostics)
	When Sub Carrier (SC) is disabled, this field corresponds to the upper 15 bits of the number of system clock periods -1 counted per incoming symbol clock period duration.
	When Sub Carrier (SC) is enabled, this field corresponds to the number of sub-carrier clock phases - 1 counted per incoming symbol bit duration.

Telemetry Rate (TELEMTRY RATE) - is the bit rate after potential Sub Carrier (SC) demodulation, Split-Phase Level (S) demodulation and Convolutional Encoding (CE) decoding, and corresponds to the telemetry bit rate.

The following variables are used in the tables hereafter: f = system clock frequency, n = SYMBOLRATE+1 (GRTMRX physical layer register field +1), and m = SUBRATE+1 (GRTMRX physical layer register field +1).

When Sub Carrier (SC) is disabled, the telemetry rate equals

TELMETRY RATE = (SUBRATE * 2**15 + SYMBOLRATE+1) / (1+CE) / (1+SP) = m * n / (1+CE) / (1+SP)

When Sub Carrier (SC) is enabled, the telemetry rate equals

TELEMETRY RATE = (SUBRATE +1)* (SYMBOLRATE+1) / (1+CE) / (1+SP) = m * n / (1+CE) / (1+SP)

141.5.9 GRTMRX Coding Sub-Layer Register

142 GRCE/GRCD - CCSDS/ECSS Convolutional Encoder and Quicklook Decoder

This IP core is only available as part of a design service.

The *Basic Convolutional Encoder* (GRCE) comprises a synchronous bit serial input and a synchronous bit serial output. The output frequency is twice the input frequency.

The *Basic Convolutional Quicklook Decoder* (GRCD) comprises a synchronous bit serial input and a synchronous bit serial output. The input frequency is twice the output frequency. The quicklook decoder decodes the incoming bit stream without correcting for bit errors.

The GRCE / GRCD models are based on the Basic Convolutional Code specified by *Consultative Committee for Space Data Systems* (CCSDS) and *European Cooperation for Space Standardization* (ECSS).

[CCSDS]   TM Synchronization and Channel Coding, CCSDS 131.0-B-2

[PSS]   Telemetry Channel Coding Standard, ESA PSS-04-103, Issue 1, September 1989

[ECSS]   Telemetry synchronization and channel coding, ECSS-E-ST-50-01C

142.1 Protocol

The basic convolutional code is a rate 1/2, constraint-length 7 transparent code which is well suited for channels with predominantly Gaussian noise:

Nomenclature:	Convolutional code
Code rate:	1/2 bit per symbol.
Constraint length:	7 bits.
Connection vectors:	G1 = 1111001 (171 octal);
	G2 = 1011011 (133 octal).
Symbol inversion:	On output path of G2.

Table 2437 shows the interface signals of the Basic Convolutional Encoder (GRCE) core (VHDL ports).

Table 2436. Signal descriptions - GRCE

Signal name	Field	Type	Function	Active
Rst_N	N/A	Input	This active low input port synchronously resets the model. The port is assumed to be deasserted synchronously with the **Cout** system clock.	Low
Cin	N/A	Input	This input port is the bit clock for the data input **Din**. The port is sampled on the rising **Cout** edge. When *Cin* is sampled as asserted, a new bit is present on the **Din** port. **Cin** is assumed to have been generated from the rising **Cout** edge, normally with a delay, and **Din** is assumed to be stable after the falling **Cin** edge.	High
Din	N/A	Input	This input port is the serial data input for the interface. Data are sampled on the rising **Cout** edge when the **Cin** input is asserted. Input data **Din** is thus qualified by the input bit clock **Cin**. For each input data bit on **Din**, two bits are output on **Dout**.	-
Cout	N/A	Output	This input port is the system clock for the model. All registers are clocked on the rising **Cout** edge. The port also acts as the bit clock for the data output **Dout**.	Rising
Dout	N/A	Output	This output port is the serial data output for the interface. The output is clocked out on the rising **Cout** edge.	-

Table 2437 shows the interface signals of the GRCD core (VHDL ports).

Table 2437. Signal descriptions - GRCD

Signal name	Field	Type	Function	Active
Rst_N	N/A	Input	This active low input port synchronously resets the model. The port is assumed to be deasserted synchronously with the **Cin** system clock.	Low
Cin	N/A	Input	This input port is the system clock for the model. All registers are clocked on the falling **Cin** edge. The port also acts as the bit clock for the data input **Din**.	Falling
Din	N/A	Input	This input port is the serial data input for the interface. Data are sampled on the falling **Cin** edge. For two input data bits on **Din**, one bit is output on **Dout**.	-
Cout	N/A	Output	This output port is the output bit clock. The output is clocked out on the falling **Cin** edge.	-
Dout	N/A	Output	This output port is the serial data output for the interface. The output is clocked out on the falling **Cin** edge. **Dout** is assumed to be sampled externally on the falling **Cout** edge.	-
Dlock	N/A	Output	This output port is asserted when the quick look decoder is in lock and producing decoded data. The output is clocked out on the falling **Cin** edge.	High

142.6 Library dependencies

Table 2442 shows the libraries used when instantiating the cores (VHDL libraries).

Table 2442. Library dependencies

Library	Package	Imported unit(s)	Description
TMTC	TMTC_Types	Component	Component declaration

142.7 Instantiation

The GRCE/ GRCD cores are fully synchronous designs based on a single clock strategy. All registers in the cores are reset synchronously or asynchronously, controlled by the syncrst VHDL generic. The reset input requires external synchronisation to avoid any setup and hold time violations.

This example shows how the cores can be instantiated.

```
    library  IEEE;
    use      IEEE.Std_Logic_1164.all;
    library  TMTC;

...

    component GRCE
    port(
      Rst_n:      in    Std_ULogic; -- Synchronous reset

143   GRTC - CCSDS/ECSS Telecommand Decoder

This IP core is only available as part of a design service.

143.1   Overview

The Telecommand Decoder (GRTC) is compliant with the Packet Telecommand protocol and specification defined by [ECSS-E-ST-50-04C]. The decoder is compatible with the [PSS-04-107] and [PSS-04-151] standards. The decoder is compatible with the CCSDS recommendations [CCSDS-231.0-B-2], [CCSDS-232.0-B-2] and [CCSDS-232.1-B-2]. The Telecommand Decoder (GRTC) only implements the Coding Layer (CL).

In the Coding Layer (CL), the telecommand decoder receives bit streams on multiple channel inputs. The streams are assumed to have been generated in accordance with the Physical Layer specifications. In the Coding Layer, the decoder searches all input streams simultaneously until a start sequence is detected. Only one of the channel inputs is selected for further reception. The selected stream is bit-error corrected and the resulting corrected information is passed to the user. The corrected information received in the CL is transfer by means of Direct Memory Access (DMA) to the on-board processor.

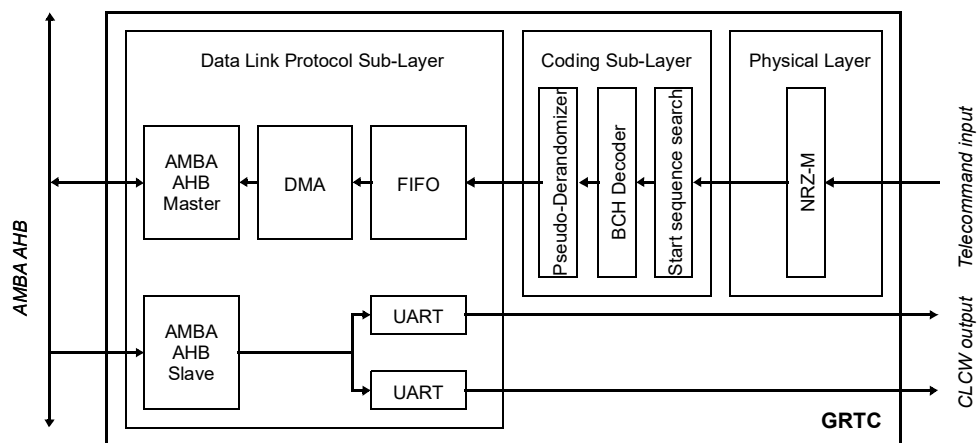
The Command Link Control Word (CLCW) and the Frame Analysis Report (FAR) can be read and written as registers via the AMBA AHB bus. Parts of the two registers are generated by the Coding Layer (CL). The CLCW can be automatically transmitted to the Telemetry Encoder (TM) for transmission to the ground. Note that most parts of the CLCW and FAR are not produced by the Telecommand Decoder (GRTC) hardware portion. This is instead done by the software portion of the decoder.


Figure 345. Block diagram

143.1.1 Concept

A telecommand decoder in this concept is mainly implemented by software in the on-board processor. The supporting hardware in the GRTC core implements the Coding Layer, which includes synchronisation pattern detection, channel selection, codeblock decoding, Direct Memory Access (DMA) capability and buffering of corrected codeblocks. The hardware also provides a register via which the Command Link Control Word (CLCW) is made available to a Telemetry Encoder. The CLCW is to be generated by the software.

The GRTC has been split into several clock domains to facilitate higher bit rates and partitioning. The two resulting sub-cores have been named Telecommand Channel Layer (TCC) and the Telecommand Interface (TCI). Note that TCI is called AHB2TCI. A complete CCSDS packet telecommand decoder can be realized at software level according to the latest available standards, staring from the Transfer Layer.

GRIP

Frontgrade Gaisler AB

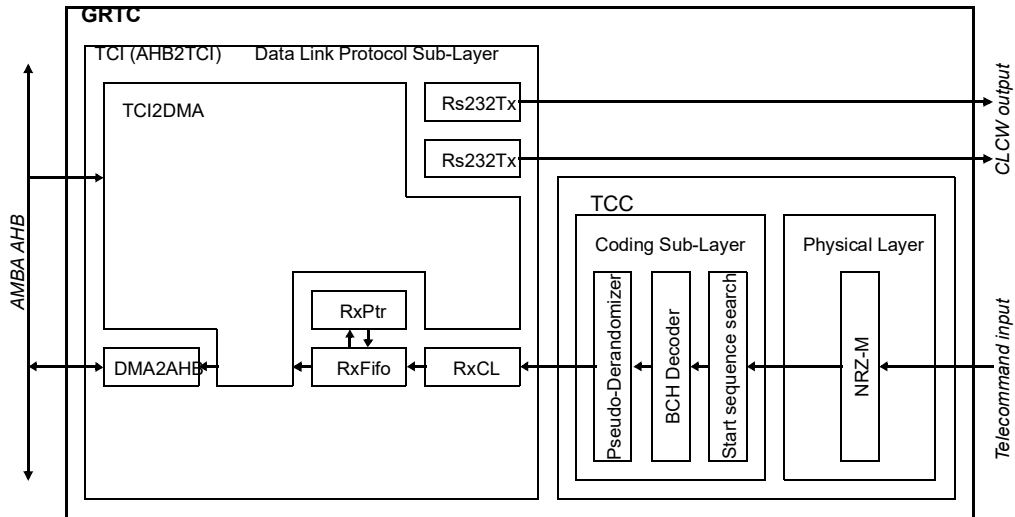
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler


Figure 346. Detailed block diagram showing the internal structure

143.1.2 Functions and options

The Telecommand Decoder (GRTC) only implements the Coding Layer of the telecommand protocol standard [ECSS-E-ST-50-04C]. All other layers are to be implemented in software, e.g. Authentication Unit (AU). The Command Pulse Distribution Unit (CPDU) is not implemented.

The following functions of the GRTC are programmable by means of registers:

- Pseudo-De-Randomisation
- Non-Return-to-Zero – Mark decoding

The following functions of the GRTC are pin configurable:

- Polarity of RF Available and Bit Lock inputs
- Edge selection for input channel clock

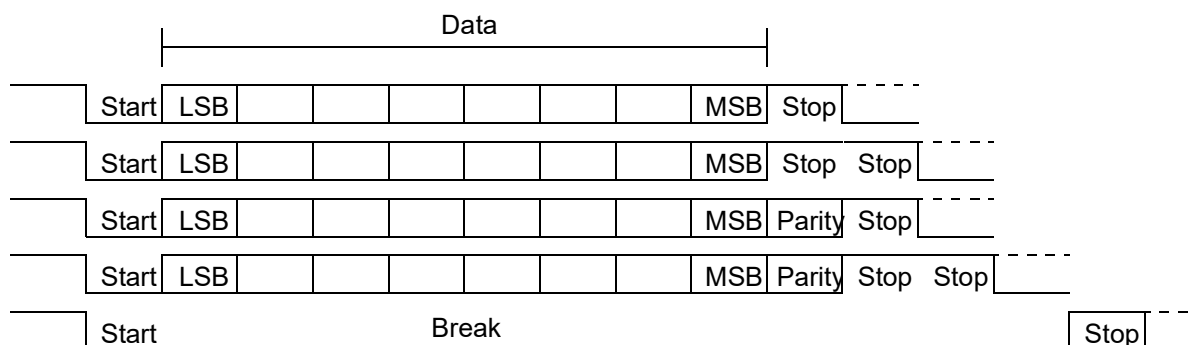
143.2.2 Waveforms


Figure 347. Bit asynchronous protocol versions
Figure 348. Telecommand input protocol

143.3 Coding Layer (CL)

The Coding Layer synchronises the incoming bit stream and provides an error correction capability for the Command Link Transmission Unit (CLTU). The Coding Layer receives a dirty bit stream together with control information on whether the physical channel is active or inactive for the multiple input channels.

The bit stream is assumed to be NRZ-L encoded, as the standards specify for the Physical Layer. As an option, it can also be NRZ-M encoded. There are no assumptions made regarding the periodicity or continuity of the input clock signal while an input channel is inactive. The most significant bit (Bit 0 according to [ECSS-E-ST-50-04C]) is received first.

Searching for the Start Sequence, the Coding Layer finds the beginning of a CLTU and decodes the subsequent codeblocks. As long as no errors are detected, or errors are detected and corrected, the Coding Layer passes clean blocks of data to the Transfer Layer which is implemented in software. When a codeblock with an uncorrectable error is encountered, it is considered as the Tail Sequence, its contents are discarded and the Coding Layer returns to the Start Sequence search mode.

The Coding Layer also provides status information for the FAR, and it is possible to enable an optional de-randomiser according to [ECSS-E-ST-50-04C].

143.3.1 Synchronisation and selection of input channel

Synchronisation is performed by means of bit-by-bit search for a Start Sequence on the channel inputs. The detection of the Start Sequence is tolerant to a single bit error anywhere in the Start Sequence pattern. The Coding Layer searches both for the specified pattern as well as the inverted pattern. When an inverted Start Sequence pattern is detected, the subsequent bit-stream is inverted till the detection of the Tail Sequence.

The detection is accomplished by a simultaneous search on all active channels. The first input channel where the Start Sequence is found is selected for the CLTU decoding. The selection mechanism is restarted on any of the following events:

- The input channel active signal is de-asserted, or
- a Tail Sequence is detected, or

GRIP
Apr 2024, Version 2024.1

2122

Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

- a Codeblock rejection is detected, or

- an abandoned CLTU is detected, or the clock time-out expires.

As a protection mechanism in case of input failure, a clock time-out is provided for all selection modes. The clock time-out expires when no edge on the bit clock input of the selected input channel in decode mode has been detected for a specified period. When the clock time-out has expired, the input channel in question is ignored (i.e. considered inactive) until its active signal is de-asserted (configurable with gTimeoutMask=1).

143.3.2 Codeblock decoding

The received Codeblocks are decoded using the standard (63,56) modified BCH code. Any single bit error in a received Codeblock is corrected. A Codeblock is rejected as a Tail Sequence if more than one bit error is detected. Information regarding Count of Single Error Corrections and Count of Accept Codeblocks is provided to the FAR. Information regarding Selected Channel Input is provided via a register.

143.3.3 De-Randomiser

In order to maintain bit synchronisation with the received telecommand signal, the incoming signal must have a minimum bit transition density. If a sufficient bit transition density is not ensured for the channel by other methods, the randomiser is required. Its use is optional otherwise. The presence or absence of randomisation is fixed for a physical channel and is managed (i.e., its presence or absence is not signalled but must be known a priori by the spacecraft and ground system). A random sequence is exclusively OR-ed with the input data to increase the frequency of bit transitions. On the receiving end, the same random sequence is exclusively OR-ed with the decoded data, restoring the original data form. At the receiving end, the de-randomisation is applied to the successfully decoded data. The de-randomiser remains in the "all-ones" state until the Start Sequence has been detected. The pattern is exclusively OR-ed, bit by bit, to the successfully decoded data (after the Error Control Bits have been removed). The de-randomiser is reset to the "all-ones" state following a failure of the decoder to successfully decode a codeblock or other loss of input channel.

143.3.4 Non-Return-to-Zero – Mark

An optional Non-Return-to-Zero – Mark decoder can be enabled by means of a register.

143.3.5 Design specifics

The coding layer is supporting 1 to 8 channel inputs ([PSS-04-151] requires at least 4).

A codeblock is fixed to 56 information bits (as per CCSDS/ECSS).

The CCSDS/ECSS (1024 octets) or [PSS-04-151] (256 octets) standard maximum frame lengths are supported, being programmable via bit PSS in the GCR register. The former allows more than 37 codeblocks to be received.

The Frame Analysis Report (FAR) interface supports 8 bit CAC field, as well as the 6 bit CAC field specified in [PSS-04-151] When the PSS bit is cleared to '0', the two most significant bits of the CAC will spill over into the "LEGAL/ILLEGAL" FRAME QUALIFIER field in the FAR. These bits will however be all-zero when [PSS-04-151] compatible frame lengths are received or the PSS bit is set to '1'. The saturation is done at 6 bits when PSS bit is set to '1' and at 8 bits when PSS bit is cleared to '0'.

The Pseudo-Randomiser decoder is included (as per CCSDS/ECSS), its usage being input signal programmable.

The Physical Layer input can be NRZ-L or NRZ-M modulated, allowing for polarity ambiguity. NRZ-L/M selection is programmable. This is an extension to ECSS: Non-Return to Zero - Mark decoder added, with its internal state reset to zero when channel is deactivated.

GRIP
Apr 2024, Version 2024.1
2123
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Note: If input clock disappears, it will also affect the codeblock acquired immediately before the codeblock just being decoded (accepted by [PSS-04-151]).

In state S1, all active inputs are searched for start sequence, there is no priority search, only round robin search. The search for the start sequence is sequential over all inputs: maximum input frequency = system frequency /(gIn+2)

The [PSS-04-151] specified CASE-1 and CASE-2 actions are implemented according to aforementioned specification, not leading to aborted frames.

Extended E2 handling is implemented:

- E2b   Channel Deactivation - selected input becomes inactive in S3

- E2c   Channel Deactivation - too many codeblocks received in S3

- E2d   Channel Deactivation - selected input is timed-out in S3
  (design choice being: S3 => S1, abandoned frame)

143.3.6 Direct Memory Access (DMA)

This interface provides Direct Memory Access (DMA) capability between the AMBA bus and the Coding Layer. The DMA operation is programmed via an AHB slave interface.

The DMA interface is an element in a communication concept that contains several levels of buffering. The first level is performed in the Coding Layer where a complete codeblock is received and kept until it can be corrected and sent to the next level of the decoding chain. This is done by inserting each correct information octet of the codeblock in an on-chip local First-In-First-Out (FIFO) memory which is used for providing improved burst capabilities. The data is then transferred from the FIFO to a system level ring buffer in the user memory (e.g. SRAM located in on-board processor board) which is accessed by means of DMA.

The following storage elements can thus be found in this design:

The shift and hold registers in the Coding Layer

The local FIFO (parallel; 32-bit; 4 words deep)

The system ring buffer (for example external SRAM; 32-bit; 1 to 256 kByte deep).

143.4 Transmission

The transmission of data from the Coding Layer to the system buffer is described hereafter.

The serial data is received and shifted in a shift register in the Coding Layer when the reception is enabled. After correction, the information content of the shift register is put into a hold register.

When space is available in the peripheral FIFO, the content of the hold register is transferred to the FIFO. The FIFO is of 32-bit width and the byte must thus be placed on the next free byte location in the word.

When the FIFO is filled for 50%, a request is done to transfer the available data towards the system level buffer.

If the system level ring buffer isn't full, the data is transported from the FIFO, via the AHB master interface towards the main processor and stored in e.g. external SRAM. If no place is available in the system level ring buffer, the data is held in the FIFO.

When the GRTC keeps receiving data, the FIFO will fill up and when it reaches 100% of data, and the hold and shift registers are full, a receiver overrun interrupt will be generated (IRQ_RX_OVER-RUN). All new incoming data is rejected until space is available in the peripheral FIFO.

When the receiving data stream is stopped (e.g. when a complete data block is received), and some bytes are still in the peripheral FIFO, then these bytes will be transmitted to the system level ring buf-

fer automatically. Received bytes in the shift and hold register are always directly transferred to the peripheral FIFO.

The FIFO is automatically emptied when a CLTU is either ready or has been abandoned. The reason for the latter can be codeblock error, time out etc. as described in CLTU decoding state diagram.

The operational state machine is shown in figure 349.

HARDWARE WRITE START → INIT: init rx_w_ptr (lower bits) → fifo 50% full? N/Y → CHECK: temp1 = rx_w_ptr, temp2 = rx_w_ptr + # bytes received, temp3 = rx_r_ptr → temp2 >= temp3-offset? Y→OVERFLOW: set overflow-flag / N→WRITE: burst of writes @ temp1 → temp1 >= end addr? Y→RESET: temp1 = start addr+x / N→INCREMENT: temp1 = temp1+x → UPDATE: rx_w_ptr = temp1

SOFTWARE READ START → INIT: init rx_r_ptr & rx_w_ptr (ASR register) → CHECK: temp1 = rx_w_ptr, temp2 = rx_r_ptr → temp1 = temp2? Y→WAIT: TBD ms / CHANNEL RESET; N→fifo 100% full? Y→CHANNEL RESET / N→READ: read @ temp2 → temp2 = end addr? Y→RESET: temp2 = start addr+y / N→INCREMENT: temp2 = temp2+y → all data read? N→loop / Y→CHECK

Legend:

143.4.2 CLTU Decoder State Diagram

Note that the diagram has been improved with explicit handling of different E2 events listed below.
Figure 350. Decoder state diagram

State   Definition:

  S1   Inactive

  S2   Search

  S3   Decode

Event   Definition:

  E1   Channel Activation

  E2a   Channel Deactivation - all inputs are inactive

  E2b   Channel Deactivation - selected becomes inactive (CB=0 -> frame abandoned)

  E2c   Channel Deactivation - too many codeblocks received (all -> frame abandoned)

  E2d   Channel Deactivation - selected is timed-out (all -> frame abandoned)

  E3   Start Sequence Found

  E4   Codeblock Rejection (CB=0 -> frame abandoned)

143.4.3 Nominal

A: When the first "Candidate Codeblock" (i.e. "Candidate Codeblock" 0, which follows Event 3 (E3):START SEQUENCE FOUND) is found to be error free, or if it contained an error which has been corrected, its information octets are transferred to the remote ring buffer as shown in table 2443. At the same time, a "Start of Candidate Frame" flag is written to bit 0 or 16, indicating the beginning of a transfer of a block of octets that make up a "Candidate Frame". There are two cases that are handled differently as described in the next sections.

Table 2443. Data format

	Bit[31…………24]	Bit[23…………16]	Bit[15………….8]	Bit[7……...…….0]
0x40000000	information octet0	0x01	information octet1	0x00
0x40000004	information octet2	0x00	information octet3	0x00
0x40000008	information octet4	0x00	end of frame	0x02
…	…		…	
0x400000xx	information octet6	0x01	information octet7	0x00
0x400000xx	information octet8	0x00	abandoned frame	0x03

Legend: Bit [17:16] or [1:0]:

    "00" = continuing octet

    "01" = Start of Candidate Frame

    "10" = End of Candidate Frame

    "11" = Candidate Frame Abandoned

GRIP

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

143.4.4 CASE 1

When an Event 4 – (E4): CODEBLOCK REJECTION – occurs for any of the 37 possible "Candidate Codeblocks" that can follow Codeblock 0 (possibly the tail sequence), the decoder returns to the SEARCH state (S2), with the following actions:

- The codeblock is abandoned (erased)
- No information octets are transferred to the remote ring buffer
- An "End of Candidate Frame" flag is written, indicating the end of the transfer of a block of octets that make up a "Candidate Frame".

143.4.5 CASE 2

When an Event 2 – (E2): CHANNEL DEACTIVATION – occurs which affects any of the 37 possible "Candidate Codeblocks" that can follow Codeblock 0, the decoder returns to the INACTIVE state (S1), with the following actions:

- The codeblock is abandoned (erased)
- No information octets are transferred to the remote ring buffer
- An "End of Candidate Frame" flag is written, indicating the end of the transfer of a block of octets that make up a "Candidate Frame"

143.4.6 Abandoned

- B: When an Event 4 (E4), or an Event 2 (E2), occurs which affects the first candidate codeblock 0, the CLTU shall be abandoned. No candidate frame octets have been transferred.
- C: If and when more than 37 Codeblocks have been accepted in one CLTU, the decoder returns to the SEARCH state (S2). The CLTU is effectively aborted and this is will be reported to the software by writing the "Candidate Frame Abandoned flag" to bit 1 or 17, indicating to the software to erase the "Candidate frame".

143.5 Relationship between buffers and FIFOs

The conversion from the peripheral data width (8 bit for the coding layer receiver), to 32 bit system word width, is done in the peripheral FIFO.

All access towards the system ring buffer are 32-bit aligned. When the amount of received bytes is odd or not 32-bit aligned, the FIFO will keep track of this and automatically solve this problem. For the reception data path, the 32 bit aligned accesses could result in incomplete words being written to the ring buffer. This means that some bytes aren't correct (because not yet received), but this is no problem due to the fact that the hardware write pointer (rx_w_ptr) always points to the last, correct, data byte.

The local FIFO ensures that DMA transfer on the AMBA AHB bus can be made by means of 2-word bursts. If the FIFO is not yet filled and no new data is being received this shall generate a combination of single accesses to the AMBA AHB bus if the last access was indicating an end of frame or an abandoned frame.

If the last single access is not 32-bit aligned, this shall generate a 32-bit access anyhow, but the receive-write-pointer shall only be incremented with the correct number of bytes. Also in case the previous access was not 32-bit aligned, then the start address to write to will also not be 32-bit aligned. Here the previous 32-bit access will be repeated including the bytes that were previously missing, in order to fill-up the 32-bit remote memory-controller without gaps between the bytes.

The receive-write-pointer shall be incremented according to the number of bytes being written to the remote memory controller.

+46 31 7758650 | frontgrade.com/gaisler

143.5.1 Buffer full

The receiving buffer is full when the hardware has filled the complete buffer space while the software didn't read it out. Due to hardware implementation and safety, the buffer can't be filled completely without interaction of the software side. A space (offset) between the software read pointer (rx_r_ptr) and the hardware write pointer (rx_w_ptr) is used as safety buffer. When the write pointer (rx_w_ptr) would enter this region (due to a write request from the receiver), a buffer full signal is generated and all hardware writes to the buffer are suppressed. The offset is hard coded to 8 bytes.

Warning: If the software wants to receive a complete 1kbyte block (when RXLEN = 0), then it must read out at least 8 bytes of data from the buffer. In this case, the hardware can write the 1024 bytes without being stopped by the rx buffer full signal.
Figure 351. Buffer full situation

143.5.2 Buffer full interrupt

The buffer full interrupt is given when the difference between the hardware write pointer (rx_w_ptr) and the software read pointer (rx_r_ptr) is less than 1/8 of the buffer size. The way it works is the same as with the buffer full situation, only is the interrupt active when the security zone is entered. The buffer full interrupt is active for 1 system clock cycle. When the software reads out data from the buffer, the security zone shifts together with the read pointer (rx_r_ptr) pointer. Each time the hardware write pointer (rx_w_ptr) enters the security zone, a single interrupt is given.
Figure 352. Buffer full interrupt (buffers size is 2kbyte in this example)

143.6 Command Link Control Word interface (CLCW)

The Command Link Control Word (CLCW) is inserted in the Telemetry Transfer Frame by the Telemetry Encoder (TM) when the Operation Control Field (OPCF) is present. The CLCW is created by the software part of the telecommand decoder. The telecommand decoder hardware provides two registers for this purpose which can be accessed via the AMBA AHB bus. Note that bit 16 (No RF Available) and 17 (No Bit Lock) of the CLCW are not possible to write by software. The information carried in these bits is based on discrete inputs.

Two PacketAsynchronous interfaces (PA) are used for the transmission of the CLCW from the telecommand decoder. The protocol is fixed to 115200 baud, 1 start bit, 8 data bits, 1 or 2 stop bits (configured by generics), with a BREAK command for message delimiting (sending 13 bits of logical zero).

The CLCWs are automatically transferred over the PA interface after reset, on each write access to the CLCW register and on each change of the bit 16 (No RF Available) and 17 (No Bit Lock).

Table 2444. CLCW transmission protocol

Byte Number	CLCWR register bits	CLCW contents						
First	[31:24]	Control Word Type	CLCW Version Number	Status Field	COP In Effect			
Second	[23:16]	Virtual Channel Id	Reserved Field					
Third	[15:8]	No RF Available	No Bit Lock	Lock Out	Wait	Retransmit	Farm B Counter	Report Type
Fourth	[7:0]	Report Value						
Fifth	N/A	[RS232 Break Command]						

143.7 Configuration Interface (AMBA AHB slave)

The AMBA AHB slave interface supports 32 bit wide data input and output. Since each access is a word access, the two least significant address bits are assumed always to be zero, address bits 23:0 are decoded. Note that address bits 31:24 are not decoded and should thus be handled by the AHB arbiter/decoder. The address input of the AHB slave interfaces is thus incompletely decoded. Misaligned addressing is not supported. For read accesses, unmapped bits are always driven to zero.

The AMBA AHB slave interface has been reduced in function to support only what is required for the TC. The following AMBA AHB features are constrained:

• Only supports HSIZE=WORD, HRESP_ERROR generated otherwise

• Only supports HMASTLOCK='0', HRESP_ERROR generated otherwise

• Only support HBURST=SINGLE or INCR, HRESP_ERROR generated otherwise

• No HPROT decoding

• No HSPLIT generated

• HRETRY is generated if a register is inaccessible due to an ongoing reset.

• HRESP_ERROR is generated for unmapped addresses, and for write accesses to register without any writeable bits

• Only big-endianness is supported.

During a channel reset the RRP and RWP registers are temporary unavailable. The duration of this reset-inactivity is 8 HCLK clock periods and the AHB-slave generates a HRETRY response during this period if an access is made to these registers.

GRIP
Apr 2024, Version 2024.1
2129
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

If the channel reset is initiated by or during a burst-access the reset will execute correctly but a part of the burst could be answered with a HRETRY response. It is therefore not recommended to initiate write bursts to the register.

GRTC has interrupt outputs, that are asserted for at least two clock periods on the occurrence of one of the following events:

- 'CLTU stored' (generated when CLTU has been stored towards the AMBA bus, also issued for abandoned CLTUs)
- 'Receive buffer full' (generated when the buffer has less than 1/8 free) (note that this interrupt is issued on a static state of the buffer, and can thus be re-issued immediately after the corresponding register has been read out by software, it should be masked in the interrupt controller to avoid an immediate second interrupt).
- 'Receiver overrun' (generated when received data is dropped due to a reception overrun)
- 'CLTU ready' (note that this interrupt is also issued for abandoned CLTUs)
- FAR interrupt 'Status Survey Data'
- CLCW interrupt 'Bit Lock'
- CLCW interrupt 'RF Available'

143.7.1 Miscellaneous

The accuracy of the transmission or reception baud rate of the bit asynchronous serial interface is dependent on the selected system frequency and baud rate. The number of system clock periods used for sending or receiving a bit is directly proportional to the integer part of the division of the system frequency with the baud rate.

The BREAK command received on the bit asynchronous serial interface is a sequence of logical zeros that is at least one bit period longer than the normal byte frame, i.e. start bit, eight data bits, optional parity, one or two stop bits. When transmitted, it is always 13 bits.

143.8 Interrupts

The core generates the interrupts defined in table 2445.

*Table 2445.*Interrupts

Interrupt offset	Interrupt name	Description
1:st	RFA	RF Available changed
2:nd	BLO	Bit Lock changed
3:rd	FAR	FAR available
4:th	CR	CLTU ready/aborted
5:th	RBF	Output buffer full
6:th	OV	Input data overrun
7:th	CS	CLTU stored

143.9 Miscellaneous

143.9.1 Numbering and naming conventions

Convention according to the CCSDS recommendations, applying to time structures:

- The most significant bit of an array is located to the left, carrying index number zero.
- An octet comprises eight bits.

Table 2446. CCSDS n-bit field definition

CCSDS n-bit field		
most significant		least significant
0	1 to n-2	n-1

Convention according to AMBA specification, applying to the APB/AHB interfaces:

- Signal names are in upper case, except for the following:
- A lower case 'n' in the name indicates that the signal is active low.
- Constant names are in upper case.
- The least significant bit of an array is located to the right, carrying index number zero.
- Big-endian support.

Table 2447. AMBA n-bit field definition

AMBA n-bit field		
most significant		least significant
n-1	n-2 down to 1	0

General convention, applying to all other signals and interfaces:

- Signal names are in mixed case.
- An upper case '_N' suffix in the name indicates that the signal is active low.

143.9.2 Performance

The uplink bit rate is supported in the range of 1 kbits/s to 1 Mbits/s.

The bit rate is set to 115200 bit/s for the PacketAsynchronous (PA) interfaces.

143.10.9Status Register (STR)

Table 2457.0x24 - STR - Status Register [7]

31					11	10	9	8	7	6	5	4	3	1	0
RESERVED						RBF	RESERVED		RFF	RESERVED		OV	RESERVED		CR
0						0	0		0	0		0	0		0
r						r	r		r	r		r	r		r

31: 11	RESERVED		
	Write:	Don't care.
	Read:	All zero.
10	RBF (RX BUFFER Full)		
	Write:	Don't care.
	Read:	'0' = Buffer not full,
		'1'= Buffer full (this bit is set if the buffer has less then 1/8 of free space)
9: 8	RESERVED		
	Write:	Don't care.
	Read:	All zero.
7	RFF (RX FIFO Full)		
	Write:	Don't care.
	Read:	'0' = FIFO not full, '1' = FIFO full
6: 5	RESERVED		
	Write:	Don't care.
	Read:	All zero.
4	OV (Overrun) [5]		
	Write:	Don't care.
	Read:	'0'= nominal, '1'= data lost
3: 1	RESERVED		
	Write:	Don't care.
	Read:	All zero.
0	CR (CLTU Ready) [5]		

There is a worst case delay from the CR bit being asserted, until the data has actually been transferred from the receiver FIFO to the ring buffer. This depends on the PCI load etc.

	Write:	Don't care.
	Read:	'1'= new CLTU in ring buffer. '0'= no new CLTU in ring buffer.

143.10.10 Address Space Register (ASR)

*Table 2458.*0x28 - ASR - Address Space Register [8]

31		10	9 8	7	0
BUFST			RESERVED	RXLEN	
0			0	0	
rw			r	rw	

31: 10	BUFST (Buffer Start Address)
	22-bit address pointer
	This pointer contains the start address of the allocated buffer space for this channel.
	Register has to be initialized by software before DMA capability can be enabled.
9: 8	RESERVED
	Write: Don't care.
	Read: All zero.
7: 0	RXLEN (*RX buffer length*)
	Number of 1kB-blocks reserved for the RX buffer.
	(Min. 1kByte = 0x00, Max. 256kByte = 0xFF)

143.10.11 Receive Read Pointer Register (RRP)

31	24 23	0
RxRd Ptr Upper	RxRd Ptr Lower	
0	0	
r	rw	

31: 24	10-bit upper address pointer
	Write: Don't care.
	Read: This pointer = ASR[31..24].
23: 0	24-bit lower address pointer.
	This pointer contains the current RX read address. This register is to be incremented with the actual amount of bytes read.

143.10.12 Receive Write Pointer Register (RWP)

*Table 2460.*0x30 - RWP - Receive Write Pointer Register [6] [9]

31	24 23	0
RxWr Ptr Upper	RxWr Ptr Lower	
0	0	
r	r	

31: 24	10-bit upper address pointer
	Write: Don't care.
	Read: This pointer = ASR[31..24].
23: 0	24-bit lower address pointer.
	This pointer contains the current RX write address. This register is incremented with the actual amount of bytes written.

Legend:

[1]   The global system reset caused by the SRST-bit in the GRR-register results in the following actions:

- Initiated by writing a '1", gives '0' on read-back when the reset was successful.

- No need to write a '0' to remove the reset.

GRIP
Apr 2024, Version 2024.1
2139
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Unconditionally, means no need to check/disable something in order for this reset-function to correctly execute.

- Could of course lead to data-corruption coming/going from/to the reset core.

- Resets the complete core (all logic, buffers & register values)

- Behaviour is similar to a power-up.

[2]   The FAR register supports the CCSDS/ECSS standard frame lengths (1024 octets), requiring an 8 bit CAC field instead of the 6 bits specified for PSS. The two most significant bits of the CAC will thus spill over into the "LEGAL/ILLEGAL" FRAME QUALIFIER field, Bit [26:25]. This is only the case when the PSS bit is set to '0'.

[3]   The number of channels are controlled with the gRFAvailable and gBitLock VHDL generics, respectively.

[4]   The channel reset caused by the CRST-bit in the COR-register results in the following actions:

- Initiated by writing a '1", gives '0' on read-back when the reset was successful.

- No need to write a '0' to remove the reset.

- All other bit's in the COR are neglected (not looked at) when the CRST-bit is set during a write, meaning that the value of these bits has no impact on the register-value after the reset.

- Unconditionally, means no need to check/disable something in order for this reset-function to correctly execute.

- Could of course lead to data-corruption coming/going from/to the reset channel.

- Resets the complete channel (all logic, buffers & register values)

- Except the ASR-register of that channel which remains it's value.

- All read- and write-pointers are automatically re-initialized and point to the start of the ASR-address.

- All registers of the channel (except the ones described above) get their power-up value.

- This reset shall not cause any spurious interrupts.

[5]   These bits are sticky bits which means that they remain present until the register is read and that they are cleared automatically by reading the register.

[6]   The value of the pointers depends on the content of the corresponding Address Space Register (ASR). During a system reset, a channel reset or a change of the ASR register, the pointers are recalculated based on the values in the ASR register. The software has to take care (when programming the ASR register) that the pointers never have to cross a 16MByte boundary (because this would cause an overflow of the 24-bit pointers). It is not possible to write an out of range value to the RRP register. Such access will be ignored with an HERROR.

[7]   An AMBA AHB ERROR response is generated if a write access is attempted to a register without any writeable bits.

[8]   The channel reset caused by a write to the ASR-register results in the following actions:

- Initiated by writing an updated value into the ASR-register.

- Unconditionally, means no need to check/disable something in order for this reset-function to correctly execute.

- Could of course lead to data-corruption coming/going from/to the reset channel.

- Resets the complete channel (all logic & buffers) but not all register values, only the following:

- COR-register, TE & RE bits get their power-up value, other bits remain their value.

- STR-register, all bits get their power-up value

- Other registers remain their value

- Updates the ASR-register of that channel with the written value

- All read- and write-pointers are automatically re-initialized and point to the start of the ASR-address.

- This reset shall not cause any spurious interrupts

[9]   During a channel reset the register is temporarily unavailable and HRETRY response is generated if accessed.

[10]   It is not possible to write an out of range value to the RRP register. Such access will be ignored without an error.

[11]   The PSS bit usage is only supported if the gPSS generic is set on the TCC module.

143.10.13 Interrupt registers

The interrupt registers give complete freedom to the software, by providing means to mask interrupts, clear interrupts, force interrupts and read interrupt status.

When an interrupt occurs the corresponding bit in the Pending Interrupt Register is set. The normal sequence to initialize and handle a module interrupt is:

- Set up the software interrupt-handler to accept an interrupt from the module.

- Read the Pending Interrupt Register to clear any spurious interrupts.

- Initialize the Interrupt Mask Register, unmasking each bit that should generate the module interrupt.

- When an interrupt occurs, read the Pending Interrupt Status Register in the software interrupt-handler to determine the causes of the interrupt.

- Handle the interrupt, taking into account all causes of the interrupt.

- Clear the handled interrupt using Pending Interrupt Clear Register.

Masking interrupts: After reset, all interrupt bits are masked, since the Interrupt Mask Register is zero. To enable generation of a module interrupt for an interrupt bit, set the corresponding bit in the Interrupt Mask Register.

Clearing interrupts: All bits of the Pending Interrupt Register are cleared when it is read or when the Pending Interrupt Masked Register is read. Reading the Pending Interrupt Masked Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register. Selected bits can be cleared by writing ones to the bits that shall be cleared to the Pending Interrupt Clear Register.

Forcing interrupts: When the Pending Interrupt Register is written, the resulting value is the original contents of the register logically OR-ed with the write data. This means that writing the register can force (set) an interrupt bit, but never clear it.

Reading interrupt status: Reading the Pending Interrupt Status Register yields the same data as a read of the Pending Interrupt Register, but without clearing the contents.

Reading interrupt status of unmasked bits: Reading the Pending Interrupt Masked Status Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register, but without clearing the contents.

The interrupt registers comprise the following:

Table 2461. Interrupt registers

Description	Name	Mode
Pending Interrupt Masked Status Register	PIMSR	r
Pending Interrupt Masked Register	PIMR	r
Pending Interrupt Status Register	PISR	r
Pending Interrupt Register	PIR	rw
Interrupt Mask Register	IMR	rw

144 TCAU - Telecommand Decoder Authentication Unit

This IP core is only available as part of a design service.

144.1 Overview

The TCAU is compatible with the Telecommand Decoder Specification defined by [PSS-04-151] and implements authentication in accordance with [CCSDS-350.0] as defined by Option B, authentication of segment. The TCAU is placed between the Transfer Sublayer and the Segmentation Sublayer.

The TCAU authentication method is a plain text with appended signature. It is based on a one-way function called "hard knapsack", which relies on a 40-bit digital signature generated by applying a secret key on the segment. The same algorithm is used for generating the signature in the transmitting end as in the receiving end.

144.2 Operation

The TCAU receives segments from the transfer sublayer octet by octet, starting with the segment header. By comparing the 5 LSBs of the segment header, the MAP address, with the configuration signal *aumap*, the TCAU determines if the segment is to be authenticated. If the *auenable* input signal is high, all segments where the MAP address is less than or equal to *aumap* will be sent to the Authentication Processor for authentication. Segments where the MAP address is higher than *aumap*, will be sent to the segmentation sublayer without processing. A special case exists for segments where the entire MAP ID equals 63. These are dedicated for the Control Command Processor of the TCAU and are always authenticated, see further section 144.9. The control commands are used to change the internal configuration of the TCAU and are always unsegmented, i.e. the segmentation flags are set to 11b.
Figure 354. Block diagram

The TCAU contains the following major functions:

- Front-end receiver
- Authentication Processor
- Final Authorisation

144.3 References

[PSS-04-151]   Telecommand Decoder Specification, ESA PSS-04-151, issue 1

[CCSDS-350.0]   The Application of CCSDS Protocols to Secure Systems, CCSDS 350.0-G-2, issue 2

144.4 Data structures

Table 2468 shows the structure of a telecommand segment with the optional authentication tail used by the TCAU. The authentication tail is mandatory for all segments that are to be authenticated.

Table 2468. Telecommand segment with authentication tail

Telecommand segment with optional tail							
Segment header			Segment data field	Authentication tail (optional)			
Sequence flags	MAP identifier			Logical authentication channel (LAC)		Signature	
	Control flag	MAP address		LAC ID	LAC count		
2 bits	1 bit	5 bits	0 to 239 octets or	2 bits	30 bits	40 bits	
1 octet			0 to 248 octets	0 or 9 octets			
1 to 249 octets							

144.5 Front-end receiver

The front-end receiver handles reception of octets from the Transfer sublayer using a handshaking protocol. Octets are placed in a 10 octet buffer, in order to accommodate the entire authentication tail. The front-end receiver counts all octets received to determine the segment length. The octets are passed on to the Authentication Processor and the Back-end transmitter.

144.6 Authentication Processor

The Authentication Processor receives the entire segment from the Front-end receiver and calculates the 40-bit digital signature using one of two on-board keys: the fixed key or the programmable key. The 40-bit digital signature is compared to the signature in the authentication tail appended to the segment. The Authentication Processor comprises the following functions:

- • Hashing Function
- • Hard Knapsack
- • Deletion Box
- • Signature Comparator

144.6.1 Hashing Function

The Hashing Function generates i 60-bit pre-signature by shifting the extended message, x, into a linear feedback shift register (LFSR). The extended message comprises the segment header, segment data, received LAC from the authentication tail and finally filler bits, comprising 24 zeros, to ensure a minimum length of the extended message. The coefficients of the LFSR are part of the keys.

When a new segment is received, the LFSR is initialized to 1000...000, i.e. bit 0 is set to 1 and all other bits are set to zero. When the entire extended message has been shifted into the LFSR, it will contain the pre-signature, P.
Figure 355. Hashing Function

144.6.2 Hard Knapsack

The purpose of the Hard Knapsack function is to make the overall system non-linear and to serve as a true one-way function, so that it is not possible to calculate the pre-signature from the signature. The Hard Knapsack consists of 60 weights, which are part of the two on-board keys, with each weight being 48 bits long. It is defined by the following transformation:

$$S' = \left(\sum_{j=0}^{59} P_j W_j \right) mod\ 2^{48}$$

Where P is the pre-signature calculated by the Hashing Function, i.e. each bit of the pre-signature selects the corresponding weight for the Hard Knapsack function.

The result of the Hard Knapsack function is the 48-bit knapsack sum, S'.

144.6.3 Deletion Box

The Deletion Box removes the 8 least significant bits, i.e. bits 40 to 47, from the knapsack sum, S', to form the authentication signature, S. It has been shown that the least significant bits are too weak from a cryptanalysis standpoint.

144.6.4 Signature Comparator

The Signature Comparator compares the received signature, s, with the calculated signature, S, and presents the result to the Final Authorisation function of the Supervisor.

144.7 Final Authorisation

When the received signature (s) and the calculated signature (S) are found to be identical, the Final Authorisation function checks that the received LAC count is identical to the LAC count of the counter indicated by the received LAC ID. If these match, the used LAC counter is incremented by 1. Note that the LAC counter is incremented even if the segment contains a control command which is found to be incorrect.

If the telecommand segment was transferred on MAP 63, it is transferred to the Control Command Processor.

The Final Authorisation also generates a report on the output *auana*, outputs the MAP on *lastmap* and pulses *auanavalid* for one clock cycle.

144.8 Control Command Processor

The Control Command Processor executes the control commands used for changing the internal configuration of the TCAU. Any commands not conforming to the specified formats are reported as non-executable.

144.9 Control Commands

Before being executed, the following checks are performed on the control commands:

- The sequence flags of the segment header are verified to be 11b (unsegmented)

- The segment is verified to contain a valid control command

- The length of the segment is verified to comply with the expected length of the command

- The LAC ID for a "Set new LAC count value" command is verified to be 00b, 01b or 10b

- The start address of a "Change programmable key block B" command is verified to be less than 112

If a segment is transferred to the Control Command Processor and fails any of these checks, it is discarded and reported in *auana*.

The control commands are listed in table 2469. Table 2470, 2471 and 2472 shows the layout of the three groups of control commands.

Table 2469. Authentication Unit Control Commands

Group	Control Command Identifier	Command name
1	0000 0000	Dummy segment
	0000 0101	Select fixed key
	0000 0110	Select programmable key
	0000 0111	Load fixed key in programmable key memory
2	0000 1001	Set new LAC count value
3	0000 1010	Change programmable key block A
	0000 1011	Change programmable key block B

Table 2470. Group 1 control commands

Segment header	Control command identifier	Authentication tail
0xFF	00000***	LAC + Signature
1 octet	1 octet	9 octets

Table 2471. Group 2 control commands

Segment header	Control command identifier	LAC value to be set		Authentication tail
0xFF	00001001	LAC ID	LAC count	LAC + Signature
1 octet	1 octet	2 bits	30 bits	9 octets

*Table 2472.*Group 3 control commands

Segment header	Control command identifier	Start address	Key-specific pattern	Authentication tail
0xFF	0000101*			LAC + Signature
1 octet	1 octet	1 octet	7 octets	9 octets

144.9.1 Dummy segment

This control command is provided for testing purposes. It has no side effects when executed, but since it is authenticated, the LAC counters will be updated and a new report will be generated.

This command is authenticated with the currently selected key.

144.9.2 Select fixed key

If authentication is successful, the result of the command is that the fixed key will be used for subsequent segments.

This control command is always authenticated using the fixed key.

144.9.3 Select programmable key

If authentication is successful, the result of the command is that the programmable key will be used for subsequent segments.

This control command is always authenticated using the programmable key.

144.9.4 Load fixed key in programmable key memory

This control command will copy the weights and the coefficients of the fixed key to the programmable key.

This command is authenticated with the currently selected key.

144.9.5 Set new LAC count value

This command sets the value of either of the three LAC counters, as determined by the LAC ID identifier in the segment data field. If authentication is successful, the selected LAC will be loaded with the value specified in the LAC count field in the segment data. The new LAC value is set after Final Authorisation, which means that if the same LAC is used for authentication, it will get it's new value after being incremented.

This command is authenticated with the currently selected key.

144.9.6 Change programmable key block

There are two change programmable key commands:

- Command A is used to change blocks starting at the first 256 octets

- Command B is used to change blocks starting at the last 112 octets

These commands changes five octets of the programmable key, starting at the address defined by the start address field in the segment data.

Generation of the five octets to be written to the programmable key is accomplished as follows:

Once the segment has been authorised by the Final Authorisation, the segment except the signature is inverted and passed once more through the Authentication Processor. The 24 bits of virtual fill z are

GRIP

+46 31 7758650 | frontgrade.com/gaisler

inserted without being inverted. The resulting 40-bit pseudo-signature is then loaded into the programmable key memory as follows:

- Bits 32 through 39 of the "pseudo-signature" are loaded into the octet indicated by the start address field in Bank A or Bank B.

- Bits 24 through 31 of the "pseudo-signature" are loaded into the octet at the next higher address (i.e. at start address + 1)

- And so on, until bits 0 through 7 are loaded into the octet indicated by the (start address field + 4)

The organization of the programmable key for the purpose of this command is depicted in table 2473.

Table 2473. Programmable key organization

Bank	Address	Authentication key		
A	0	40	W0(40 to 47)	47
	1	32	W0(32 to 39)	39
	2	24	W0(24 to 31)	31
	3	16	W0(16 to 23)	23
	4	8	W0(8 to 15)	15
	5	0	W0(0 to 7)	7
	6	40	W1(40 to 47)	47
	7	32	W1(32 to 39)	39
	255	16	W42(16 to 23)	23
B	0	8	W42(8 to 15)	15
	103	0	W59(0 to 7)	7
	104		59 C(59 to 56)	56
	105	55	C(55 to 48)	48
	106	47	C(47 to 40)	40
	107	39	C(39 to 32)	32
	108	31	C(31 to 16)	24
	109	23	C(23 to 16)	16
	110	15	C(15 to 8)	8
	111	7	C(7 to 0)	0

144.10 Programmable Key Memory

The weights of the programmable key is stored in an internal memory in the TCAU, while the coefficients are stored in registers. The memory is protected by TMR, to avoid errors in the weights. To remove bit flips from the memories, the programmable key is scrubbed (cf. section 144.10.1)

144.10.1 Scrubber

The TCAU contains a scrubber that scrubs the programmable key memory whenever the core is idle. The scrubber reads each octet from the memory and writes them back unconditionally, thereby ensuring that all three memories get the same value.

144.11 Fixed Key

The fixed key is provided to the TCAU by means of the input signal *fixedkey*.

144.12 Back-end transmitter

The Back-end transmitter is a serial output that can be connected to a Segmentation sublayer. The TCAU can function without connecting the Back-end transmitter, if the Segmentation sublayer receives the segment independently from the TCAU, e.g. reads them from a memory. In this case, the authentication result signals from the Final Authorisation is sufficient for the Segmentation sublayer to determine if the segment is to be processed.

The Back-end transmitter receives octets directly from the Front-end receiver buffer.

144.12.1 Non-authenticated segments

Segments transmitted on non-authenticated MAPs or while the AU is disabled, are output independently of the Authentication Processor. In this case, the entire segment is transmitted on the serial link.

144.12.2 Authenticated data segments

For authenticated data segments, the Back-end transmitter transmits the segment in parallel with the authentication process, to avoid having to buffer the entire segment. To be able to remove the authentication tail from the segment, the Back-end transmitter always waits until the Front-end receiver buffer contains at least 10 octets or the Front-end receiver has received the entire segment. When the entire segment has been received and the buffer contains less than 10 octets, all of these belong to the authentication tail.

When the entire segment has been received, the Back-end transmitter waits until the Final Authorisation function has completed before completing the transfer. If the authorisation fails, the transfer is aborted and if the authorisation succeeds, the transfer is completed.

144.12.3 Control Commands

If a segment containing a control command is received, the Back-end transmitter consumes all data without transmitting any octets.

144.13 Cold start state

After reset, the TCAU is in the following state:

- Fixed key is in use
- Principal LAC and Auxiliary LAC are all ones
- Recovery LAC is *rlac_rstval_c*
- Programmable key is unknown

144.14 Registers

The core does not implement any memory mapped registers.

144.15 Implementation

144.15.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core implements a separate generic for selecting between synchronous and asynchronous reset and resets all registers in both configurations.

144.16 Configuration options

Table 2474 shows the configuration options of the core (VHDL generics).

Table 2474. Configuration options

Generic	Function	Allowed range	Default
tech	Selects technology for the programmable key memory.	0 - NTECH	inferred
syncrst	Enable synchronous reset.	0 - 1	0
ft	Enable fault-tolerance against SEU errors. The core can optionally be implemented with fault-tolerance against SEU errors in the programmable key memory. The fault-tolerance is enabled through the ft VHDL generic to 1. If ft is set to 1, TMR memories will be implemented.	0-1	0

144.17 Signal descriptions

Table 2475 shows the interface signals of the core (VHDL ports).

Table 2475. Signal descriptions

Signal name	Field	Type	Function	Description	Active
RST_N	N/A	Input	Synchronous reset		Low
ARST_N	N/A	Input	Asynchronous reset		Low
CLK	N/A	Input	Clock		-
TLCRI	BEGINS	Input	Data unit start	Pulses when a new segment is to be sent from the transfer sublayer.	High
	PROGRESSES		In progress	High throughout the segment transfer.	High
	COMPLETES		End of data	Pulses to indicate the successful completion of a segment transfer.	High
	ABORTS		Abort data unit	Pulses to indicate the erroneous completion of a segment transfer.	High
	REQUEST		Data valid strobe	Pulses to transmit a new octet to the TCAU from the transfer sub-layer.	High
	DATA		8-bit data	Segment data	-
TLCRO	ACCEPTING	Output	Ready for segment	Indicates that the TCAU is idle and can accept a new segment. When this output transits from low to high, it indicates that a segment has been fully processed, including any control command processing.	High
	BUSY		Not ready for octet	Indicates that the TCAU is ready to receive a new octet in an ongoing segment.	High

145 GRTC_HW - CCSDS/ECSS Telecommand Decoder - Hardware Commands

This IP core is only available as part of a design service.

145.1 Overview

145.1.1 Concept

The Telecommand Decoder - Hardware Commands provides access to an output port via telecommands.

The decoder implements the following layers:

- Application Layer:

  - Hardware command decoding and execution

- Space Packet Protocol:

  - Packet Extraction

  - Path Recovery

- Data Link - Protocol Sub-Layer:

  - Virtual Channel Packet Extraction

  - Virtual Channel Reception:

    - Support for Command Link Control Word (CLCW)

  - Virtual Channel Demultiplexing

  - Master Channel Demultiplexing

  - All Frames Reception

- Data Link - Synchronization and Channel Coding Sub-Layer:

  - Pseudo-Derandomization

  - BCH codeblock decoding

  - Start Sequence Search

- Physical Layer:

  - Non-Return-to-Zero Level/Mark de-modulation (NRZ-L/M)

The Channel Coding Sub-Layer and the Physical Layer are shared with the Telecommand Decoder and are therefore not repeated here.

145.2 Operation

In the Application Layer and the Data Link - Protocol Sub-Layer, the information octets from the Channel Coding Sub-Layer are decoded as follows.

145.2.1 All Frames Reception

The All Frames Reception function performs two procedures:

- Frame Delimiting and Fill Removal Procedure; and

- Frame Validation Check Procedure, in this order.

The Frame Delimiting and Fill Removal Procedure is used to reconstitute Transfer Frames from the data stream provided by the Channel Coding Sub-Layer and to remove any Fill Data transferred from the Channel Coding Sub-Layer. The Frame Length field is checked to correspond to a fixed value as listed below. The number of information octets is checked to be a fixed number 21.

The Fill Data is checked to match the 0x55 pattern, or the corresponding pseudo-randomized pattern when pseudo-derandomization is enabled (pin configurable). Note that it is assumed that the Fill Data is <u>not</u> pseudo-randomized at the transmitting end.

The Frame Validation Checks procedure performs the following checks:

- Version Number is checked to be 0
- Bypass Flag is checked to be 1
- Control Command Flag is checked to be 0
- Reserved Spare bits are checked to be 0
- Spacecraft Identifier is compared with a pin configurable input value
- Virtual Channel identifier is compared with a pin configurable input value
- Frame Length field is checked to be a fixed value of 0000010011_b (i.e. 20-1)
- Frame Sequence Number is checked to be a fixed value of 0
- The Frame Error Control Field is checked to match the recomputed CRC value

145.2.2 Master Channel Demultiplexing

The Master Channel Demultiplexing is performed implicitly during the All Frames Reception procedure described above.

145.2.3 Virtual Channel Demultiplexing

The Virtual Channel Demultiplexing is performed implicitly during the All Frames Reception procedure described above.

145.2.4 Virtual Channel Reception

The Virtual Channel Reception supports Command Link Control Word (CLCW) generation and transfer to the Telemetry Encoder, according to the following field description.

- Control Word Type field is 0
- CLCW Version Number field is 0
- Status Field is 0
- COP in Effect field is 1
- Virtual Channel Identification is taken from pin configurable input value
- Reserved Spare field is 0
- No RF Available Flag is 0, but is overwritten by the Telemetry Encoder
- No Bit Lock Flag is 0, but is overwritten by the Telemetry Encoder
- Lockout Flag is 1
- Wait Flag is 0
- Retransmit Flag is 0
- FARM-B Counter is taken from the to least significant bits of a reception counter
- Reserved Spare field is 0
- Report Value field is 0

145.2.5 Virtual Channel Packet Extraction

The Virtual Channel Packet Extraction function extracts the Space Packet from the Frame Data Unit on the Virtual Channel, received from the Virtual Channel Reception function.

No blocking of Space Packets is permitted.

The Packet Version Number is checked to be 000, before delivered to the next function, else the Space Packet is discarded.

145.2.6 Path Recovery

The Path Recovery function receives and demultiplexes Space Packets received from the underlying subnetwork. The Path Recovery function receives Space Packets from the underlying subnetwork and demultiplex, if necessary, the received Space Packets on the basis of the Path Identifier of each Space Packet.

The Path Identifier is derived directly from the Application Identifier (APID) of the Space Packet, which is checked to be 00000000000, else the Space Packet is discarded.

Since the application layer uses the Octet String Service, the received Space Packets are delivered to the user through the Packet Extraction function described hereafter.

145.2.7 Packet Extraction

The Packet Extraction function extracts service data units from Space Packets. The Packet Extraction function extracts Octet Strings by stripping the Packet Primary Header, and the Packet Error Control field.

The following checks are performed before the Octet Strings (i.e. User Data Field) is forwarded to the Application Layer, else it is discarded:

• Packet Version field is 000_b

• Packet Type is 1_b

• Secondary Header Flagis 0_b

• Application Process identifer is compared with a pin configurable input value

• Sequence Flagsare 11_b

• Packet Data Length is 0000000000000110_b

The Packet Extraction Function does <u>not</u> check the continuity of the Packet Sequence Count, since Packet Name is used.

The Packet Extraction function verifies the correctness of the Packet Error Control field to match the recomputed CRC value (calculated over the complete Space Packet), if incorrect the Space Packet is not forwarded to the Application Layer, being discarded.

145.2.8 Application Layer

The Application Layer interprets only Transfer Frames that have successfully passed the Data Link Layer and Space Packet Protocol checks as described above.

The Application Layer interprets the Octet Strings (i.e. User Data Field) of the Packet Data Field.

The User Data Field consists of 5 octets comprising the hardware command, as defined in the bit order hereafter (MSB of first octet corresponds to OUTPUT(0), LSB of last octet corresponds to PULSE(7):

- OUTPUT(0 to 31) (32 bits in total)
- PULSE(0 to 7) (8 bits in total)

Before a hardware command is executed, the following is checked that:

- no hardware command is ongoing

The OUTPUT bits 0 to 31 correspond to the tcgpio[] bits 0 to 31.

The PULSE field has three interpretations: 0 to clear bits, 255 to set bits, 1 to 254 to generate pulses on bits:

- When PULSE field is 0, the corresponding bits that are <u>not</u> set in the OUTPUT field are cleared on the tcgpio outputs (AND function).
- When PULSE field is 255, the corresponding bits that are set in the OUTPUT field are set on the tcgpio outputs (OR function).
- When PULSE field is in the range 1 to 254, the corresponding bits that are set in the OUTPUT field are set on the tcgpio outputs for a duration of PULSE * 8192 system clock cycles, after which they are cleared again.

The tcgpio[0:31] outputs are cleared to logical 0 at reset.

146 GRTC_UART - CCSDS/ECSS Telecommand Decoder - UART

This IP core is only available as part of a design service.

146.1 Overview

A UART is used for the transmission of the CLTU from the telecommand decoder to the suer. The protocol has a fixed to baud rate, 1 star bit, 8 data bits, optional odd parity, 1 or 2 stop bits, with a BREAK command for message delimiting (sending 13 bits of logical zero).

The output contains the corrected information octets, which comprises the Telecommand Transfer Frame and any filler data octets. This is followed by the transmission of a BREAK command.

Note: The Telecommand Decoder Coding Layer does not inspect the contents of the corrected information octets. All corrected information octets are output on the UART interface.

146.2 Asynchronous bit serial data format

The asynchronous bit serial interface complies to the data format defined in [EIA 232]. It also complies to the data format and waveform shown in table 2485 and figure 357. The interface is independent of the transmitted data contents. Positive logic is considered for the data bits. The number of stop bits can optionally be either one or two. The parity bit can be optionally included.

Asynchronous bit serial format	start	D0	D1	D2	D3	D4	D5	D6	D7	parity	stop	stop
first		*lsb*							*msb*			*last*
General data format $i = \{0, n\}$		$8*i+7$	$8*i+6$	$8*i+5$	$8*i+4$	$8*i+3$	$8*i+2$	$8*i+1$	$8*i$			
		last							*first*

147   GRTCTX - CCSDS/ECSS Telecommand Transmitter

This IP core is only available as part of a design service.

147.1   Overview

The CCSDS/ECSS/PSS Telecommand Transmitter implements part of the Data Link Layer, covering the Protocol Sub-layer and the Frame Synchronization and Coding Sub-layer and part of the Physical Layer of the packet telecommand protocol.

The operation of the Telecommand Transmitter is highly programmable by means of control registers.

The Telecommand Transmitter comprises several encoders and modulators implementing the Consultative Committee for Space Data Systems (CCSDS) recommendations, European Cooperation on Space Standardization (ECSS) and the European Space Agency (ESA) Procedures, Standards and Specifications (PSS) for telecommand and channel coding. The Telecommand Transmitter comprises the following:

- Frame Error Control Field (FECF)
- Pseudo-Randomiser (PSR) / Bit Transition Generator (BTG)
- Communications Link Transmission Unit (CLTU)
  - Start Sequence insertion
  - Bose-Chaudhuri-Hocquenghem (BCH)
  - Tail Sequence insertion
- Physical Layer Operations Procedures (PLOP-1, PLOP-2)
- Non-Return-to-Zero Mark/Level (NRZ)

147.3 Layers

147.3.1 Introduction

The relationship between Packet Telecommand (or simply Telecommand or TC) standard and the Open Systems Interconnection (OSI) reference model is such that the OSI Data Link Layer corresponds to two separate layer, namely the Data Link Protocol Sub-layer and Synchronization and Channel Coding Sub-Layer. The OSI Data Link Layer is covered here.

The OSI Physical Layer is also covered here to some extended, as specified in [ECSS04] and [PPS107]. The OSI Network Layer or higher layers are not covered here.

147.3.2 Data Link Protocol Sub-layer

The following functionality is implemented in the core:

•   All Frame Generation:

•Frame Error Control Field (FECF) calculation and insertion

147.3.3 Synchronization and Channel Coding Sub-Layer

The following functionality is implemented in the core:

- Pseudo-Randomiser (PSR) / Bit Transition Generator (BTG)
- Communications Link Transmission Unit (CLTU)
    - Start Sequence insertion
    - Bose-Chaudhuri-Hocquenghem (BCH)
    - Tail Sequence insertion

147.3.4 Physical Layer

The following functionality is implemented in the core:

- Physical Layer Operations Procedures (PLOP-1, PLOP-2)
- Non-Return-to-Zero (NRZ) modulation

147.4 Operation

147.4.1 Introduction

The DMA interface provides a means for the user to send blocks of data of arbitrary length, normally this is Communications Link Transmission Units (CLTU).

147.4.2 Descriptor setup

The DMA interface is used for sending data on the uplink. The transmission is done using descriptors located in memory. A single descriptor is shown in tables 2491 through 2494. The address field of the descriptor should point to the start of the data to be sent. The address need not be word-aligned. If the interrupt enable (IE) bit is set, an interrupt will be generated when the transfer has completed (this requires that the interrupt enable bit in the control register is also set). The interrupt will be generated regardless of whether the transfer was successful or not. The wrap (WR) bit is also a control bit that should be set before transmission and it will be explained later in this section.

Table 2491.GRTCTX descriptor word 0 (address offset 0x0)

31		16	15		8	7	6		4	3	2	1	0
	LEN			RESERVED		UR		SEL		-	WR	IE	EN

31: 16	(LEN) - Length in bytes (note that maxium length is limited to 2048 bytes, and minimum to 2 bytes)
15: 8	RESERVED
7:	Underrun (UR) - Underrun detected during transmission.
6: 4	Select output (SEL) - Select output for bit clock, bit lock and bit data (0 to 7)
3:	RESERVED
2:	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 16. The pointer automatically wraps to zero when the 16 kB boundary of the descriptor table is reached.
1:	Interrupt Enable (IE) - an interrupt will be generated when the data for this descriptor has been sent provided that the transmitter interrupt enable bit in the control register is set. The interrupt is generated regardless if it was transferred successfully or if it terminated with an error.
0:	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.

STATUS0	

31: 0   (STATUS0) - External status information

*Table 2494.*GRTCTX descriptor word 3 (address offset 0xC)
31	0
STATUS1	

31: 0   (STATUS1) - External status information

To enable a descriptor the enable (EN) bit should be set and after this is done, the descriptor should not be touched until the enable bit has been cleared by the core.

147.4.3 Starting transmission

Enabling a descriptor is not enough to start transmission. A pointer to the memory area holding the descriptors must first be set in the core. This is done in the descriptor pointer register. The address must be aligned to a 16 kByte boundary. Bits 31 to 14 hold the base address of descriptor area while bits 13 to 4 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the core, the pointer field is incremented by 16 to point at the next descriptor. The pointer will automatically wrap back to zero when the next 16 kByte boundary has been reached. The WR bit in the descriptors can be set to make the pointer wrap back to zero before the 16 kByte boundary.

The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when transmission is active.

The final step to activate the transmission is to set the enable bit in the DMA control register. This tells the core that there are more active descriptors in the descriptor table. This bit should always be set when new descriptors are enabled, even if transmission is already active. The descriptors must always be enabled before the transmission enable bit is set.

147.4.4 Descriptor handling after transmission

When the transmission has finished, status is written to the first word in the corresponding descriptor. The other bits in the first descriptor word are set to zero after transmission while the second word is left untouched. The enable bit should be used as the indicator when a descriptor can be used again, which is when it has been cleared by the core. Additionally, the last two words in the corresponding descriptor are written with external status information.

There are multiple bits in the DMA status register that hold status information.

The Transmitter Interrupt (TI) bit is set each time a DMA transmission ended successfully. The Transmitter Error (TE) bit is set each time an DMA transmission ended with an error. For either event, an interrupt is generated for descriptor for which the Interrupt Enable (IE) was set. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

GRIP

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The Transmitter AMBA error (TA) bit is set when an AMBA AHB error was encountered either when reading a descriptor or when writing data. Any active transmission was aborted and the DMA channel was disabled. It is recommended that the Telecommand Transmitter is reset after an AMBA AHB error. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

147.5 Registers

The core is programmed through registers mapped into APB address space.

148   GRCTM - CCSDS Time Manager

This IP core is only available as part of a design service.

148.1   Overview

The CCSDS Time Manager (GRCTM) provides basic time keeping functions such an Elapsed Time (ET) counter according to the Consultative Committee for Space Data Systems (CCSDS) Unsegmented Code specification, [CCSDS]. It comprises a Frequency Synthesizer (FS) by which a binary frequency is generated to drive the ET counter. The GRCTM provides support for setting the increment rate of the ET counter as well as of the FS counter.

The GRCTM provides datation services that sample the ET counter value on external events. It also provides generation of periodic pulses with cycle periods of less than one second. All services in the GRCTM core are accessible via an AMBA AHB slave interface.

The GRCTM provides a service for sampling the ET counter value on the occurrence of the time strobe generated by for example the Packet Telemetry Encoder (PTME), generating a Standard Spacecraft Time Source Packet according to the ESA Packet Telemetry Standard, [PSS]. The Time Source Packet can be read out via the AMBA AHB slave interface and is transmitted directly to a telemetry encoder via a serial interface.

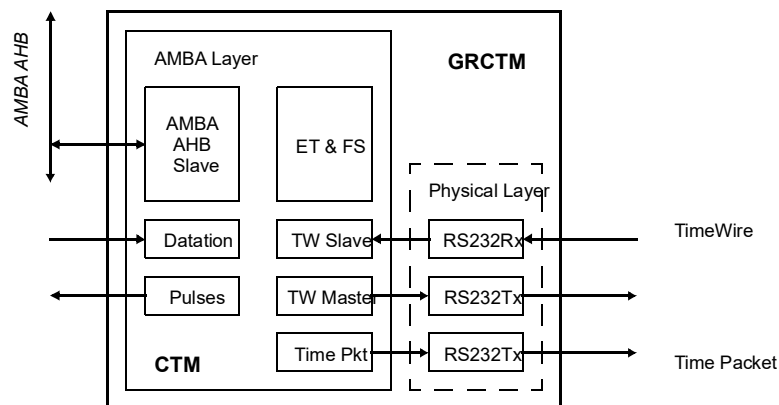
The GRCTM can act as a master and/or a slave in a time distribution system. As a master only, the GRCTM distributes the ET to GRCTM slaves via a TimeWire (TW) interface. As a slave only, the GRCTM receives the ET via the TimeWire interface. When acting as a master and slave, the GRCTM receives the ET from a master GRCTM, but can also distribute the ET to other slaves.


Figure 361. Block diagram

148.1.1 Foreseen usage of the core

On-board time maintenance and distribution is to be handled through a master CCSDS Time Manager (GRCTM) and one or more slave GRCTMs. Using a dedicated synchronisation line (TimeWire), the slave time manager can be synchronised with the master GRCTM. The slave GRCTM can further distribute the time to the payload. The GRCTM slaves will thus be slaved to the master GRCTM, but also act as masters for other modules. This isolates the master GRCTM from the payloads. The slave GRCTM provides four datation register into which the Elapsed Time (ET) counter can be latched on the occurrence of an external triggering event.

It is not possible to synchronise or set the ET counter in the master GRCTM. The ET counter can only be cleared by means of hardware or software reset.

148.1.2 Description of a general system using the core

The general approach to accurately maintaining on-board time is to have a central time reference measuring the elapsed time from an arbitrary epoch and to distribute regularly this time information to on-board applications by means of messages and synchronisation pulses. Another approach would be to have a centralised time system, where each application that needs to time stamp data could request the unit maintaining the central time reference to provide the relevant time information. Such an approach would have several inherent drawbacks, e.g. in systems with many users, the accuracy of a time stamp could be jeopardised due to long service latency and excessive bus traffic could degrade the overall performance of the data handling system.

The purpose of the GRCTM is to provide a building block for such time distribution services by providing the means for CCSDS compliant time keeping and a set of basic user time services. Most time distribution implementations have required support from the application processor to maintain synchronisation between the central and the local time references. Protocols and formats for distributing time information have differed between spacecraft and have sometimes only provided low resolution or poor accuracy. The purpose of the GRCTM is to provide an accurate time coherence throughout the spacecraft.

The correlation between the central time reference and ground has already been foreseen by providing a time strobe from the Packet Telemetry encoder. The time strobe has a deterministic relationship to the bit structure of the telemetry frame. This makes it possible to establish the time relation between the assertion of this time strobe on-board and the reception of the relevant frame on ground, taking into account the down link propagation delay. Each GRCTM instance maintains its own copy of the central elapsed time reference with which on-board applications can time stamp their data. This unbroken chain of time relationships on-board, and between the spacecraft and ground, provides a solution to the problem of knowing when an event took place on-board in any given space-time frame.

The GRCTM is foreseen to be used both as a central elapsed time reference in the spacecraft data management system, as well as the local elapsed time reference in an instrument or other subsystem. By using standardised AMBA interfaces, the integration of the GRCTM should be simple for most systems.

148.1.3 Functions not included

The GRCTM does not support alarm services.

The GRCTM does not support setting of an arbitrary epoch time.

148.2 Data formats

All Elapsed Time (ET) information handled by GRCTM is compliant with the CCSDS Unsegmented Code defined in [CCSDS] and repeated hereafter.

148.2.1 Reference documents

[CCSDS]   Time Code Formats, CCSDS 301.0-B-4, www.ccsds.org

[PSS]   Packet Telemetry Standard, ESA PSS-04-106, Issue 1, January 1988

148.2.2 CCSDS Unsegmented Code: Preamble Field (P-Field)

The time code preamble field (P-Field) may be either explicitly or implicitly conveyed. If it is implicitly conveyed (not present with T-Field), the code is not self-identified, and identification must be

obtained by other means. As presently defined, the explicit representation of the P-Field is limited to one octet whose format is described hereafter.

Table 2510. CCSDS Unsegmented Code P-Field definition

Bit	Value		Interpretation
0	0		Extension flag
1 - 3	"001"	1958 January 1 epoch (Level 1) [1]	Time code identification
	"010"	Agency-defined epoch (Level 2) [1]	
4 - 5	(number of octets of coarse time) - 1		Detail bits for information on the code
6 - 7	(number of octets of fine time)		

1 *For the Standard Spacecraft Time Source Packet defined in the ESA Packet Telemetry Standard, bits 1 to 3 must are set to 010_b.*

148.2.3 CCSDS Unsegmented Code: Time Field (T-Field)

For the unsegmented binary time codes described herein, the T-Field consists of a selected number of contiguous time elements, each element being one octet in length. An element represents the state of 8 consecutive bits of a binary counter, cascaded with the adjacent counters, which rolls over at a modulo of 256.

Table 2511. CCSDS Unsegmented Code T-Field definition

CCSDS Unsegmented Code													
Preamble	Time Field												
Field	Coarse time								Fine time				
-	2^{31}	2^{24}	2^{23}	2^{16}	2^{15}	2^{8}	2^{7}	2^{0}	2^{-1}	2^{-8}	2^{-9}	2^{-15}	2^{-16}	2^{-24}

The basic time unit is the second. The T-Field consists of 32 bits of coarse time (seconds) and 24 bits of fine time (sub seconds). The coarse time code elements are a count of the number of seconds elapsed from the epoch. The 32 bits of coarse time results in a maximum ambiguity period of approximately 136 years. Arbitrary epochs may be accommodated as a Level 2 code. The 24 bits of fine code elements result in a resolution of 2-24 second (about 60 nanoseconds). This code is not UTC-based and leap second corrections do not apply according to CCSDS.

Figure 363. Pulse generation waveform

148.3 Operation

The CCSDS Time Manager (GRCTM) synthesizable core can be configured for various purposes. The different functions presented hereafter can be used to from a GRCTM to act as a master, slave, or master and slave.

148.3.1 Elapsed Time (ET)

The local Elapsed Time (ET) counter is based on a default 32 bit coarse time field and a 24 bit fine time field, complying to the CCSDS Unsegmented Code (CUC) T-Field. The width of the two time fields is fixed. The counter implementing the ET is incremented on the system clock only when enabled by the frequency synthesizer described below. The ET is incremented with a pre-calculated increment value, which matches the synthesised frequency. The local ET is output in the CUC format, P-Field and T-Field, to be used by an application embedding the GRCTM. The P-Field is static with the Time Code Identifier is set to 010b.

148.3.2 Frequency Synthesizer (FS)

The binary frequency required to determine the ET counter increment is derived from the system clock using a frequency synthesizer. The frequency synthesizer is incremented with a pre-calculated increment value, which matches the available system clock frequency. The FS simply generates a tick every time it wraps around, which makes the ET to step forward with the pre-calculated increment value. The output of the frequency synthesizer is used for enabling the increment of the local ET as described above. A 24 to 32 bit wide FS causes a systematic drift of less than 1 second/day.

148.3.3 TimeWire Interface (TW)

The GRCTM provides two TimeWire (TW) interfaces, one for the master function and one for the slave function. The TimeWire interface is used for distributing the Elapsed Time (ET) of a GRCTM master to one or more GRCTM slaves. The information carried in the synchronisation message comprises the Elapsed Time Field, which is 4 bytes, and a synchronisation pulse which is sent as a BREAK command. The synchronisation pulse is used for synchronising both the ET and the phase of the Frequency Synthesiser (FS) and is done once every second.

The GRCTM slave automatically synchronizes its ET with that of the GRCTM master without requiring any user support. A GRCTM that acts both as a master and a slave will be slaved to another master via a slave TimeWire interface, and will simultaneously distribute its own ET to other GRCTM slaves. The GRCTM slave will continue to work undisturbed in case a GRCTM master has failed. It is also possible to disable the synchronisation by means of a register further to avoid failure propagation. The TimeWire interface provides means for synchronising a GRCTM slave from a GRCTM that acts both as a master and a slave, which being synchronised in turn from another GRCTM master.

The message is sent just before the synchronisation instance. A BREAK command is sent just after the message to indicate the synchronisation pulse. The instance of the synchronisation actually depends on the reception of the BREAK command and the time it takes to generate an internal pulse

GRIP
Apr 2024, Version 2024.1
2180
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

in the receiver on which the previously sent message is latched into the ET counter of the slave. The baseline is to send the synchronisation message and pulse to coincide with the wrap around of the sub-second bits in the ET. However, the time at which the message is sent out from the master is configurable by means of a generic (based on the fine part of the ET). An additional generic is provided for the fine tuning of the message start. On the slave side, a generic is provided to set the fine part of the ET at which the synchronisation pulse will occur. It is thus possible to synchronise the two units at any arbitrary point in time, provided it is done once a second.

To tolerate large skew and drift differences between the clocks driving the master and the slave GRCTM, a staged approach has been taken for the distribution of the synchronisation message and the synchronisation pulse. The first GRCTM master in a time chain synchronises its GRCTM slaves before it is time for these to act as masters and in turn send their synchronisation messages and pulses to their slaves. This is done to avoid that the first GRCTM master will synchronise the GRCTM slaves in such a way that no synchronisation messages are being sent out from these GRCTM due to clock drift. Since the synchronisation only occurs once a second, the first GRCTM master in a time chain has one second of time available to synchronise its GRCTM slaves before they synchronise their slaves in turn.

The TimeWire interface is based on a bit asynchronous interface (RS232/422) with the following programmable specification:

- 115200 baud (configured by generics/register bits)

- 1 start bit, 8 bit data, 1 or 2 stop bits (configured by generics/register bit)

- odd parity is generated in transmitter, but ignored in the receiver (configured by generics/register bit)

- no handshake

- message delimiting via BREAK command (13 bits when sent)

- synchronisation via BREAK command (13 bits when sent)

Table 2512. TimeWire transmission protocol

Byte Number	Elapsed Time Coarse Register (ETCR)	CCSDS Unsegmented Code Time Field Coarse Part		Comment
First	[31:24]	2^{31}	2^{24}	
Second	[23:16]	2^{23}	2^{16}	
Third	[15:8]	2^{15}	2^{8}	
Fourth	[7:0]	2^{7}	2^{0}	
Fifth	N/A	[RS232 Break Command]		Used as synchronisation pattern

Note that it is not possible for the TimeWire to carry sub-second phase information due to the usage of the above RS232/422 type of interface.

148.3.4 Datation

The GRCTM comprises three datation registers for the purpose of datation of user events relative the ET counter. The datation is triggered by three external edge sensitive inputs (programmable rising or falling edge).

A fourth datation register is provided for sampling the ET counter when generating a Standard Spacecraft Time Source Packet as described below.

Each of the three general datation services is automatically disabled after an occurrence and is not re-enabled until the corresponding fine time register is read. The format of all four datation registers is compliant to the CUC T-Field.

GRIP
Apr 2024, Version 2024.1

2181

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The ET counter can be accessed directly via the AMBA AHB interface. This can be used for direct datation from software.

148.3.5 Interrupts

The GRCTM provides individual interrupt lines for the incoming datation inputs, the time strobe input and the occurrence of the individual pulse outputs. The interrupt lines are asserted for at least two system clock cycles and can be connected to an external interrupt controller. The interrupts indicate that a new datation value can be read. The interrupts defined in table 2513 are generated.

Table 2513. Interrupts

Interrupt offset	Interrupt name	Description
1:st	DRL0	Datation Register 0 Latched
2:nd	DRL1	Datation Register 1 Latched
3:rd	DRL2	Datation Register 2 Latched
4:th	STL	Spacecraft Time Register Latched
5:th	PULSE0	Pulse 0 interrupt
6:th	PULSE1	Pulse 1 interrupt
7:th	PULSE2	Pulse 2 interrupt
8:th	PULSE3	Pulse 3 interrupt
9:th	PULSE4	Pulse 4 interrupt
10:th	PULSE5	Pulse 5 interrupt
11:th	PULSE6	Pulse 6 interrupt
12:th	PULSE7	Pulse 7 interrupt
13:th	ETSET	ET set (only when VHDL generic gSetET is 1)

148.3.6 Pulses

The GRCTM provides eight external outputs used for clock pulse distribution. The timing of each pulse output is individually derived from the Elapsed Time counter. It is possible to program for each pulse output individually the following parameters:

- periodicity pulse
- width of pulse
- polarity of pulse
- enable/disable pulse generation (reset status is disabled)

The pulse has two parts, the active and the inactive part. The active part always starts the pulse, followed by the inactive part. The polarity or logical level of the active part is programmable. The inactive part takes the logical inversion of the active pulse, and is the default output from the generator when the pulse is not issued or the overall generation is disabled. The leading edge of the active pulse part is aligned with the 1 second transition of the Elapsed Time counter.

The periodicity of the pulse corresponds to one of the ET bits that can be selected in the range 2^7 to 2^{-8} seconds, providing a range from 128 seconds to 3,91 ms, i.e. 0,0078 to 256 Hz frequency. See register definition for details.

The width of the active part of the pulse corresponds to one of the ET bits that can be selected in the range 2^6 to 2^{-9} seconds, providing a range from 64 seconds to 1,95 ms. See register definition for details.

It is possible to generate a pulse that has a duty cycle of 50%. It is also possible to generate a pulse for which the active part is as short as 2^{-9} seconds, and its period is as high as 2^7 seconds. The effective duty cycle can be as low as $2^{-9}/2^7$ for the longest period, up to 50% for the shortest period of 2^{-8} sec-

GRIP
Apr 2024, Version 2024.1
2182
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

onds = 256 Hz. The duty cycle choice becomes more restricted as the frequency increases. Note that it is only possible to reduce the duty cycle in one direction: 50%/50%, 25%/75% ... 1%/99%. The active part of the pulse can thus never be more than 50% of the cycle. It should be noted that the active pulse width must be at most 50% of the pulse period. This is a requirement on the software usage.

The pulse outputs are guaranteed to be spike free. If the re-synchronisation of the GRCTM in slave mode occurs within 0,5 ms of the expected synchronisation instance, the ongoing pulse output width will be accurate to within 0,5 ms. Else, the pulse output will remain unchanged corresponding to up to four times the expected output width.

If a pulse output is disabled by means of writing to the corresponding register (PDRx) (i.e. writing a zero to the Pulse Enable bit (PE)), the pulse output will be immediately driven to the inversion of the Pulse Level bit (PL), which corresponds to the level of the inactive part of the pulse. It is thus possible to modify immediately the pulse output by disabling it using the PE bit and then changing the PL bit, since the output will always drive the inversion of the PL bit while disabled.

148.3.7 Standard Spacecraft Time Source Packet

As mentioned above, the GRCTM comprises one datation register for sampling the ET counter when generating a Standard Spacecraft Time Source Packet according to the ESA Packet Telemetry Standard, AD2, according to the following programmable bit asynchronous protocol specification:

- 115200 baud (configured by generics/register bit)
- 1 start bit, 8 bit data, 1 or 2 stop bits (configured by generics/register bit)
- odd parity is generated (configured by generics/register bit)
- no handshake (note that there is a BUSY signal for internal handshake, that can block the generation of additional packets)
- message delimiting via BREAK command (13 zero bits when sent)

The Spacecraft Time Coarse Register (STCR) and the Spacecraft Time Fine Register (STFR) are available for readout of the datation time from the software. The software cannot block or initiate a datation on these registers, since controlled from an external input pin. If multiple datation have

13	T-Field (2^{-9} to 2^{-16})	
14	T-Field (2^{-17} to 2^{-24})	

Table 2515. Time sample rate

Bit	Rate (in frames)	Bit	Rate (in frames)
0000_b	1	0101_b	32
0001_b	2	0110_b	64
0010_b	4	0111_b	128
0011_b	8	1000_b	256
0100_b	16	others	undefined

148.3.8 AMBA AHB slave interface

All time services, including the Elapsed Time counter in the embedded GRCTM core, are clocked by the AMBA AHB clock HCLK. All input signals are assumed to be synchronous with the AMBA AHB interface clock HCLK. No input signal synchronisation is performed in the core. All outputs are synchronous with the AMBA AHB interface clock.

The AMBA AHB slave interface supports 32 bit wide data input and output. Since each access is a word access, the two least significant address bits are assumed always to be zero. Only address bits 23:0 are decoded. Note that address bits 31:24 are not decoded and should thus be handled by the AHB arbiter/decoder. The address input of the AHB slave interfaces is thus incompletely decoded. Misaligned addressing is not supported. One wait state is introduced for read and write accesses.

When the CCSDS field is narrower than the AMBA data width, zeros are padded to the right. Remapping between the opposing numbering conventions in the CCSDS and AMBA documentation is performed automatically. For read accesses, unmapped bits are always driven to zero.

The interface provides direct access to the T-Field of the ET counter.

The AMBA AHB interface has been reduced in function to support only what is required for the GRCTM. The following AMBA AHB features are constrained:

+46 31 7758650 | frontgrade.com/gaisler

- Only supports HSIZE=WORD, HRESP_ERROR generated otherwise
- Only supports HMASTLOCK='0', HRESP_ERROR generated otherwise
- Only supports HBURST=SINGLE and INCR, HRESP_ERROR generated otherwise
- No HPROT decoding
- No HSPLIT generated
- No HRETRY generated
- HRESP_ERROR generated for unmapped addresses, and for write accesses to register without any writeable bits
- Only big-endianness is supported.
- Frequency synthesis and time increment configuration

The increment values for the ET and FS counters depend on the implemented width of each counter and the frequency of the available on the system clock.

148.3.9 Miscellaneous

The accuracy of the transmission or reception baud rate of the bit asynchronous serial interface is dependent on the selected system frequency and baud rate. The number of system clock periods used for sending or receiving a bit is directly proportional to the integer part of the division of the system frequency with the baud rate.

The BREAK command received on the bit asynchronous serial interface is a sequence of logical zeros that is at least one bit period longer than the normal byte frame, i.e. start bit, eight data bits, optional parity, one or two stop bits. When transmitted, it is always 13 bits.

148.3.10 Numbering and naming conventions

Convention according to the CCSDS recommendations, applying to time structures:

- The most significant bit of an array is located to the left, carrying index number zero.
- An octet comprises eight bits.

Table 2516. CCSDS n-bit field definition

CCSDS n-bit field		
most significant		least significant
0	1 to n-2	n-1

Convention according to AMBA specification, applying to the APB/AHB interfaces:

- Signal names are in upper case, except for the following:
- A lower case 'n' in the name indicates that the signal is active low.
- Constant names are in upper case.
- The least significant bit of an array is located to the right, carrying index number zero.
- Big-endian support.

Table 2517. AMBA n-bit field definition

AMBA n-bit field		
most significant		least significant
n-1	n-2 down to 1	0

General convention, applying to all other signals and interfaces:

GRIP

- Signal names are in mixed case.
- An upper case '_N' suffix in the name indicates that the signal is active low.

148.4 Registers

The core is programmed through registers mapped into AHB I/O address space. Only 32-bit single-accesses to the registers are supported.

Legend:

[1]   The global system reset caused by the SRST-bit in the GRR-register results in the following actions:

- Initiated by writing a '1", gives '0' on read-back when the reset was successful.

- No need to write a '0' to remove the reset.

- Unconditionally, means no need to check/disable something in order for this reset-function to correctly execute.

- Could of course lead to data-corruption coming/going from/to the reset core.

Behaviour:

- Resets the complete core (all logic, buffers & register values)

 (except for the ET and FS counters which continue running undisturbed)

- Behaviour is similar to a power-up.

- This reset shall not cause any spurious interrupts

{Note that the above actions require that the HRESET signal is fed back inverted to HRESETn}

[2]   The channel reset results in the following actions:

Not implemented in Global Configuration Register.

[3]   This bit is sticky which means that it remains asserted until the corresponding STFR register is read at which time the bit is cleared. The corresponding registers should be read in the STCR – STFR order.

[4]   This bit is sticky which means that it remains asserted until the corresponding Defraud register is read at which point the bit is cleared. The corresponding registers should be read in the DCRx – DFRx order.

[5]   When ETCR is read, the ETFR register is latched and are not released until ETFR has been read. The registers should be read in the ETCR – ETFR order.

[6]   The coarse and fine time part of the register pair is latched on an external event and is released on reading the corresponding fine time register. No new event is accepted until the corresponding fine time register has been read.

[7]   The coarse and fine time part of the register pair is latched on an external event. No new event is accepted until the corresponding fine time register has been read. This does not prevent datations to occur and Standard Spacecraft Time Source Packet to be generated.

[8]   An AMBA AHB ERROR response is generated if a write access is attempted to a register which does not have any writeable bits.

[9]   The GSR.SARM bit is set when the SetETFR register is written to. It is cleared when an active high signal is detected on the CTMIN.SETET input, at which point the SetETCR and SetETFR contents are written to the ET counter (ETCR and ETFR) and the frequency synthesizer is reset. Only available when gSetET VHDL generic is set to 1.

148.4.25 Interrupt registers

The interrupt registers give complete freedom to the software, by providing means to mask interrupts, clear interrupts, force interrupts and read interrupt status.

When an interrupt occurs the corresponding bit in the Pending Interrupt Register is set. The normal sequence to initialize and handle a module interrupt is:

GRIP

Apr 2024, Version 2024.1

2196

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

- Set up the software interrupt-handler to accept an interrupt from the module.

- Read the Pending Interrupt Register to clear any spurious interrupts.

- Initialize the Interrupt Mask Register, unmasking each bit that should generate the module interrupt.

- When an interrupt occurs, read the Pending Interrupt Status Register in the software interrupt-handler to determine the causes of the interrupt.

- Handle the interrupt, taking into account all causes of the interrupt.

- Clear the handled interrupt using Pending Interrupt Clear Register.

Masking interrupts: After reset, all interrupt bits are masked, since the Interrupt Mask Register is zero. To enable generation of a module interrupt for an interrupt bit, set the corresponding bit in the Interrupt Mask Register.

Clearing interrupts: All bits of the Pending Interrupt Register are cleared when it is read or when the Pending Interrupt Masked Register is read. Reading the Pending Interrupt Masked Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register. Selected bits can be cleared by writing ones to the bits that shall be cleared to the Pending Interrupt Clear Register.

Forcing interrupts: When the Pending Interrupt Register is written, the resulting value is the original contents of the register logically OR-ed with the write data. This means that writing the register can force (set) an interrupt bit, but never clear it.

Reading interrupt status: Reading the Pending Interrupt Status Register yields the same data as a read of the Pending Interrupt Register, but without clearing the contents.

Reading interrupt status of unmasked bits: Reading the Pending Interrupt Masked Status Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register, but without clearing the contents.

The interrupt registers comprise the following:

- Pending Interrupt Masked Status Register[PIMSR]R

- Pending Interrupt Masked Register[PIMR]R

- Pending Interrupt Status Register[PISR]R

- Pending Interrupt Register[PIR]R/W

- Interrupt Mask Register[IMR]R/W

- Pending Interrupt Clear Register[PICR]W

148.6 Configuration options

Table 2544 shows the configuration options of the core (VHDL generics).

Table 2544. Configuration options

Generic	Function	Description	Allowed range	Default
GRLIB AMBA plug&play settings				
hindex	AHB slave index		Integer	0
hirq	AHB slave interrupt		Integer	0
singleirq	Single interrupt	Enable interrupt registers	Integer	0
ioaddr	IO area address		0 - 16#FFF#	0
iomask	IO area mask		0 - 16#FFF#	16#FFF#
syncrst	synchronous reset		0 - 1	0
Features settings				
gProgrammable	Programmable	ET and FS increment, and TimeWire	0 - 1	0
gExternal	External support	Support for external synchronization input	0 - 1	0
gMaster	Master CTM support		0 - 1	0
gSlave	Slave CTM support		0 - 1	0
gDatation	Datation support		0 - 1	0
gPulse	Pulse support		0 - 1	0
gTimePacket	Time Packet support		0 - 1	0
gSetET	Set ET support	Register from which ET is set on next. input	0 - 1	0
Frequency synthesizer and Elapsed Time counter settings				
gFrequency	Frequency Synthesizer	Defines the accuracy of the synthesized reference time, the wider the synthesizer the less drift is induced.	2 - 32	30
gETIncrement	Increment of ET counter	Defines with what value the Elapsed Time counter is to be incremented each time when the Frequency Synthesizer wraps around. The ET increment needs to match the synthesized frequency.	Integer	4
gFSIncrement	Increment of FS counter	Defines increment value of the Frequency Synthesizer which is added to the counter every system clock cycle. It defines the frequency of the synthesized reference time. Should match ET increment.	Integer	135107990
TimeWire settings				
gTWStart	ETF at msg start	ET Fine at start of message [1]	Integer	16#FFE330#
gTWAdjust	Adjust phase of msg	System clock based tuning of message start	Integer	5
gTWTransmit	ETF at transmission	ET Fine at synchronisation (master) [1]	Integer	16#000000#
gTWRecieve	ETF at reception	ET Fine at synchronisation (slave) [1] [2]	Integer	16#FFE000#
gDebug	Debug when set	Only used for TW settings adjustments.	0 - 1	0
Asynchronous bit serial interface settings (TimeWire and Time Packet)				
gSystemClock	System frequency	System clock frequency [Hz]	Integer	33333333
gBaud	Baud rate	[Baud]	Integer	115200
gOddParity	Odd parity	Odd parity generated, but not checked	0 - 1	0
gTwoStopBits	Number of stop bits	0=one stop bit, 1=two stop bits	0 - 1	0

148.7 Signal descriptions

Table 2545 shows the interface signals of the core (VHDL ports).

Table 2545. Signal descriptions

Signal name	Field	Type	Function	Description	Active
HRESETn	N/A	Input	Reset	Resets the ET & FS in the VHDL core. The signal is assumed synchronous with rising HCLK edge.	Low
CRESETn	N/A	Input	Reset	Resets all logic but the ET & FS in the VHDL core. The signal is assumed synchronous with rising HCLK edge.	Low
HCLK	N/A	Input	Clock		-

*Table 2545.*Signal descriptions

Signal name	Field	Type	Function	Description	Active
CTMIN	TWSLAVE	Input	TimeWire slave	TimeWire input	-
	DATATION		Datation input	The inputs are sampled on rising HCLK edge.	-
	TIMEMODE		Time rate select	Selects the rate of the time strobe periodicity	-
	TIMESTROBE		Time strobe input		-
	TIMEBUSY_N		Time packet busy		Low
	EXTERNALTIME		Elapsed Time	ET coarse [31:0] & ET fine [-1:-24]	-
	EXTERNALSYNC		Synchronization		High
	SETET		Set ET	Pulse to set ET from reg.	High
CTMOUT	TWMASTER	Output	TimeWire master	TimeWire output	
	PULSES		Pulse outputs	The outputs are driven on rising HCLK edge.	-
	TIMEPKT		Time packet data		-
	ELAPSEDTIME		Elapsed Time	ET coarse [31:0] & ET fine [-1:-24]	-
	ELAPSEDNEXT		Next Elapsed Time	ET coarse [31:0] & ET fine [-1:-24]	-
	ELAPSEDEVENT		ET increment		High
	ELAPSEDSYNC		Synchronisation		High
AHBIN	*	Input	AMB slave input signals		-
AHBOUT	*	Output	AHB slave output signals		-
	HIRQ(hirq+12)		Interrupts	ETSET output	Location on HIRQ bus depends on *hirq* generic. If *hirq*=0, no interrupt will be generated. If *singleirq*=1 only one common interrupt will be generate using *hirq*.
	HIRQ(hirq+11)			PULSES(7) output	
	HIRQ(hirq+10)			PULSES(6) output

148.8 Signal definitions and reset values

The signals and their reset values are described in table 2546.

Table 2546. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
twmaster	Output	UART transmit data line	-	Logical 1
twslave	Input	UART receive data line	-	-
pulses	Output	Pulse output	-	Logical 0
datation	Input	Datation input	-	-
timemode	Input	Time rate select	-	-
timestrobe	Input	Time strobe input	-	-
timepkt	Output	Time packet data	-	Logical 0
timebusy_n	Input	Time packet busy	-	Low

148.9 Timing

The timing waveforms and timing parameters are shown in figure 364 and are defined in table 2547.
Figure 364. Timing waveforms

Table 2547. Timing parameters

Name	Parameter	Reference edge	Min	Max	Unit
t_{GRCTM0}	clock to output delay	rising *clk* edge	TBD	TBD	ns
t_{GRCTM1}	input to clock hold	rising *clk* edge	-	-	ns
t_{GRCTM2}	input to clock setup	rising *clk* edge	-	-	ns

Note: The inputs are re-synchronized internally. The signals do not have to meet any setup or hold requirements.

148.10 Library dependencies

Table 2548 shows libraries used when instantiating the core (VHDL libraries).

Table 2548. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions
TMTC	TMTC_Types	Signals, component	Signals and component declaration

148.11 Instantiation

This example shows how the core can be instantiated.

148.12 Configuration tuning

The gFrequency generic defines the width of the Frequency Synthesiser (FS). The greater the width, the smaller the drift induced. The gFSIncrement generic defines with what value the FS counter should be incremented to obtain a synthesized frequency that matches the least significant bit of the Elapsed Time (ET) counter, normally being $2**24$ Hz. It is also possible to synthesize a frequency less than $2**24$ Hz, which will require the gETIncrement generic to have a higher value than the default 1.

The gETIncrement generic defines with what value the ET counter should be incremented. The specified value is added to the current ET counter value. The addition is done to the least significant bit in the fine part of the ET counter, i.e. gETIncrement is multiplied with $2**-24$ before the addition. The gETIncrement is normally set to 1, since the obtained synthesised frequency is normally $2**24$ Hz.

GRIP

Apr 2024, Version 2024.1

2204

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

For lower frequencies, the gETIncrement generic must be larger than 1. Note that the synthesized frequency must always be a power of two.

The following paragraphs define synchronization via the optional TimeWire master and slave interfaces.

The gTWStart generic defines at what time the transmission of the TimeWire message should start on the TWMaster output. The gTWStart value corresponds to the ET counter fine part assuming 24 bit resolution. E.g. 16#FFE330# corresponds to bit 2**-1 to 2**-24. The gTWAdjust generic defines the number of HCLK periods that should pass between the gTWStart time has occurred and the TimeWire message should be sent. This allows for fine grained adjustment of the starting point for the TimeWire message.

The gTWTransmit generic defines the ET fine part value that is transmitted virtually to the slave. Its only consequence is to decide whether the ET coarse part to be sent in the TimeWire message should be the same as the current ET in the master or be incremented by one second. The gTWRecieve generic defines the ET fine part value that should be loaded into the ET at synchronisation. Normally this will be 0 for slave only applications of the GRCTM.

When the gDebug generic is 1, the ET counter reset will be 0x000000 for the coarse part and 0xFF0000 for the fine part (assuming CUC 32 & 24 bit resolution). This achieves an ET synchronisation early in a simulation without the need to wait for a second of simulation time.

148.12.1 Master configuration

The master configuration is used for the source of the time chain and supports the following features:

- Frequency Synthesizer (FS) and Elapsed Time (ET) counters
- Master TimeWire interface
- Datation by means of direct read out of the ET counter via AMBA AHB interface

The following register are available in this configuration: GRR, GCR, GSR, ETCR, ETFR.

149   SPWCUC - SpaceWire - CCSDS Unsegmented Code Transfer Protocol

This IP core is only available as part of a design service.

149.1   Overview

This interface implements the SpaceWire - CCSDS Unsegmented Code Transfer Protocol (CUCTP), providing automatic SpaceWire Time-Code transmission and reception, and automatic CUCTP packet reception. It also provides support for CUCTP packet transmission.

The SpaceWire - CCSDS Unsegmented Code Transfer Protocol interface (SPWCUC) is assumed to operate in an AMBA bus system where AMBA APB bus is present. The AMBA APB bus is used for configuration, control and status handling. The interface is tightly coupled with the CCSDS Time Manager (GRCTM) and the SpaceWire codec with AHB host Interface and RMAP target (GRSPW2).

149.2   Protocol

The SpaceWire - CCSDS Unsegmented Code Transfer Protocol (CUCTP) provides synchronization between Elapsed Time (ET) counters in the local node and remote nodes, by means of SpaceWire Time-Codes and SpaceWire packets. The time format conforms to the CCSDS Unsegmented Code format.

Table 2552. SpaceWire - CCSDS Unsegmented Code Transfer Protocol

Destination Logical Address	Protocol Identifier	CCSDS Unsegmented Code									CRC	EOP
		P-Field		T-Field								
		1st	2nd	Coarse Time				Fine Time				
				2^{31} 2^{24}	2^{23} 2^{16}	2^{15} 2^8	2^7 2^0	2^{-1} 2^{-8}	2^{-9} 2^{-16}	2^{-17} 2^{-24}		*weight*
		0 7	8 15	0 7	8 15	16 23	24 31	32 39	40 47	48 55		*index*
8 bits	8 bits	8 bits	8 bits	8 bits	8 bits	8 bits	8 bits	8 bits	8 bits	8 bits	8 bits	*no. of bits*

SpaceWire Time-Codes are continuously transmitted from a master node to all slave nodes. The transmission of the Time-Codes is synchronized with the local ET counter in the master node. The six bits of the Time-Code time information correspond to six bits of the local ET counter (its exact mapping being programmable by means of register access). The ET bits with lower weights than the size bits mapped to the Time-Code time information bits are all zero at time of Time-Code transmission.

When a Time-Code is received in a slave node, the Time-Code time information is first verified to be an increment of the previously received time-information. The event of the Time-Code reception is assumed to occur synchronously with the local ET counter in the slave node. It is possible to allow a window of tolerance surrounding the exact time at which the reception event was expected. If the event was outside the window of tolerance a tolerance error has occurred and the no further synchronization is performed. Note that the check means that the ET counter bits with weights lower than the six ET bits mapped to the Time-Code time information are checked to have an expected value. This expected value is programmable by means of register access and should be seen as an offset from the all zero value (c.f. Time-Code transmission timing above). The check of the ET counter bits with the lower weights is done with respect to the expected value and the expected value -1 (see further down for the definition of -1). Thus, the ideal point at which a Time-Code can be received is just at the transition to the expected value. The window of tolerance means that a programmable number of ET bits with the lowest weights are ignored in the above comparisons. Note also that the window of tolerance is symmetrical around the expected value and that the -1 subtraction corresponds to the ET bit with the lowest weight that is not ignored due to the window of tolerance.

If the Time-Code reception event was within the window of tolerance, the time information is compared with the corresponding bits in the local ET counter. If there is a match then the two ET counters are considered to be synchronized. If there is a mismatch, then a synchronization error has occurred. Note that during synchronization only the six bits of the ET mapped to the Time-Code time informa-

tion bits are considered for synchronization. If no Time-Code is received within the window, then the local ET is considered to still be in synchronization but it is freewheeling on Time-Code level.

Additionally, whenever the Time-Code time information wraps from 0x3F to 0x00 it is possible to synchronize the ET bits that have a higher weight than the bits mapped to the Time-Code time information bits. This is performed whenever a new CUCTP packet has been received preceding the reception of the Time-Code with the wrapping time information. If no such packet has been received, then the synchronization will be as described above, but with an increment of the ET bits with the higher weight. If a new and valid CUCTP packet has been received, then in addition to checking the six ET bits, the ET bits with a higher weight are compared with the corresponding ET bits received in the CUCTP packet. If there is a mismatch, then a wrapping error has occurred. If no packet has been received, then the local ET is considered to still be in synchronization but it is freewheeling on packet level.

To summarize, ET bits mapped to the Time-Code time information bits and ET bits with lower weight are checked for every Time-Code received; whilst ET bits with higher weight are checked when ever time information is wrapping. ET bits with lower weight can be offset from the all zero value. ET bits with the lowest weight can be ignored to form a window of tolerance.

Table 2553. Example of synchronization

CCSDS index	AMBA index	Weight	Time-Code mapping	Tolerance	Elapsed Time counter bits (T-Field)
0	31	2^{31}			Ideal synchronization point (OFFSET=0x00000000) / Window of tolerance
...	...	...			
17	14	2^{14}			
18	13	2^{13}			
19	12	2^{12}

149.3 Functionality

The interface implements the following functions:

- transmission of SpaceWire Time-Codes

- reception of SpaceWire Time-Codes

- reception of SpaceWire - CCSDS Unsegmented Code Transfer Protocol (CUCTP) packets

- verification of SpaceWire Time-Codes to be received within window of tolerance

- synchronization of SpaceWire Time-Codes time information with local Elapsed Time counter in CCSDS Time Manager (GRCTM) using its external synchronization interface

- synchronization of SpaceWire - CCSDS Unsegmented Code Transfer Protocol (CUCTP) packets with local Elapsed Time counter in CCSDS Time Manager (GRCTM) using its external synchronization interface, occurring on the wrapping of SpaceWire Time-Codes time information

- support for transmission of SpaceWire - CCSDS Unsegmented Code Transfer Protocol (CUCTP) packets

149.3.1 SpaceWire Time-Code transmission

SpaceWire Time-Code transmission is normally performed by a single master node in a system.

SpaceWire Time-Code transmission can be enabled by means of register access. SpaceWire Time-Codes can be transmitted simultaneously on one to four possible outputs, selectable by means of register access.

The six bits of the Time-Code time information are mapped to six bits of the local ET counter, by means of register access. The least significant time information bit [index 0] can be mapped to one of the 32 ET counter bits with the lowest weights.

When Time-Code time information is transmitted, an interrupt is generated (TickTx). If the Time-Code time information is wrapping from 0x3F to 0x00, an interrupt is generated (TickTxWrap).

149.3.2 SpaceWire Time-Code reception

SpaceWire Time-Code reception can be enabled by means of register access. SpaceWire Time-Codes can be received from one of four possible inputs, selectable by means of register access.

When SpaceWire Time-Code reception is enabled, the received Time-Code time information is checked to be an increment of the previously received Time-Code time information. If not, a Time-Code reception error interrupt is generated (TickRxError). If the received Time-Code time information is not an increment, then the received Time-Code time information is stored for the next comparison but is not used for further processing as described hereafter. If the received Time-Code time information is equal to the previously received Time-Code time information, then no action is taken and no interrupts are generated.

The Time-Code control flag can be checked to be "00", selectable by means of register access. If checking is enabled, control flag differing from "00" will generate a Time-Code reception error interrupt (TickRxError).

If the expected Time-Code time information (and optionally control flags) is received, an interrupt is generated (TickRx). If the Time-Code time information is wrapping from 0x3F to 0x00, an interrupt is generated (TickRxWrap). Both events qualify the Time-Code time information for further processing as described hereafter.

149.3.3 CCSDS Unsegmented Code Transfer Protocol (CUCTP) packet reception

SpaceWire - CCSDS Unsegmented Code Transfer Protocol packets can be automatically received when enabled by means of register access. General SpaceWire communication is performed by the

GRIP

GRSPW2 SpaceWire codec, which outputs received characters unfiltered to the SPWCUC interface. The SPWCUC interface implements the reception and checking of the CUCTP packet format.

Destination Logical Address (DLA) as per ECSS-E-ST-50-51C. Packets with non-matching DLA are discarded. The DLA is programmable in the range 0x00 to 0xFF by means of register access. The DLA can also be masked with a programmable mask pattern, by means of register access.

The Protocol Identifier as per ECSS-E-ST-50-51C. Packets with non-matching Protocol Identifier are discarded. The Protocol Identifier is programmable in the range 0x00 to 0xFF, as per ECSS-E-ST-50-51C, by means of register access.

Fixed and programmable bits of the P-Field are checked with expected values. The Detail bits for information on the code are fixed to "1111". The Time code identification is optionally compared to a programmable value, accessible through register access. Reserved bits for future use are checked to be fixed to "000000". If any of the bits of the received P-Field are incorrect, the packet is discarded and an error interrupt is generated (PktError).

The packet CRC is the same as for RMAP as per ECSS-E-ST-50-52C.

Packets with incorrect CRC are discarded and an error interrupt is generated (PktError).

Packet without an End-Of-Packet (EOP) or an Error-End-of-Packet (EEP) are discarded and an error interrupt is generated (PktError). Too long or too short packets are discarded and an error interrupt is generated (PktError).

A correctly received packet is considered for synchronization, and an interrupt is generated (PktRx). Note that the fully, partially or incorrectly received packet is accessible through register access.

149.3.4 Verification of Time-Codes to be received within tolerance

SpaceWire Time-Code reception can be enabled by means of register access.

The reception time offset is programmable by means of register access. The offset is always counted from the all zero value corresponding to the time at which the Time-Code transmission started. The programmable offset is 32 bit wide and corresponds to the ET bits with the lowest weight.

The window of tolerance is programmable by means of register access. Up to 31 least significant bits can be ignored during Time-Code event comparison with the local ET counter. Note that the window of tolerance is a binary coded window.

If a received Time-Code event is outside the window of tolerance an error interrupt is generated (ToleranceError) and no further synchronization check are attempted for this specific Time-Code. The status will indicate that the local ET is out of synchronization (InSync, FreeSync and FreePkt are cleared).

The window of tolerance should not have a larger width than half the offset. Note that bits in the offset can be masked and ignored by the window of tolerance and will then not be used in the comparison.

If no Time-Code is received within the window of tolerance, then the local ET is considered to still be in synchronization (InSync set) but it is freewheeling on Time-Code level (FreeSync set).

149.3.5 Synchronization via Time-Codes

Synchronization by means of Time-Code reception can be enabled by means of register access, and occurs on reception Time-Codes the window of tolerance as described above.

If the check passes, the status indicates that the local ET is in synchronization (InSync set) and an interrupt is generated (Sync).

If the check fails, an error interrupt is generated (SyncError). The status indicates that the local ET is out of synchronization (InSync, FreeSync and FreePkt are cleared).

If the received Time-Code time information was wrapping and no new CUCTP packet was previously received, then the status indicates that the local ET is freewheeling on packet level (FreePkt set).

149.3.6 Synchronization via CUCTP packets

Synchronization by means of CUCTP packets can be enabled by means of register access, and occurs on reception Time-Codes the window of tolerance as described above when the time information is wrapping. Only correctly received and checked CUCTP packet are considered for synchronization, which have bit 15 in the P-Field cleared (meaning synchronization).

If the check passes, the status indicates that the local ET is in synchronization (InSync set) and an interrupt is generated (Wrap).

If the check fails, an error interrupt is generated (WrapError). The status indicates that the local ET is out of synchronization (InSync, FreeSync and FreePkt are cleared).

149.3.7 Initialization via CUCTP packets

Initialization by means of CUCTP packets can be enabled by means of register access, and occurs on reception Time-Codes the window of tolerance as described above when the time information is wrapping. Only correctly received and checked CUCTP packet are considered for synchronization, which have bit 15 in the P-Field set (meaning initialization).

No other checks are performed. The status indicates that the local ET is in synchronization (InSync set) and an interrupt is generated (Init).

149.3.8 CCSDS Unsegmented Code Transfer Protocol (CUCTP) packet transmission support

CUCTP packet transmission is normally performed by a single master node in a system.

When a Time-Code has been transmitted with time information that is wrapping from 0x3F to 0x00, an interrupt is generated (TickTxWrap) which can be used as a starting point for software controlled generation and transmission of CUCTP packets. The next T-Field to be sent in the CUCTP packet can be read out by means of register access.

149.4 Data formats

All Elapsed Time (ET) information is compliant with the CCSDS Unsegmented Code defined in [CCSDS] and repeated hereafter.

149.4.1 Numbering and naming conventions

Convention according to the CCSDS recommendations, applying to time structures:

- The most significant bit of an array is located to the left, carrying index number zero.
- An octet comprises eight bits.

Table 2554. CCSDS n-bit field definition

CCSDS n-bit field		
most significant		least significant
0	1 to n-2	n-1

Convention according to AMBA specification:

- The least significant bit of an array is located to the right, carrying index number zero.
- Big-endian support.

Table 2555. AMBA n-bit field definition

AMBA n-bit field		
most significant		least significant
n-1	n-2 down to 1	0

[RMAP] Space engineering: SpaceWire - Remote memory access protocol, ECSS-E-ST-50-52C

149.4.3 CCSDS Unsegmented Code: Preamble Field (P-Field)

The time code preamble field (P-Field) may be either explicitly or implicitly conveyed. If it is implic- itly conveyed (not present with T-Field), the code is not self-identified, and identification must be obtained by other means. As presently defined, the explicit representation of the P-Field is limited to one octet whose format is described hereafter.

Table 2556. CCSDS Unsegmented Code P-Field definition

Bit	Value		Interpretation
0	"1"		Extension flag, P-Field extended with 2nd octet
1 - 3	"001"	1958 January 1 epoch (Level 1)	Time code identification
	"010"	Agency-defined epoch (Level 2)	
4 - 5	"11"	(number of octets of coarse time) - 1	Detail bits for information on the code
6 - 7	"11"	(number of octets of fine time)	
8	"0"		Extension flag, P-Field not extended with 3rd octet
9-14	"000000"	Don't care	Reserved for future use
15	"1"=Initialize,"0"=Synchronize		Initialization

Note: Revision 0 of the core used bit 8 for Initialize/Synchronize selection. Bit 15 is used from Revi- sion 1 and forward, since bit 8 has the meaning of an extension flag for a third octet.

149.4.4 CCSDS Unsegmented Code: Time Field (T-Field)

For the unsegmented binary time codes described herein, the T-Field consists of a selected number of contiguous time elements, each element being one octet in length. An element represents the state of 8 consecutive bits of a binary counter, cascaded with the adjacent counters, which rolls over at a modulo of 256.

Table 2557. CCSDS Unsegmented Code T-Field definition

CCSDS Unsegmented Code										
Preamble	Time Field									
Field	Coarse time						Fine time			
-	2^{31}	2^{24}	2^{23}	2^{16}	2^{15}	2^{8}	2^{7} 2^{0}	2^{-1} 2^{-8}	2^{-9} 2^{-15}	2^{-16} 2^{-24}
0:15	0						31	32		55

The basic time unit is the second. The T-Field consists of 32 bits of coarse time (seconds) and 24 bits of fine time (sub seconds). The coarse time code elements are a count of the number of seconds elapsed from the epoch. The 32 bits of coarse time results in a maximum ambiguity period of approx- imately 136 years. Arbitrary epochs may be accommodated as a Level 2 code. The 24 bits of fine code elements result in a resolution of 2-24 second (about 60 nanoseconds). This code is not UTC-based and leap second corrections do not apply according to CCSDS.

Interrupt registers

The interrupt registers give complete freedom to the software, by providing means to mask interrupts, clear interrupts, force interrupts and read interrupt status.

When an interrupt occurs the corresponding bit in the Pending Interrupt Register is set. The normal sequence to initialize and handle a module interrupt is:

- Set up the software interrupt-handler to accept an interrupt from the module.

- Read the Pending Interrupt Register to clear any spurious interrupts.

- Initialize the Interrupt Mask Register, unmasking each bit that should generate the interrupt.

- When an interrupt occurs, read the Pending Interrupt Status Register in the software interrupt-handler to determine the causes of the interrupt.

- Handle the interrupt, taking into account all causes of the interrupt.

- Clear the handled interrupt using Pending Interrupt Clear Register.

Masking interrupts: After reset, all interrupt bits are masked, since the Interrupt Mask Register is zero. To enable generation of a module interrupt for an interrupt bit, set the corresponding bit in the Interrupt Mask Register.

Clearing interrupts: All bits of the Pending Interrupt Register are cleared when it is read or when the Pending Interrupt Masked Register is read. Reading the Pending Interrupt Masked Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register. Selected bits can be cleared by writing ones to the bits that shall be cleared to the Pending Interrupt Clear Register.

Forcing interrupts: When the Pending Interrupt Register is written, the resulting value is the original contents of the register logically OR-ed with the write data. This means that writing the register can force (set) an interrupt bit, but never clear it.

Reading interrupt status: Reading the Pending Interrupt Status Register yields the same data as a read of the Pending Interrupt Register, but without clearing the contents.

Reading interrupt status of unmasked bits: Reading the Pending Interrupt Masked Status Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register, but without clearing the contents.

150   GRPW - PacketWire Interface

This IP core is only available as part of a design service.

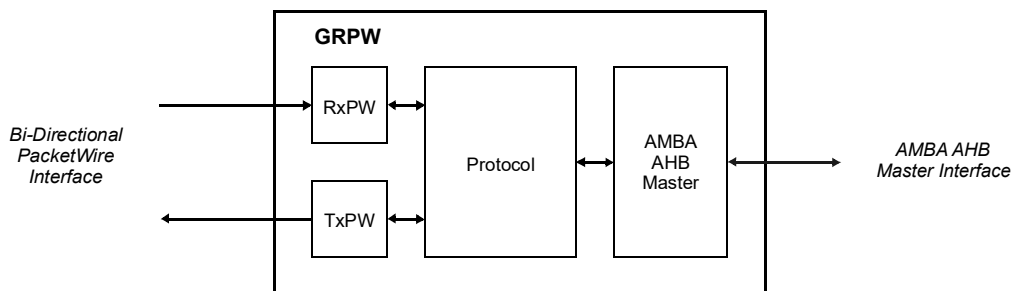
The *PacketWire to AMBA AHB Interface* (GRPW) comprises a bi-directional PacketWire link and an AMBA AHB master interface. The purpose of the interface is to allow read and write accesses on an AMBA AHB bus to be initiated from the PacketWire interface. The protocol allows single or multiple reads per command, each command specifying a read or write access, the number of word transfers and the starting address. For a write access, word oriented data is transmitted to the interface, and for read accesses word oriented data is received from the interface.


Figure 365. Block diagram

In a typical application, the PacketWire interface would be used as a remote control interface of a System-On-a-Chip device based around the AMBA AHB bus. An example could be a Packet Telemetry and Telecommand device which can be controlled remotely from a processor board via a PacketWire link. The link would provide both the capability to read and write registers, and to make block transfers to and from the target device and its memories.

This interface is based on the de facto standard PacketWire interface used by the *European Space Agency* (ESA). At the time of writing there were no relevant documents available from the *European Cooperation for Space Standardization* (ECSS).

150.1   Operation

150.1.1 Protocol

The communication protocol is based on the protocol used in the LEON processor. Commands are sent to the interface as messages over the bi-directional PacketWire interface. The protocol allows read and write accesses, as shown in table 2579. For each command, the number of 32-bit words to be transferred are specified, ranging from 1 to 64 words. For each command access, a 32-bit starting byte address is specified.

All transfers are assumed to be word aligned, effectively ignoring the two least significant bits of the address, assuming them to be both zero. There are no restrictions on the address, allowing a wrap around at the end of the address space during a transfer. The start address can thus be set to any position in the address space. The address is automatically incremented by 4 after each word access during

GRIP

a transfer. The address and data bit numbering in table 2579 correspond to the AMBA AHB bit numbering conventions.

Table 2579. Protocol on PacketWire side

	Control		Address				Data first word				second word				...	last word			
Cmd	Write																			
Octet	0		1	2	3	4	5	6	7	8	9	10	11	12	...	n-4	n-3	n-2	n-1

150.1.2 Bi-directional PacketWire interface

The bi-directional PacketWire interface comprises two PacketWire links, one in each direction, the PacketWire input link and the PacketWire output link. Each link comprises three ports for transmitting the message delimiter, the bit clock and the serial bit data. Each link also comprises an additional port for busy signalling, indicating when the receiver is ready to receive the next octet.

The interface accepts and generates the waveform format shown in figure 366.
Figure 366. Synchronous bit serial waveform

The PacketWire protocol follows the CCSDS transmission convention, the most significant bit being sent first, both for octet transfers (control), and for word transfer (address or data). Transmitted data should consist of multiples of eight bits otherwise the last bits will be lost. The input message delimiter port is used to delimit messages (commands). It should be asserted while a message is being input, and deasserted in between. In addition, the message delimiter port should define the octet boundaries in the data stream, the first octet explicitly and the following octets each subsequent eight bit clock cycles.

The maximum receiving input baud rate is defined as twice the frequency of the system clock input (f_{HCLK}). The maximum receiving throughput is limited by the AMBA AHB system into which this core is integrated. There is no lower limit for the input baud rate in the receiver. Note however that there are constraints on the input baud rate related to the automatic baud rate detection, as described hereafter.

The output baud rate is automatically adjusted to the incoming baud rate, provided that the incoming baud rate is less than half the frequency of the system clock input (f_{HCLK}). The lower limit for the input baud rate detection is $f_{HCLK}/512$. If the input baud rate is less than this limit, the output baud rate will equal $f_{HCLK}/512$. The input baud rate is determined by measuring the width of the logical one phase of the input bit clock.

GRIP
Apr 2024, Version 2024.1

2226

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The handshaking between the PacketWire links and the interface is implemented with busy ports, one in each direction. When a message is sent, the busy signal on the PacketWire input link will be asserted as soon as the first data bit is detected, it will then be deasserted as soon as the interface is ready to receive the next octet. This gives the transmitter ample time to stop transmitting after the completion of the first octet and wait for the busy signal deassertion before starting the transmission of the next octet. The handshaking is continued through out the message. At the end of message, the busy signal will be asserted until the completion of the message. For a write command, the busy signal will be deasserted after the completion of the AMBA AHB write access of the last word. For a read command, the busy signal will be deasserted after the completion of the AMBA AHB read access of the last word and its transmission on the PacketWire output link. It is therefore not possible for the external transmitter to send a new command until the previous has been completed.

Illegal commands are prevented from being executed. An illegal command is defined as a control octet for which the two most significant bits are neither 11_b nor 10_b. No accesses to the AMBA AHB bus will be performed and no response will be generated on the PacketWire link for a read command. A new command will be accepted as soon as the input message delimiter has been deasserted and a new command is transmitted.

A command can be aborted by prematurely deasserting the message delimiter on the PacketWire input link. This can be done at any point of the message, e.g. during the control octet, during the address or during the data transfer for write accesses. An aborted message will immediately terminate the access on the AMBA AHB bus. Note that it is not possible to predict whether or not the last word write access to the AMBA AHB bus has been completed or not in the case the message is aborted.

It is not possible to determine whether or not an access has been successfully completed on the AMBA AHB bus. For read accesses, a data response will be generated on the PacketWire output link independently of whether the AMBA AHB access was terminated with an *OKAY* or *ERROR*.

In the case an AMBA AHB access is not terminated because of indefinite *RETRY* or *SPLIT* responses, the command will not be completed and the busy port on the PacketWire input link will not be deasserted. This locked state can be observed by monitoring the response on the PacketWire input link, for which the busy signal will not be deasserted. For read accesses, this locked state can also determine if no data is received on the PacketWire output link. To overcome this locked stated, the message delimiter should be firstly deasserted on the PacketWire input linked. The message delimiter should then be asserted and a new control octet should then be transmitted, even though the busy port is asserted on the PacketWire input link. This action will abort any AMBA AHB accesses and restore the state of the interface. The newly started message should then be completed using the handshake method previously described. Note that it is not possible to determine at what time instant the abort will occur, possibly ruining the on going access. This is however acceptable considering being a recovery from a locked state.

150.1.3 AMBA AHB master interface

The AMBA AHB master interface has been reduced in functionality to support only what is required for the core. The following AMBA AHB features are constrained:

- only generates **HSIZE** = HSIZE_WORD
- only generates **HLOCK** = 0_b
- only generates **HPROT** = 0000_b
- only generates **HBURST** = HBURST_SINGLE
- never generates **HTRANS** = HTRANS_BUSY
- both **HRESP** = HRESP_OKAY and **HRESP** = HRESP_ERROR are treated as a successfully completed access
- both **HRESP** = HRESP_RETRY and **HRESP** = HRESP_SPLIT will result in a rescheduling the previous access until terminated with HRESP_OKAY or HRESP_ERROR

GRIP

Apr 2024, Version 2024.1

2227

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

- only big-endianness is supported

The interface can act as a default AHB master generating idle accesses when required. It only implements a single word access at a time, without bursts, to reduce complexity for retry and split handling, and not requiring the 1024 byte boundary imposed by the AMBA specification on burst transfers to be taken into account.

150.1.4 Advanced Microcontroller Bus Architecture

Convention according to the Advanced Microcontroller Bus Architecture (AMBA) Specification, applying to the AHB and APB interfaces:

- Signal and port names are in upper case, except for the following:

- A lower case '*n*' in the name indicates that the signal or port is active low.

- Constant names are in upper case.

- The *least* significant bit of an array is located to the *right*, carrying index number zero.

Table 2580. AMBA n-bit field definition

AMBA n-bit field		
most significant		least significant
n-1	n-2 down to 1	0

150.1.5 Consultative Committee for Space Data Systems

Convention according to the Consultative Committee for Space Data Systems (CCSDS) recommendations, applying to all relevant structures:

- The *most* significant bit of an array is located to the *left*, carrying index number zero, and is transmitted first.

- An octet comprises eight bits.

General convention, applying to signals, ports and interfaces:

- Signal or port names are in mixed case.

- An upper case '*_N*' suffix in the name indicates that the signal or port is active low.

Table 2581. CCSDS n-bit field definition

CCSDS n-bit field		
most significant		least significant
0	1 to n-2	n-1

150.2 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x032. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

150.3 Implementation

150.3.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual).

150.9 Instantiation

The core is an almost fully synchronous design based on a single system clock strategy. The asynchronous part is related to the PacketWire (PW) input interface, for which the receiving shift register is implemented as a separate clock domain. All signals going between clock domains are clocked twice before being used to reduce the risk for metastability.

All registers in the core are reset asynchronously. The reset input can be asserted asynchronously, but requires synchronous deassertion to avoid any recovery time violations.

The **PWI.Valid** input should be deasserted for at least 4 **HCLK** clock periods between messages. The **PWI.Data** input is clocked into a receiving shift register on the rising **PWI.Clk** edge. The **PWI.Clk** input should have a 50% duty cycle.

The **PWI.Busy_N** should be asserted as soon as possible by the receiver, allowing the transmitter to halt the transmission between octets. The input is synchronised using two registers clocked on the rising **HCLK** edge.

This example shows how the core can be instantiated.

151 GRPWRX - PacketWire Receiver

This IP core is only available as part of a design service.

151.1 Overview

The PacketWire Receiver implements a receiver function with Direct Memory Access (DMA) support. Packets (or blocks of data, normally CCSDS Space Packets) are automatically stored to memory, for which the user configures a descriptor table with descriptors that point to each individual packet or one or more packets stored in a fixed length fields (framing mode).

The core provides the following external and internal interfaces:

- Packet Wire interface (serial bit data, bit clock, packet delimiter, abort, ready, busy)
- AMBA AHB master interface, with sideband signals as per [GRLIB]
- AMBA APB slave interface, with sideband signals as per [GRLIB]

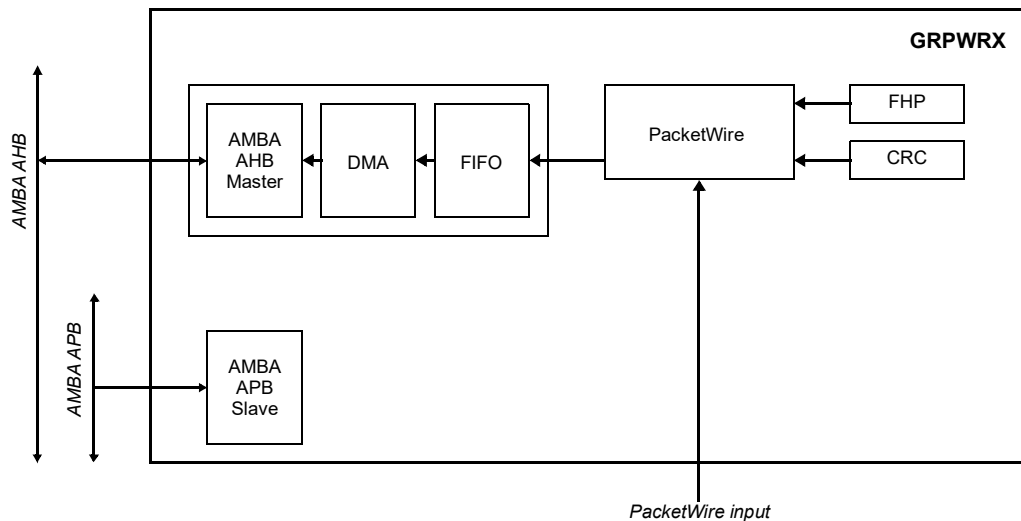
The operation of the receiver is highly programmable by means of control registers.


Figure 368. Block diagram

151.2 PacketWire interface

A PacketWire link comprises four ports for transmitting the message delimiter, the bit clock, the serial bit data and an abort signal. A link also comprises additional ports for busy signalling, indicating when the receiver is ready to receive the next octet, and for ready signalling, indicating that the receiver is ready to receive a complete packet. The waveform format shown in figure 369.

+46 31 7758650 | frontgrade.com/gaisler

The PacketWire protocol follows the CCSDS transmission convention, the most significant bit being sent first, both for octet transfers (control), and for word transfer (address or data). Transmitted data should consist of multiples of eight bits otherwise the last bits will be lost. The message delimiter port is used to delimit messages (commands). It should be asserted while a message is being input, and deasserted in between. In addition, the message delimiter should define the octet boundaries in the data stream, the first octet explicitly and the following octets each subsequent eight bit clock cycles. The delimiter should be de-asserted for at least eight bit periods between messages.

The handshaking between the PacketWire link and the interface is implemented with a busy port. When a message is sent, the busy signal on the PacketWire link will be asserted as soon as the first data bit is detected, it will then be deasserted as soon as the interface is ready to receive the next octet. This gives the transmitter ample time to stop transmitting after the completion of the first octet and wait for the busy signal deassertion before starting the transmission of the next octet. The handshaking is continued through out the message. At the end of message, the busy signal will be asserted until the completion of the message.

151.3 Operation

151.3.1 Introduction

The DMA interface provides a means for the user to receive blocks of data of arbitrary length (maximum 65535 bytes), normally these are packet structures such as CCSDS Space Packets. It also supports reception of one or more blocks of data into a fixed length field such as a CCSDS Telemetry Transfer Frame Data Field (framing mode).

151.3.2 Descriptor setup

The DMA interface is used for receiving data. The reception is done using descriptors located in memory. A single descriptor is shown in tables 2587 through 2588. The address field of the descriptor should point to the start of where the received data is to be stored. The address need not be word-aligned. If the interrupt enable (IE) bit is set, an interrupt will be generated when the transfer has completed (this requires that the interrupt enable bit in the control register is also set). The interrupt will be

GRIP

2233

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

generated regardless of whether the transfer was successful or not. The wrap (WR) bit is also a control bit that should be set before reception and it will be explained later in this section.

*Table 2587.*GRPWRX descriptor word 0 (address offset 0x0)

31 16	15 9	8	7	6 4	3	2	1	0
LEN	RESERVED	CERR	OV	RESERVED	FHP	WR	IE	EN

31: 16	(LEN) - Length in bytes (note that length is limited to 2048 bytes for framing mode)
	In packet mode, the LEN field is written by the hardware after the reception.
	In framing mode, the LEN field is written by the software before reception.
15: 9	RESERVED
8:	Cyclic Redundancy Code Error (CERR) - (read only) Set to one when a CRC error was detected in a packet (speculative, only useful if CRC is present in received packet)
7:	Overrun (OV) - (read only) Overrun detected during transmission.
6: 3	RESERVED
3:	First Header Pointer (FHP) - First Header Pointer to be stored (2 bytes)
2:	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 16. The pointer automatically wraps to zero when the 16 kB boundary of the descriptor table is reached.
1:	Interrupt Enable (IE) - an interrupt will be generated when data for this descriptor has been received provided that the receive interrupt enable bit in the control register is set. The interrupt is generated regardless if the data was transferred successfully or if it terminated with an error.
0:	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.

*Table 2588.*GRPWRX descriptor word 1 (address offset 0x4)

31   0
ADDRESS

31: 0	Address (ADDRESS) - Pointer to the buffer area to where data will be stored.

To enable a descriptor the enable (EN) bit should be set and after this is done, the descriptor should not be touched until the enable bit has been cleared by the core.

151.3.3 Packet mode

In packet mode, each descriptor corresponds to one received packet. The maximum length of a packet can be 65535 bytes. There is no check for too long packets. Reception of any too long packet will result in indeterministic behavior. The length of the received packet is automatically written into descriptor word 0.

151.3.4 Framing mode

In framing mode, each pair of descriptors correspond to one fixed length field as the CCSDS Telemetry Transfer Frame Data Field. The first descriptor defines the length (fixed for a field) and position in memory where the data is to be stored. The second descriptor in a pair defines the fixed length (2 bytes) and position of the memory where the First Header Pointer (FHP) calculated for the data received in a field belonging to the previous descriptor is to be stored. The First Header Pointer is calculated according to CCSDS: if the first packet starts at the beginning of the field then it is all zeros, if no packet starts in the field then it is all ones, any other location of the start of the first packet in a field is its count from the start of the field minus one. The First Header Pointer write-back is enabled by setting the FHP bit in the descriptor word 0. Normally the start location of First Header Pointer is two bytes in front of the field when CCSDS Telemetry Transfer Frames are used.

+46 31 7758650 | frontgrade.com/gaisler

151.3.5 Starting transmission

Enabling a descriptor is not enough to start transmission. A pointer to the memory area holding the descriptors must first be set in the core. This is done in the descriptor pointer register. The address must be aligned to a 16 kByte boundary. Bits 31 to 14 hold the base address of descriptor area while bits 13 to 4 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the core, the pointer field is incremented by 16 to point at the next descriptor. The pointer will automatically wrap back to zero when the next 16 kByte boundary has been reached. The WR bit in the descriptors can be set to make the pointer wrap back to zero before the 16 kByte boundary.

The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when reception is active.

The final step to activate the reception is to set the enable bit in the DMA control register. This tells the core that there are more active descriptors in the descriptor table. This bit should always be set when new descriptors are enabled, even if transmission is already active. The descriptors must always be enabled before the transmission enable bit is set.

151.3.6 Descriptor handling after transmission

When the reception of a packet (or field in framing mode) has finished, status is written to the first word in the corresponding descriptor, while the second word is left untouched. The other bits in the first descriptor word are set to zero after reception. The enable bit should be used as the indicator when a descriptor can be used again, which is when it has been cleared by the core.

If the Cyclic Redundancy Code (CRC) bit is set, a CRC calculated over all but the two last octets, will be checked and the results stored in the descriptor. The CRC is defined in CCSDS 132.0-B-1. This is not supported in framing mode.

There are multiple bits in the DMA status register that hold status information.

The Receiver Interrupt (RI) bit is set each time a DMA reception ended successfully. The Receiver Error (RE) bit is set each time an DMA reception ended with an error. For either event, an interrupt is generated for transfers for which the Interrupt Enable (IE) was set in the descriptor. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

The Receiver AMBA error (RA) bit is set when an AMBA AHB error was encountered either when reading a descriptor or when writing data. Any active reception was aborted and the DMA channel was disabled. It is recommended that the receiver is reset after an AMBA AHB error. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

151.4 Registers

The core is programmed through registers mapped into APB address space.

152   GRPWTX - PacketWire Transmitter

This IP core is only available as part of a design service.

152.1   Overview

The PacketWire Transmitter implements a transmit function with Direct Memory Access (DMA) suppport. Packets (or blocks of data, normally CCSDS Space Packets) are automatically fetched from memory, for which the user configures a descriptor table with descriptors that point to each individual packet.

The core provides the following external and internal interfaces:

*   Packet Wire interface (serial bit data, bit clock, packet delimiter, abort, ready, busy)

*   AMBA AHB master interface, with sideband signals as per [GRLIB]

*   AMBA APB slave interface, with sideband signals as per [GRLIB]

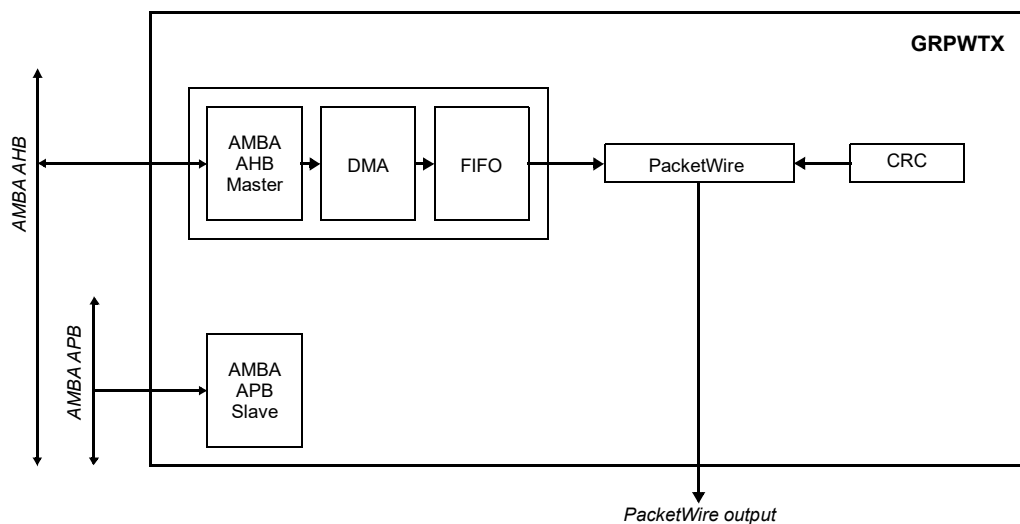
The operation of the transmitter is highly programmable by means of control registers.


Figure 371. Block diagram

152.2   PacketWire interface

A PacketWire link comprises four ports for transmitting the message delimiter, the bit clock, the serial bit data and an abort signal. A link also comprises additional ports for busy signalling, indicating when the receiver is ready to receive the next octet, and for ready signalling, indicating that the receiver is ready to receive a complete packet. The waveform format shown in figure 372.

The PacketWire protocol follows the CCSDS transmission convention, the most significant bit being sent first, both for octet transfers (control), and for word transfer (address or data). Transmitted data should consist of multiples of eight bits otherwise the last bits will be lost. The message delimiter port is used to delimit messages (commands). It should be asserted while a message is being input, and deasserted in between. In addition, the message delimiter port should define the octet boundaries in the data stream, the first octet explicitly and the following octets each subsequent eight bit clock cycles.

The handshaking between the PacketWire link and the interface is implemented with a busy port. When a message is sent, the busy signal on the PacketWire link will be asserted as soon as the first data bit is detected, it will then be deasserted as soon as the interface is ready to receive the next octet. This gives the transmitter ample time to stop transmitting after the completion of the first octet and wait for the busy signal deassertion before starting the transmission of the next octet. The handshaking is continued through out the message. At the end of message, the busy signal will be asserted until the completion of the message.

152.3 Operation

152.3.1 Introduction

The DMA interface provides a means for the user to send blocks of data of arbitrary length, normally these are packet structures such as CCSDS Space Packets.

152.3.2 Descriptor setup

The DMA interface is used for sending data on the uplink. The transmission is done using descriptors located in memory. A single descriptor is shown in tables 2602 through 2603. The address field of the descriptor should point to the start of the data to be sent. The address need not be word-aligned. If the interrupt enable (IE) bit is set, an interrupt will be generated when the transfer has completed (this requires that the interrupt enable bit in the control register is also set). The interrupt will be generated regardless of whether the transfer was successful or not. The wrap (WR) bit is also a control bit that should be set before transmission and it will be explained later in this section.

Table 2602. GRPWTX descriptor word 0 (address offset 0x0)

31 LEN 16	15 RESERVED 8	7 UR	6 RESERVED 4	3 CRC	2 WR	1 IE	0 EN

31: 16	(LEN) - length in bytes
15: 8	RESERVED
7:	Underrun (UR) - Underrun detected during transmission.
6: 4	RESERVED
3:	Cyclic Redundancy Code (CRC) - Insert CRC, overwriting the two last octets of a data block
2:	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 16. The pointer automatically wraps to zero when the 16 kB boundary of the descriptor table is reached.
1:	Interrupt Enable (IE) - an interrupt will be generated when the data from this descriptor has been sent provided that the transmitter interrupt enable bit in the control register is set. The interrupt is generated regardless if the data was transferred successfully or if it terminated with an error.
0:	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.

Table 2603. GRPWTX descriptor word 1 (address offset 0x4)

31 ADDRESS 0

31: 0	Address (ADDRESS) - Pointer to the buffer area to where data will be fetched.

To enable a descriptor the enable (EN) bit should be set and after this is done, the descriptor should not be touched until the enable bit has been cleared by the core.

152.3.3 Starting transmission

Enabling a descriptor is not enough to start transmission. A pointer to the memory area holding the descriptors must first be set in the core. This is done in the descriptor pointer register. The address must be aligned to a 16 kByte boundary. Bits 31 to 14 hold the base address of descriptor area while bits 13 to 4 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the core, the pointer field is incremented by 16 to point at the next descriptor. The pointer will automatically wrap back to zero when the next 16 kByte boundary has been reached. The WR bit in the descriptors can be set to make the pointer wrap back to zero before the 16 kByte boundary.

The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when transmission is active.

If the Cyclic Redundancy Code (CRC) bit is set, a CRC calculated over all but the two last octets, will be inserted overwriting the two last octets of a data block. The CRC is defined in CCSDS 132.0-B-1.

The final step to activate the transmission is to set the enable bit in the DMA control register. This tells the core that there are more active descriptors in the descriptor table. This bit should always be set when new descriptors are enabled, even if transmission is already active. The descriptors must always be enabled before the transmission enable bit is set.

152.3.4 Descriptor handling after transmission

When the transmission has finished, status is written to the first word in the corresponding descriptor. The other bits in the first descriptor word are set to zero after transmission, while the second word is left untouched. The enable bit should be used as the indicator when a descriptor can be used again, which is when it has been cleared by the core.

There are multiple bits in the DMA status register that hold status information.

The Transmitter Interrupt (TI) bit is set each time a DMA transmission ended successfully. The Transmitter Error (TE) bit is set each time an DMA transmission ended with an error. For either event, an interrupt is generated for which the Interrupt Enable (IE) was set in the descriptor. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

The Transmitter AMBA error (TA) bit is set when an AMBA AHB error was encountered either when reading a descriptor or data. Any active transmission was aborted and the DMA channel was disabled. It is recommended that the transmitter is reset after an AMBA AHB error. The interrupt is maskable with the Interrupt Enable (IE) bit in the control register.

153   PW2APB - PacketWire receiver to AMBA APB Interface

This IP core is only available as part of a design service.

153.1 Overview

The PacketWire to AMBA APB Interface implements the PacketWire protocol used by the Packet Telemetry Encoder (PTME) IP core and the Virtual Channel Assembler (VCA) device.

The core provides the following external and internal interfaces:

- Packet Wire interface (serial bit data, bit clock, packet delimiter, abort, ready, busy)
- AMBA APB slave interface, with sideband signals as per [GRLIB]

The core incorporates status and monitoring functions accessible via the AMBA APB slave interface. This includes:

- Valid and abort signalling from PacketWire interface
- Data overrun

Data is received on the PacketWire interface and read via the AMBA APB slave interface. It is possible to receive and read out one octet at a time.The packet delimiter and abort signals are observable via the control register, together with busy, ready and overrun signals. The baud rate is detected automatically and read via a configuration register.

153.2 PacketWire interface

A PacketWire link comprises four ports for transmitting the message delimiter, the bit clock, the serial bit data and an abort signal. A link also comprises additional ports for busy signalling, indicating when the receiver is ready to receive the next octet, and for ready signalling, indicating that the receiver is ready to receive a complete packet. The waveform format shown in figure 374.
Figure 374. Synchronous bit serial waveform

The PacketWire protocol follows the CCSDS transmission convention, the most significant bit being sent first, both for octet transfers (control), and for word transfer (address or data). Transmitted data should consist of multiples of eight bits otherwise the last bits will be lost. The message delimiter port is used to delimit messages (commands). It should be asserted while a message is being input, and deasserted in between. In addition, the message delimiter port should define the octet boundaries in the data stream, the first octet explicitly and the following octets each subsequent eight bit clock cycles.

The maximum receiving input baud rate is defined as twice the frequency of the system clock input (f_{CLK}). The maximum receiving throughput is limited by the AMBA system into which this core is integrated. There is no lower limit for the input baud rate in the receiver.

The handshaking between the PacketWire link and the interface is implemented with a busy port. When a message is sent, the busy signal on the PacketWire link will be asserted as soon as the first data bit is detected, it will then be deasserted as soon as the interface is ready to receive the next octet. This gives the transmitter ample time to stop transmitting after the completion of the first octet and

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

wait for the busy signal deassertion before starting the transmission of the next octet. The handshaking is continued through out the message.

To ensure that the receiver recognizes that the delimiter has been de-asserted, an application specific minimum time for the de-assertions should be imposed. Alternatively, ready signalling can be implemented in software, where the ready signal is asserted when the receiver software is ready to receive a packet, and is then immediately de-asserted when the first octet of a packet has been received. The transmitter software should thus only check the ready signal before starting to send a packet. This is illustrated in figure 375.

Figure 375. Handshake with ready signalling

To ensure that an abort is properly signalled, the abort signal should be de-asserted at the time the delimiter is asserted in the beginning of a packet, else the abort will be ignored. The abort signal should then be asserted while the delimiter is still asserted, to signal an abort to the receiver.

153.3 Registers

The core is programmed through registers mapped into APB address space.

154 APB2PW - AMBA APB to PacketWire Transmitter Interface

This IP core is only available as part of a design service.

154.1 Overview

The AMBA APB to PacketWire Interface implements the PacketWire protocol used by the Packet Telemetry Encoder (PTME) IP core and the Virtual Channel Assembler (VCA) device.

The core provides the following external and internal interfaces:

• Packet Wire interface (serial bit data, bit clock, packet delimiter, abort, ready, busy)

• AMBA APB slave interface, with sideband signals as per [GRLIB]

The core incorporates status and monitoring functions accessible via the AMBA APB slave interface. This includes:

• Busy and ready signalling from PacketWire interface

Data are transferred to the PacketWire interface by writing to the AMBA APB slave interface. It is possible to transfer one, two or four bytes at a time, following the AMBA big-endian convention regarding send order. Data are output serially on the PacketWire interface.The packet delimiter and abort signals are controlled, together with the data size, through the control register. The progress of the interface can be monitored via the AMBA APB slave interface, through the control register. The baud rate is set via a configuration register.

154.2 PacketWire interface

A PacketWire link comprises four ports for transmitting the message delimiter, the bit clock, the serial bit data and an abort signal. A link also comprises additional ports for busy signalling, indicating when the receiver is ready to receive the next octet, and for ready signalling, indicating that the receiver is ready to receive a complete packet. The waveform format shown in figure 377.
Figure 377. Synchronous bit serial waveform

The PacketWire protocol follows the CCSDS transmission convention, the most significant bit being sent first, both for octet transfers (control), and for word transfer (address or data). Transmitted data should consist of multiples of eight bits otherwise the last bits will be lost. The message delimiter port is used to delimit messages (commands). It should be asserted while a message is being input, and deasserted in between. In addition, the message delimiter port should define the octet boundaries in the data stream, the first octet explicitly and the following octets each subsequent eight bit clock cycles.

The handshaking between the PacketWire link and the interface is implemented with a busy port. When a message is sent, the busy signal on the PacketWire link will be asserted as soon as the first data bit is detected, it will then be deasserted as soon as the interface is ready to receive the next octet. This gives the transmitter ample time to stop transmitting after the completion of the first octet and wait for the busy signal deassertion before starting the transmission of the next octet. The handshaking is continued through out the message.

To ensure that the receiver recognizes that the delimiter has been de-asserted, an application specific minimum time for the de-assertions should be imposed. Alternatively, ready signalling can be imple-

155   AHB2PP - AMBA AHB to Packet Parallel Interface

This IP core is only available as part of a design service.

155.1   Overview

The AMBA AHB to Packet Parallel Interface implements the PacketParallel protocol used by the Packet Telemetry Encoder (PTME) IP core and the Virtual Channel Assembler (VCA) device.

The core implements the following functions:

- Packet Parallel protocol

- General Purpose Input Output port

The core provides the following external and internal interfaces:

- Packet Parallel interface (octet data, packet delimiter, write strobe, abort, ready, busy)

- AMBA AHB slave interface, with sideband signals as per [GRLIB]

- AMBA APB slave interface, with sideband signals as per [GRLIB]

The core incorporates status and monitoring functions accessible via the AMBA APB slave interface. This includes:

- Busy and ready signalling from Packet Parallel interface

- Read back of output data

- Interrupts on ready for new word, or ready for new packet

Data is transferred to the Packet Parallel interface by writing to the AMBA AHB slave interface, located in the AHB I/O area. Writing is only possible when the Packet Parallel packet valid delimiter is asserted, else the access results in an AMBA access error. It is possible to transfer one, two or four bytes at a time, following the AMBA big-endian convention regarding send order. The last written data can be read back via the AMBA AHB slave interface. Data are output as octets on the Packet Parallel interface.

In the case the data from a previous write access has not been fully transferred over the Packet Parallel interface, a new write access will result in an AMBA retry response. The progress of the interface can be monitored via the AMBA APB slave interface. An interrupt is generated when the data from the last write access has been transferred. An interrupt is also generated when the Packet Parallel ready indicator is asserted.

155.2   Interrupts

Two interrupts are implemented by the Packet Parallel interface:

Index:Name:Description:

0   NOT BUSYReady for a new data (word, half-word or byte)

1   READYReady for new packet

The interrupts are configured by means of the *pirq* VHDL generic.

155.3 Registers

The core is programmed through registers mapped into APB address space.

*Table 2635.*AHB2PP registers

APB address offset	Register
0x000	Configuration Register
0x004	Status Register
0x008	Control Register
0x010	Data Input Register
0x014	Data Output Register
0x018	Data Direction Register

155.3.1 Configuration Register (R/W)

*Table 2636.*0x000 - CONF - Configuration Register

31		3	0
RESERVED		WS	
0		0	
r		rw	

3-0:   WS   Number of additional Wait States

All bits are cleared to 0 at reset.

The width of the write strobe can be extended by mean of the WS field. The nominal asserted width is one system clock period (corresponding to WS=0). The asserted period can be extended up to a total asserted width of 16 system clock periods.

The minimum gap between octet write accesses when the strobe is de-asserted is one system clock period when WS={0, 3}, two when WS={4, 7}, three when WS={8, 11}, and four when WS={12, 15}.

155.3.2 Status Register)

*Table 2637.*0x004 - STAT - Status register

1b = output = driven

All bits are cleared to 0 at reset.

Note that the GPIO functionality can only be used when the Packet Parallel interface is disabled via the Control Register above.

155.4 AHB I/O area

Data to be transferred to the Packet Parallel interface is written to the AMBA AHB slave interface which implements a AHB I/O area. See [GRLIB] for details.

Note that the address is not decoded by the core. Address decoding is only done by the AMBA AHB controller, for which the I/O area location and size is configured by means of the *ioaddr* and *iomask* VHDL generics.

It is possible to transfer one, two or four bytes at a time, following the AMBA big-endian convention regarding send order. The last written data can be read back via the AMBA AHB slave interface. Data are output as octets on the Packet Parallel interface.

Table 2642. AHB I/O area - data word definition

156   GRRM - Reconfiguration Module

This IP core is only available as part of a design service.

156.1   Overview

The core processes different alarms and provides reconfiguration commands as outputs. When alarm conditions are matched the reconfiguration sequences are fetched from the external memory, these sequences are processed and output commands are provided specific to an alarm. The core operates in an AMBA bus system where both the AMBA AHB bus and the APB bus are present. The AMBA APB bus is used for configuration, control and status handling and the AMBA AHB Master is used to generate read and write access on the AMBA AHB bus.

156.2   Operation

According to the alarm activated and the current state of the core an alarm pattern is formed, the alarm pattern provides the address from which the reconfiguration sequences should be fetched. The AMBA AHB bus is used for retrieving the reconfiguration sequences in memory external to the core. The reconfiguration sequences consist of internal commands and external commands. The internal commands are processed by internal command processor which performs actions like masking the alarm that got activated and changing the state according to the internal commands. The external commands are formed into packets and sent to the command pulse distribution unit using PacketWire interface. The alarms can be logged to external memory along with the time instance at which the alarm is triggered. During initialization the core can configure itself or other systems available in the AHB bus.

*Figure 380.* Block diagram

156.3   Alarms

External alarms (external discrete signal inputs), watchdog timeout and software alarms (alarm triggered by processors or any other unit capable of writing the APB register space) are the alarm inputs.

Using watchdog and software alarms the core can monitor the processor module and using external alarms the core can monitor high-level system alarms for example low battery indicator. All alarms are individually maskable using the alarm mask AM register.

156.3.1 External alarms

The external alarm inputs are processed and an alarm event is generated when the input matches the conditions specified in the alarm monitoring unit. For external alarms the monitoring unit consist of mask AM, polarity AP and delay AD registers, these registers must be configured according to the requirement for a particular external alarm. An external input should pass the above mentioned condition and produces the alarm event which is registered as a pending event in the alarm pending AP register.

156.3.2 Watchdog timeout

Watchdog timeout: it is a down-counter that must be cyclically reloaded upon by the processor. If it is not reloaded an alarm event is triggered which is registered as a pending event in the alarm pending AP register. The corresponding mask AM register must be enabled.

156.3.3 Software alarms

The processor can trigger a software alarm event by configuring the register SWNP. The SWNP.SWPM0 register bits can be configured with a value corresponds to a particular software alarm. The value 0b000 is reserved and all other values trigger an alarm respectively (seven software alarm). The SWNP.EN bit must also be set to trigger the alarm.

The software alarms can also be used to check the functionality of the core by allocating one of the alarms to be self check alarm, the processor can trigger that alarm and expect the reconfiguration sequences to clear that alarm pending event. The reconfiguration sequence must also be configured according to the need.

The software alarm 0b001 has the highest priority and 0b111 has the lowest priority.

156.4 Alarm Pattern

Alarm pending AP register memorizes any alarm that has triggered an alarm event. Each alarm becomes a pending event. The reconfiguration sequences are selected according to the highest priority pending alarm event and the current state of the state machine. The highest priority is given to external alarms, followed by watchdog alarms and finally software alarms.

Alarm pattern is formed by concatenation of the priority vector (LSB) and the state machine output (MSB). This vector is used as a pointer to the first address of the reconfiguration sequence to be executed. On this basis, the reconfiguration sequences are read from the external memory and stored in the internal buffers for processing.

The core includes a state machine STAT.STATE register of which the state can be modified by the reconfiguration sequences. The updates to the state machine by reconfiguration sequence allows another reconfiguration sequence to be executed for the same alarm if a previous reconfiguration attempt did not remedy the alarm situation.

156.5 Reconfiguration Log

After occurrence of every alarm event, the alarm pattern is stored in a circular buffer (available in the external memory area) allocated for reconfiguration log. Only previous 16 patterns (alarm events) can be stored. The alarm log address ALA register specify the location where the log must be stored. Each

GRIP

Apr 2024, Version 2024.1

2267

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

log consist of 2 words. The log consist of time instance at which the alarm event occurred and the alarm pattern (state+alarm). The content of the log is shown in the table below.

Table 2647. Alarm Log Content

Word 1	Coarse Time (32 bits)	
Word 2	Fine Time (23 bits)	ALARM PATTERN (9 bits)

156.6   Reconfiguration Sequences

The reconfiguration sequences are fetched and stored into the internal buffers for an alarm event. The commands are processed one by one. Each reconfiguration sequence is made up of 64 Commands sent to Command Pulse Distribution Unit (CPDU) separated by delay and 64 commands for RM internal configuration (split into two - internal1 and internal2 of each containing 32 commands). The order of execution is internal1 commands, external commands followed by internal2 commands. The starting address of the initial (highest priority alarm) reconfiguration sequence location is provided by the RSA.SA register and for the other alarms the address from which the sequences are fetched is computed by the core itself using the particular alarm event and state of the alarm. A spreadsheet is provided along with this document to facilitate the configuration of these reconfiguration sequences, the output file from the spreadsheet can be used to load the reconfiguration sequences into an external memory.

GRIP

Apr 2024, Version 2024.1

2268

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

156.6.1 Internal commands

The internal 64 commands are split into 2 blocks each containing 32 commands. The internal commands will perform internal control of the RM like masking the alarm currently in process, changing the state machine value (to try different pattern or reconfigure). The table below list the commands.

Table 2648. Internal Commands

Command	Parameter (maximum 24 bits)	Code	Purpose
Clear all pending	No	0x00	Clear all pending alarms
Clear current pending	No	0x01	Clear current pending alarm
Mask all	No	0x02	Mask all alarms
Mask current	No	0x03	Mask current pending alarms
Unmask all	No	0x04	Unmask all alarms
Unmask current	No	0x05	Unmask current alarm
Rearm Watchdog Nominal	Yes (24 bit value)	0x06	Rearm watchdog with the value in the parameter
Rearm Watchdog Redundant	Yes (24 bit value)	0x07	Rearm watchdog with the value in the parameter
Delay	Yes (16 bit value)	0x08	Perform delay of processing according to the parameter value. The prescaler for this delay is taken from the CP register
Set state	Yes (4 bit value)	0x09	Set state according to parameter
Set active SGM	Yes (3 bit value)	0x0A	Set which safe guard memory (SGM) contains the active content. According to this the GSC.CONT registers are updated
Check alarm	Yes (4 bit value)	0x0B	Check that the alarm is not triggered again after a reconfiguration, if triggered again increment the state and perform another reconfiguration sequence. This must be used in combination with other internal commands (delay, pending mask). For example: clear the corresponding pending alarm, unmask the processed alarm, provide a delay (if needed to check that the alarm happens again) and finally provide the Check alarm command, the state will be incremented only when the alarm is still pending.
Processor Write protect	Yes (4 bit value)	0x0C	According to this value the PSC.PMWP registers are updated. The registers are driven as output signals and connected to the write protection unit
End internal command	No	0xFE	After this the internal command execution moves to the next stage (to external command if internal command 1 was processed or end of command processing if internal 2 was processed)
Do nothing	No	0xFF	Skip a command execution

156.6.2 External commands

The External commands are sent as CPDU packets using PacketWire interface.

The format of each external command is shown below and the format of the final packet generated is explained in the next section. If all the external commands are not needed for processing the external command execution can be stopped by setting the delay section (see below table) of the reconfiguration sequence to be 0xFFFE.

+46 31 7758650 | frontgrade.com/gaisler

Table 2649. External command format

31	16	15	4	3	2	0
Delay		PULSE		-	LEN	
-						

31: 16   Delay - Delay needed in between different external commands (resolution of 1 ms and configurable using the CP register)

15: 4   PULSE - Pulse output number

3   Reserved

2: 0   LEN - Pulse Length

156.7 CPDU Packet Generator

The external commands (PULSE and LEN in the above table) in the reconfiguration sequences are formed into CPDU Packets that contain one Command Instruction. These are sent as output on a PacketWire interface as TeleCommand segments.

The block that generates the CPDU packets uses the flowing input data: 11-bit Application Process ID (programmable through CC.APID register), 12-bit pulse output number and 3-bit pulse length (PULSE and LEN in the above table). The Segment is illustrated in the table below.

Table 2650. CPDU Segment.

Telecommand Segment													
Segment Header		Packet Header							Packet Data Field				
Seq. Flags	MAP Id.	Packet ID				Packet Seq Control		Packet Length	Command Instruction				Packet Error Control
		Version Number	Type	Data Filed Header Flag	Application Process ID	Seq. Flags	Seq. Count		Output No. LSB	Output No. MSB	Reserved	Pulse Length	
3	0	0	1	0	Configurable	3	Auto Incr.	3	Configurable	Configurable	0	Configurable	Enabled
2	6	3	1	1	11	2	14	16	8	4	1	3	
8		16				16		16	16				16

The sequence counter is automatically incremented after each packet

156.8 Initial Core Configuration

During initialization the core can configure itself or other systems available in the AHB bus. The Initial configuration address ICA.CA register specify the initial configuration base address. Each configuration consist of four word of information described in the table below.

Table 2651. Initial Configuration

Commands	Purpose
Address Source	Source from where the data must be fetched
Address Destination	Destination to where the data must be stored
Length in words (4 bytes)	number of words to be transferred. Always one more than the number specified here. (Zero means 1 and 31 means 32, maximum 512 bytes i.e. 128 words)
Pointer	Next command base address. Least significant bit specify next command is available or not. If more configurations need to be performed set the least significant bit must be set to'1' other wise '0'

The configuration must be performed before the initial delay before start of alarm monitoring ID.DELAY register pass out. This delay is provided for the external units and processor to set the alarm inputs at their right nominal state and thus ensure that untimely reconfiguration are not executed because the system is still booting.

156.9 Health Communication

The RM can send its role and health informations to another RM if an health link is available in between them. By default one of the RM is set to be the master and the other Slave. The CTRL.ACTMST register specify whether the RM is active or inactive.

The active master will set itself to be in execute state (after the initial delay timeout) and the inactive slave set itself to be in the monitor state. The health state is available in the health status HSTAT.HSTATE register. The master RM can send active message to the slave RM using the communication link. The HCTRL.COMM, HCTRL.TXEN and HCTRL.RXEN must be set in both RM to properly send and receive. The interval of the message transfer is configurable using HMSG register, similarly the timeout to receive the message for slave is configurable using HMTO register. If the health send and health message timeout is enabled then when the message is not received by the slave after the timeout the slave set itself to be master. The previous master RM set itself to be in inactive state and mask all the alarms. The redundant RM will set itself to be master and process any pending alarm. The redundant RM move from monitor to execute state.

Similar to this the health alarm timeout HATO register can be configured, in this case when an alarm is not processed for a long time the active RM set itself to be inactive and send a message to the redundant RM to go active. If the health alarm timeout is enabled in the slave then redundant RM set itself to be active and set the other to be inactive.

By using the HCTRL.FORCE register the state of active and inactive RM can be changed. The force can move an RM from execute to inactive state and inactive to execute state. Using the HCTRL.FORCE the RM can also move from monitor to execute state.

156.10 RM Error

The following errors can occur in the RM unit which are updated in the RME register, Init error IER - the initial delay (before start of alarm monitoring) timed out before the configurations are completed, Log write error LOGER - error writing the alarm log, Initial configuration read error CRER, Initial configuration write error CWER and Sequence Read Error SEQER - Error in reading the reconfiguration sequences after an alarm event. RM Error (RMER) - This field will go high when any of the above error occurs. The errors can be cleared by writing '1' to the corresponding register. The errors must be rectified before it can be cleared otherwise the same errors will occur. For example the init error can be rectified by properly configuring the device before timeout (CTRL.CONFDONE is high before timeout) and clear the init error. Similarly the configuration read and write error can be cleared by configuring the RM unit using external unit and clear the corresponding error bits. The configuration read and write error can also be corrected by fixing the memory fetch in which the error occurs and making a core reset by activationg CTRLRESET.

It is possible to reconfigure (switch other RM to be active) because of an error, if the CTRL.EREC is enabled. The switchover can be based on any of the following critical error - Initial configuration read error CRER, Initial configuration write error CWER and Sequence Read Error SEQER. The Switchover can happen only when the health communication is available between the two RM. If no health communication is available it is possible to provide reset using the HCTRL.RESET register. By providing the HCTRL.RESET the RM will set itself to be in default init state and the RM registers must be configured properly by an external unit to start functioning again.

	0b10 = Only External
	0b11 = Both Available
11: 6	RESERVED
5	reset (RESET) - Resets all the registers in the core.
4	Error reconfigure (EREC) -- If this field is one then for every error mentioned in the RME register switch over to redundant reconfiguration module will occur.
3	RESERVED
2	ACTIVE - If this field is set to one then active master. By default an external input is provided to this field which specify the system is active or not,
	Connected to the signal master
1	Configuration done (CONFDONE) - If the CONFEN is set to one then if the initial configuration is successfully performed this field will go high. It is not mandatory to use the RM DMA for initial configuration, the initial configuration can be performed by some other unit and this field can be enabled by the external unit performing the initial configuration. This field must be enabled by any of the above specified option and also this must be enabled before the initial time out is configured in the ID register otherwise RM error is triggered (RME.IE register).
	Connected to the signal confdone
0	Configuration enable (CONFEN) - External units can write 1 to this field and start the initial configuration. This field is also controller by how the core is implemented, the reset value for this field is provided by an external input signal. If the initial configuration should be performed by the RM DMA after the system reset is disabled the external input should be 1, other option is by keeping the input zero and writing this field with 1 by some other unit to start the initialization process.
	Connected to the signal initconf

156.12 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x09A. For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

156.13 Implementation

156.13.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

156.13.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

156.16 Signal definitions and reset values

The signals and their reset values are described in table 2683.

Table 2683. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
txd[]	Output	UART transmit data line	-	Logical 1
rtsn[]	Output	Ready To Send	Low	Logical 1
rxd[]	Input	UART receive data line	-	-
ctsn[]	Input	Clear To Send	Low	-

156.17 Timing

The timing waveforms and timing parameters are shown in figure 381 and are defined in table 2684.
Figure 381. Timing waveforms

Table 2684. Timing parameters

Name	Parameter	Reference edge	Min	Max	Unit
$t_{APBUART0}$	clock to output delay	rising *clk* edge	TBD	TBD	ns
$t_{APBUART1}$	input to clock hold	rising *clk* edge	-	-	ns
$t_{APBUART2}$	input to clock setup	rising *clk* edge	-	-	ns

Note: The *ctsn[]* and *rxd[]* inputs are re-synchronized internally. These signals do not have to meet any setup or hold requirements.

156.18 Library dependencies

Table 2685 shows libraries that should be used when instantiating the core.

Table 2685. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	APB signal definitions
TMTC	GRRM	Signals, component	Signal and component declaration

156.19 Instantiation

This example shows how the core can be instantiated.
