- The selected error detection type, which can be FFC and/or CRC defined in the Configuration Mode Register (CONFIG);

- If error correction is enabled or not, which is defined in the CORM bit of the Configuration Mode Register (CONFIG);

- The number of errors detected in the scrubbing run, which is presented in the RECNT bitfield of the Number of Errors Detected Register (ECNT) (if correction is enabled).

Table 1066 generically describes the time parameters that affects the scrubbing period.

Table 1066. Generic timing description

Name	Description
SCRUBP	Scrubbing period
TFRD	Time to read one frame from the FPGA
TFWR	Time to write one frame to the FPGA
TD	Time to detect error in a frame
TC	Time to correct one frame

Considering the readback scrubbing mode with only detection enabled, the scrubbing period would be:

$$SCRUBP = [time\ to\ read\ frame\ and\ detect\ error]\ *\ [number\ of\ frames]$$
$$SCRUBP = (TFRD + TD)*FCNT$$

Considering the readback scrubbing mode with detection and correction enabled, the scrubbing period would be:

$$SCRUBP = [detection\ time] + [correct\ erroneous\ frames] + [recheck\ corrected\ frames]$$
$$SCRUBP = (TFRD + TD)*FCNT + (TC + TFWR)*RECNT + (TFRD + TD)*RECNT$$

65.16 Electrical characteristics and requirements

Since the GRSCRUB signals are directly connected to the SelectMap interface of the target FPGA, one must carefully observe the required voltage levels of the FPGA I/O bank and the I/Os of the system with the GRSCRUB.

65.17 Configuration options

Table 1067 shows the configuration options of the GRSCRUB (VHDL generics).

Table 1067. Configuration options

Generic name	Function	Allowed range
hindex	AMBA AHB master index	0 - NAHBMST-1
pindex	AMBA APB slave index	0 - NAPBSLV-1
paddr	Address field of the APB bar	0 - 16#FFF#
pmask	Mask field of the APB bar	0 - 16#FFF#
pirq	Interrupt line used by the GRSCRUB	0 - NAHBIRQ-1
cfg_tech	Implementation technology	0 - NTECH
ffc_en	Enable the FFC capability (0) disable, (1) enable	0 - 1
crc_en	Enable the CRC capability (0) disable, (1) enable	0 - 1
smap_buswide	SelectMap data bus width [1:0] (00) 8-bit wide (01) 16-bit wide (10) 32-bit wide (11) Not used	"00", "01", "10"
smap_sync_delay	Number of clock cycles delay for SelectMAP input data synchronization. No delay is set as default. A delay might be required due to setup configuration.	0 - 15
config_interface	Configuration interface. Currently, only SelectMap is supported [1:0]. bit#0 SelectMap: (0) disable, (1) enable	"00", "01"
syncfifo_abits	Internal fifo address bits	0 - 16#FFFF#
syncfifo_ft	Internal fifo fault tolerance enable (only applicable for GRLIB FT)	0 - 1
fpga_timeout	Timeout in clock cycles to wait for FPGA response	0 - 16#FFFFFFFF#
ioreg_arst	Enable the asynchronous reset of SelectMap IO registers (0) disable, (1) enable	0 - 1

65.18 Signal descriptions

Table 1068 shows the interface signals of the GRSCRUB (VHDL ports).

Table 1068. Signal descriptions

Signal name	Field	Type	Function	Active
RSTN	N/A	Input	Reset signal considering the CLK clock domain.	Low
CLK	N/A	Input	System clock.	-
SMAPRSTN	N/A		Reset signal for the internal SelectMap module, considering the SMAPCLKI clock domain.	Low
SMAPCLKI	N/A	Input	SelectMap clock. This clock is used by the internal module directly connect to the SelectMap interface.	-
TICK_IN	N/A	Input	Tick signal used as reference to apply delay in periodic scrubbing runs. The Delay Register (DELAY) presents the number of ticks that the GRSCRUB must wait during the holding time. The TICK_IN signal must be asserted for one system clock cycle to be counted.	High
AHBMI	*	Input	AMB master input signals	-

66 GRSHYLOC - Wrapper for the SHYLOC compressor with DMA engine

66.1 Overview

GRSHYLOC implements a wrapper for the SHYLOC compressor, enabling two possible configurations by means of a generic. Both configurations have common control and data interfaces. Additionally, GRSHYLOC features a DMA engine to fetch the raw image and store the compressed bitstream from/to external memory through the AMBA AHB master interface.

The compressed samples are temporary stored into a local SRAM. This reduces the risk of missing output data in case of delays accessing the AHB bus. The content of the memory is written to the external memory when the DMA controller is not busy fetching raw data for the SHYLOC core.

GRSHYLOC also includes an AMBA AHB slave interface for configuration and control. There are three sets of registers: one for configuring the CCSDS123 IP, another for the CCSDS121 encoder (optional) and a global set for controlling the overall compression process.

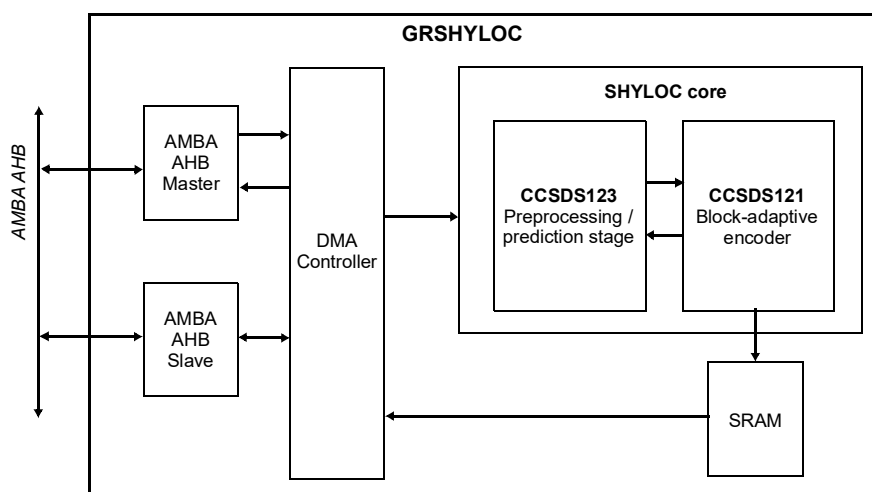
The block diagrams below depict the two possible configurations for GRSHYLOC. The first one involves the complete SHYLOC system: the CCSDS123 IP performs the prediction stage, whereas CCSDS121 implements the block-adaptive coding. On the other hand, the second configuration only instantiates the CCSDS123, which performs both as predictor and as sample-adaptive encoder.


Figure 162. GRSHYLOC block diagram when implementing the SHYLOC compressor
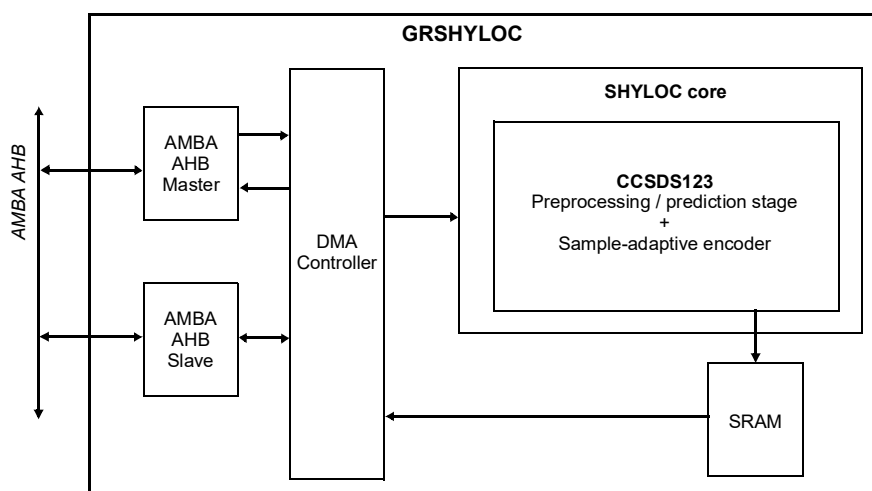

Figure 163. GRSHYLOC block diagram when implementing the standalone CCSDS123

66.2 Compression IPs description

The image compression is performed by two different IPs that may operate standalone or combined to form the so-called SHYLOC system. The following sections briefly describe the purpose of both IPs. For more detailed information please refer to the SHYLOC datasheet, also available in GRLIB.

66.2.1 CCSDS123

The CCSDS123 IP core performs lossless compression for multi-spectral and hyper-spectral images according to the CCSDS123 standard (Lossless Multispectral & Hyperspectral Image Compression. Recommendation for Space Data System Standards, CCSDS 123.0-B-1. Blue Book. Issue 1).

The first stage of the compression is the predictor. The IP is able to compress samples that are received in BSQ, BIL and BIP order. The predictor architecture shall be selected at implementation time by means of a generic, so it is not configurable at run-time. Some of the architectures require external memory for storing intermediate data. A dedicated AHB master interface is used for this purpose.

The second stage of the compression is the encoder. This step can be achieved using either the CCSDS123 or the CCSDS121 IP. For the latter, more information can be found in the next section. If the CCSDS123 is used as encoder, it performs sample-adaptive coding.

The compression process is configured by means of registers mapped into AHB address space. The IP shall receive the configuration prior to starting the compression of the raw data.

66.2.2 CCSDS121

The CCSDS121 IP core is a lossless universal compressor based on Rice adaptive coding, as per the CCSDS121 standard (Lossless Data Compression. Recommendation for Space Data System Standards, CCSDS 121.0-B-2. Blue Book. Issue 2).

The IP may be used in conjunction with the CCSDS123 IP core, forming the SHYLOC system. In this case, the CCSDS123 is solely in charge of the prediction, thus producing the mapped prediction residuals. These residuals are the inputs for the CCSDS121 IP, which performs the block-adaptive coding of the data. The output of the IP is the compressed bitstream.

The compression process is configured by means of registers mapped into AHB address space. The IP shall receive the configuration prior to starting the compression of the raw data.

66.2.3 SHYLOC considerations

When the SHYLOC system is used, both CCSDS121 and CCSDS123 must be separately configured prior to starting any compression. Some compatibility rules must be followed in this case:

- Same reset behavior for both IPs (asynchronous or synchronous).
- Same configured image size for both IPs (Nx, Ny, Nz).
- Same input dynamic range for both IPs (D).
- CCSDS121 shall be configured to be big-endian.

66.3 Operation

This section describes the operation of GRSHYLOC when both CCSDS121 and CCSDS123 IPs are instantiated. The same steps shall be followed if the CCSDS123 is working as a standalone IP, with the exception that the CCSDS121 shall not be configured via the AMBA AHB slave interface, as it is not present.

Before starting a compression, both compression IPs shall be configured through the AHB slave interface. All the registers must be written to, even if the default or the previous values are to be kept. CCSDS121 and CCSDS123 shall be configured separately following the rules as indicated in 66.2.3.

This mainly involves the characteristics of the image, the encoding type and the parameters for the predictor and encoders. Once a valid configuration has been set, the compression core indicates that is no longer waiting for a new configuration, and is ready to receive the first samples.

With the CCSDS121 and CCSDS123 fully configured, the user may need to set the initial address of both the input raw data and the output compressed bitstream, so that the DMA engine can start fetching/storing valid data.

Finally, the compression may start by setting the Start bit in the GRSHYLOC control register to 1b. The samples will be sequentially fetched by the DMA controller and passed to the compressor when ready. The compressed outputs will be internally stored into a local SRAM before being written to the AHB memory.

Optionally, the compression may be aborted by setting the ForceStop bit in the GRSHYLOC control register to 1b. This immediately stops the DMA fetching/storage, as well as the image compression.

The compression may finish successfully or with errors, or it may have been aborted as explained above. In any case, once the compression ends, the user shall clear both Start and ForceStop bits to 0b (GRSHYLOC control register) before starting the next compression.

The overall status of the compression can be obtained by reading the GRSHYLOC Status Register. Two bits determine whether the compression is ongoing or has finished, and the size of the output bitstream is also made available. The content of this register is valid until the user ends the compression by clearing the GRSHYLOC control register. Please note that if the Finished bit is set to 1b, the core has completed both the image compression and the storage into the AHB memory.

For more in-depth status information, the respective Control/Status Register for each compression core may also be checked. These registers tell whether the internal cores are awaiting a new configuration or are ready to receive new samples, as well as if there has been any compression errors.

66.4   Registers

The core is programmed through registers mapped into AHB address space. Only 32-bit single accesses to the registers are supported.

For more information regarding the compression parameters, please refer to the SHYLOC Datasheet.

Table 1071.GRSHYLOC registers

AHB address offset	Register
0x000	GRSHYLOC Capability Register
0x004	GRSHYLOC Status Register
0x008	GRSHYLOC Control Register

66.4.1 GRSHYLOC Capability Register

*Table 1072.*0x000 - CAP - GRSHYLOC Capability Register

31		3	2	1	0
Reserved			PredSel		Enc-Sel
All 0's			0		0
r			r		r

2-1:   PredSel   Architecture selected for the predictor. BIP-Base (00b), BIP-Mem (01b), BSQ (10b) or BIL (11b).
0:     EncSel   Encoder selected:
                      0b: SHYLOC system. CCSDS121 acts as a block-adaptive encoder.
                      1b: Standalone CCSDS123. It implements a sample-adaptive encoder.

Note: if the BIP-Mem or the BSQ architectures are selected for the predictor, the compression core makes use of the external memory for intermediate calculation.

66.4.2 GRSHYLOC Status Register

*Table 1073.*0x004 - STAT - GRSHYLOC Status Register

31	16
NW	
0x0000	
r	

15		2	1	0
Reserved			FIN	ON
All 0's			0	0
r			r	r

31-16:   NW   Number of words (32 bits) stored into the external AHB memory for the current compression. When FIN is 1b (compression finished), it shall be interpreted as the size of the output bitstream.
1:     FIN   Compression finished. Only set to 1b if the compression is successful (i.e. not if interrupted).
0:     ON   Compression ongoing.

Note: NW, FIN and ON are cleared when the user finishes the compression by clearing both ForceStop and Start bits in the GRSHYLOC Control Register.

66.4.3 GRSHYLOC Control Register

*Table 1074.*0x008 - CTRL - GRSHYLOC Control Register

31		3	2	1	0
Reserved			FS	ST	RST
All 0's			0	0	0
r			rw	rw	rw

2:     FS   ForceStop. It stops immediately both the compression and the DMA activity.
1:     ST   Start. If the compression core is ready, it starts fetching the raw data from memory.
0:     RST   Reset. It performs a complete software reset of the core when set to 1b. Self-clearing.

Note: when the compression finishes, the user shall set both FS and ST to 0b before starting a new compression. This effectively clears the content of the GRSHYLOC Status Register.

66.5   Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0B7 (GRSHYLOC). For description of vendor and device identifiers see GRLIB IP Library User's Manual.

66.6   Implementation

66.6.1   Reset

The core changes its reset behavior depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

GRSHYLOC will feature a synchronous reset if the parameter *grlib_async_reset_enable* is not set in the GRLIB configuration package. On the contrary, it will implement an asynchronous reset if *grlib_async_reset_enable* is set.

67   GRSPFI - SpaceFibre codec with DMA, RMAP target and Bus Master Interface

67.1   Overview

GRSPFI provides an interface between the system bus (such as AHB or AXI) and a SpaceFibre network. It features a single-lane implementation of a SpaceFibre node designed in accordance to the SpaceFibre specification ECSS-E-ST-50-11C, as well as a flexible DMA engine with a programmable number of independent DMA channels (from 1 to 8). Each channel has its own bus master interface for optimizing the throughput of the IP. There are wrappers available adapting the generic bus master interfaces to either AMBA AHB 2.0 or AXI4.

The core is configured through a set of registers accessed through an AHB slave interface. The Space-Fibre packets are autonomously handled by the DMA channels, both in transmission and reception. Each DMA channel is assigned a sub-set (or all) of the Virtual Channels and/or the Broadcast Channel; this assignment is programmed in run-time via the AHB registers.

An optional RMAP target adhering to the ECSS-E-ST-50-52C standard can be included to handle RMAP commands autonomously without software intervention. If present, every DMA channel features its own hardware RMAP target, which can be enabled and configured separately.

GRSPFI requires an external SerDes for the connection to the SpaceFibre network, either on the chip or external to the chip. In total, there are up to four clock domains: the system clock for the AMBA and DMA layers, the SpaceFibre codec clock, the SpaceFibre transmitter clock (optional) and the SpaceFibre recovered clock for the receiver.

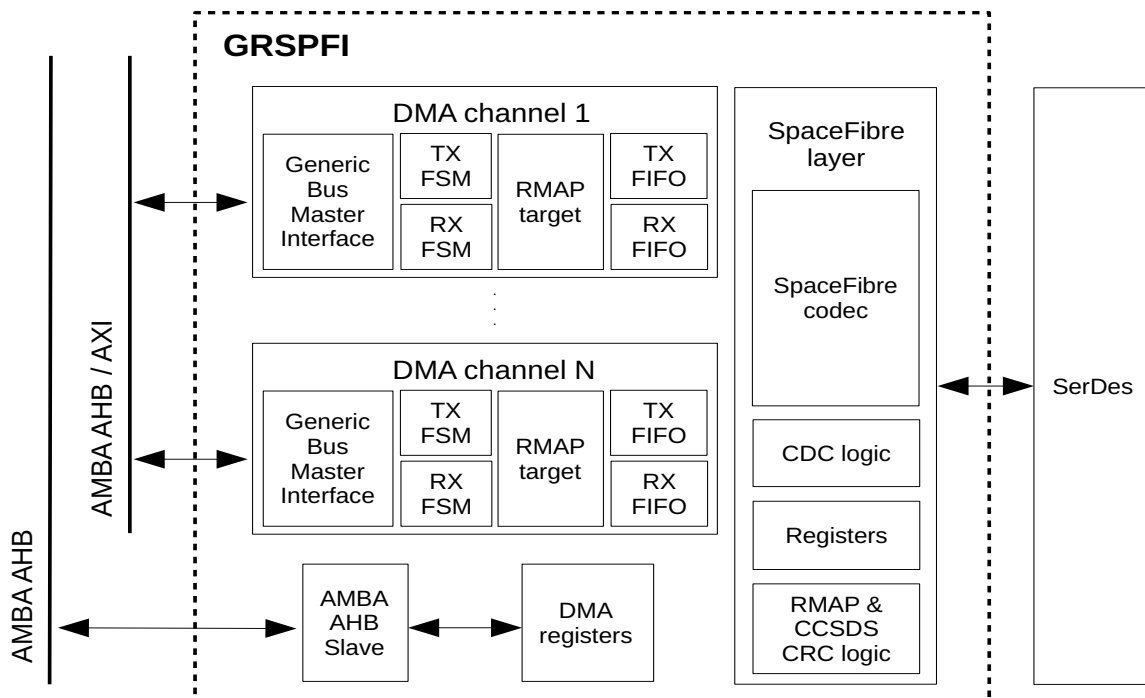
The block diagram of GRSPFI can be seen in the figure below:


Figure 164. GRSPFI block diagram

67.2 Operation

67.2.1 Functional description

The main sub-blocks of the IP are the SpaceFibre codec, the DMA engine, the optional RMAP target and the IP registers accessed through the AHB slave interface. Note that the SerDes is not part of the IP, but it is always required in order to achieve the typical high bit-rates of SpaceFibre.

The core of the IP is the SpaceFibre codec. It has been designed in accordance with the SpaceFibre specification ECSS-E-ST-50-11C. The codec can be split into several layers from a functional point of view:

- Interface Layer. This layer serves as the interface between the Physical and the Lane layers. It is in charge of the symbol synchronization, 8B/10B encoding, cross-domain crossing and polarity inversion, among other tasks.

- Lane Layer. Functions here are those typically related to the Data-Link layer, according to the OSI model: link initialization management, error words counters, PRBS generator, loss of signal and standby detection, etc.

- Retry Layer. It contains the retry buffers, where transmitted words are stored until they are acknowledged, in case they shall be retransmitted. The Retry Layer also interprets the words received, implements the word priority logic and calculates the CRC.

- Virtual Channel Layer. This layer contains the Virtual Channel buffers for both transmission and reception, and implements FCT counter logic, control character monitoring and bandwidth and time-slot management.

- Broadcast Channel Layer. As the name suggests, the functionality related to the Broadcast Channel is covered here, including the monitoring of the bandwidth allocated to the Broadcast Channel.

The codec (GRSPFI_CODEC) is further described in a dedicated section of the GRLIB IP Core User's Manual as a separate IP. Please refer to it for further information about the configuration of the core and its control and status signals. Notice that the codec does not feature any internal register.

On the other hand, GRSPFI features a flexible DMA engine, in which the number of DMA channels is configurable from 1 to 8 via a generic. Each DMA channel comprises a transmit and a receive finite state machine, as well as RX and TX FIFOs. Additionally, every DMA channel has its own bus master interface for accessing the AMBA bus and an optional RMAP target.

In runtime, the user shall assign the Virtual Channels and the Broadcast Channel to the existing DMA channels. There are no restrictions on how many VC/BC channels can be handled by each DMA channel: arbitration among the channels is resolved in a Round-Robin fashion, except for the Broadcast Channel which always has the highest priority. However, it must absolutely be avoided to assign the same VC or the BC to more than one DMA channel, as this could potentially result in a packet being transmitted or stored multiple times, thus compromising the functionality of the IP.

Transmission and reception of packets for the Virtual Channels are based on descriptors. There are two descriptor tables per VC: one for transmission and another one for reception. Once a descriptor has been read and verified by the DMA channel handling the Virtual Channel, the packet can be fetched from external memory and transmitted using the codec (transmitter) or read from the codec and stored into external memory (receiver). Packets and descriptors are read and written through the generic bus master interface.

A DMA channel also contains an RX and a TX FIFO for insertion/extraction of control characters (FILL, EOP and EEP) and for 32-bit word alignment. The FIFOs serve as the interface between the FSMs and the codec. Once a complete packet has been read by the SpaceFibre codec (transmission) or written to external memory (reception), the FIFO is emptied, ready for the next SpaceFibre packet.

GRIP

Apr 2024, Version 2024.1

927

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The RMAP target is an optional part of the core which can be enabled with a VHDL generic. The RMAP target handles incoming packets which are determined to be RMAP commands instead of the receiver DMA engine. The RMAP command is decoded and, if it is valid, the operation is performed on the bus. If a reply was requested it is automatically transmitted back to the source by the RMAP transmitter.

Every DMA channel features its own RMAP target and associated AHB registers, thus making it possible to enable and configure the RMAP targets separately. A DMA channel only checks the format of packets received over the assigned virtual channels.

The bus master interfaces present in the IP are generic, so that the user can connect a wrapper in order to adapt it to their custom protocol. Wrappers for AMBA 2.0 AHB and AXI4 are readily available from Frontgrade Gaisler.

GRSPFI includes the registers to configure and control the IP. These registers are accessible through the AMBA AHB slave interface.

GRSPFI will generate AMBA interrupts under certain circumstances:

- SpaceFibre Link events

- Errors during read/write accesses through the bus master interface

- Transmission and reception of SpaceFibre packets associated with a specific Virtual Channel

- Transmission and reception of broadcast messages

The user can configure which events shall cause interrupts both at IP level (by an AHB register) and per individual packet (a specific bit in the descriptor).

67.2.2 Protocol support

The SpaceFibre codec has been designed in accordance with the SpaceFibre standard ECSS-E-ST-50-11C. It is a Single-Lane implementation of the protocol; therefore the optional Multi-Lane layer is not part of the IP. The optional RMAP target has been implemented as per the ECSS-E-ST-50-52C specification.

The core only accepts packets with a valid destination address in the first byte received. Packets with address mismatch will be silently discarded. The second byte of a packet is typically the protocol ID and determines how a packet is processed by the IP. The RMAP protocol (ID = 0x01) is the only protocol handled separately in hardware while other packets are stored in external memory. If the RMAP target is present and enabled, all RMAP commands will be processed, executed and replied automatically in hardware. Otherwise RMAP commands are stored in memory via hardware descriptors in the same way as any other packets. RMAP replies are always handled via descriptors.

When the RMAP target is not present or is disabled, there is no need to include a protocol ID in the packets and the data can start immediately after the address. In transmission, the address and protocol-ID fields must be included in the buffers from where data is fetched. They are *not* automatically added by the core under any circumstances. The figure below depicts the packet formats supported by the core, depending on whether RMAP is present and enabled or not.

Addr	ProtID	D0	D1	D2	D3	..	Dn-2	Dn-1	EOP

Addr	D0	D1	D2	D3	D4	..	Dm-2	Dm-1	EOP
Figure 165. SpaceFibre packet types supported by the core

When a package is received with a protocol ID = 0x02 (CCSDS) the core can, if enabled, automatically calculate and check the CCSDS/CCITT CRC-16 and 16-bit ISO-checksum (J.G. Fletcher, ISO 8473-1:1998) of the data bytes. CCSDS packets are always handled via descriptors.

GRIP

Apr 2024, Version 2024.1

928

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

67.2.3 Endianness

The core is designed for big-endian and little-endian systems.

When connected to an AHB bus, GRSPFI automatically detects the endianness of the system by reading a dedicated sideband signal included in the AMBA records. If the AXI wrapper is used instead, the endianness is configured via the VHDL generic *lendian*. When accessing the bus, the data may be swapped depending on the selected endianness and the type of data involved in the transfer:

- Words belonging to TX and RX descriptors are never swapped and shall be read and written using 32-bit accesses. These words shall be located at the same address offsets (0x0, 0x4, 0x8 and 0xC) regardless of the endianness.

- Words associated with broadcast messages are never swapped and shall be accessed using 32-bit accesses, similarly to descriptors. Likewise the address offsets shall be preserved as well.

- Data in standard SpaceFibre packets are treated as a stream of bytes, i.e. the bytes will be located in the same memory positions in both big- and little-endian systems. If *addr* is the address configured in the corresponding field of a descriptor, the first byte shall be located at *addr*, the second byte at *addr+1*, and so on. This implies that GRSPFI will internally swap the data words in little-endian configurations when accessing the AMBA bus.

- Data in RMAP packets are also treated as a stream of bytes for all commands (Read, Write and Read-Modify-Write). The first data byte of an RMAP packet is associated with the address in the packet. GRSPFI will swap the data bytes in little-endian configurations. Note: the user shall take the endianness of the host system into account. This means that, when accessing APB registers and 32-bit descriptors via RMAP, the user shall swap the bytes of the command in little-endian host systems.

67.3 SpaceFibre codec

This section provides some guidelines for configuring and controlling the internal SpaceFibre codec. For a detailed description of generics and signals, please refer to the specific section dedicated to the SpaceFibre codec IP (GRSPFI_CODEC).

67.3.1 Configuration

Most generics available in GRSPFI are related to the functionality to implement in the SpaceFibre codec. Some of the most important generics are described below:

The generic *num_vc* determines the number of Virtual Channels featured by the core, which ranges from 1 to 32. Each Virtual Channel includes a pair of TX and RX buffers, whose depths are configured by *depth_vc_tx_buf* and *depth_vc_rx_buf*, respectively.

The Retry Layer contains separate buffers for data, broadcast and FCT words. Their depths are configured through the generics *depth_rbuf_data*, *depth_rbuf_bc* and *depth_rbuf_fct*, respectively.

The SpaceFibre standard requires 8B/10B encoding. However, some SerDes may already incorporate the encoding; otherwise this can be performed inside the codec by setting the generic *use_8b10b*. Depending on the SerDes interface, the IP can be configured to have a 20- or 40-bit wide interface with the generic *sel_16_20_bit_mode*. If the narrow interface of 20 bits is chosen, the generic *use_sep_txclk* shall be enabled, and the transmitter clock input signal (tx_clk) shall be provided.

Additional generics are required in order to get proper timing parameters in the IP, as well as to define the width of some counters. Please refer to 67.11.2 for a comprehensive description of the generics.

67.3.2 Control

The SpaceFibre link is controlled by means of the Codec Control Register (CTRL). The link can be reset by setting the Link Reset bit (CTRL.LIR). As a consequence, outbound packets are spilled up to and including the next EOP and inbound packets are terminated by an EEP.

GRIP

Apr 2024, Version 2024.1   929   Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

If the Lane Start bit (CTRL.LS) is set, the Lane Layer in the codec will actively try to build up a connection with the far-end by sending out INIT1 words. If the Auto-start bit (CTRL.AS) is set, the lane layer will passively listen to incoming words from the far-end node and start the handshake procedure once INIT1 words are received. To keep the link disabled, both CTRL.LS and CTRL.AS shall be kept low. The lane can be reinitialized by setting the CTRL.LNR bit to '1'; note that this does not reset either the registers nor the codec. Ongoing packets will probably get delayed, but never canceled.

The scrambling of data is controlled by the CTRL.SCR bit. The codec also supports loop-back mode for debugging purpose by enabling the CTRL.LB bit. The standby reason can be specified by writing the CTRL.SBR field.

67.3.3 Status

The codec provides several signals to inform about its internal status. These signals are mapped to the Lane Layer Status Register (LNSTS) and the Retry Layer Status Register (RTSTS). Among others, the following signals are available:

- Lane state

- Far-end status: link reset, standby, loss of signal

- Error counters

- Polarity inversion

- Link errors: CRC-16 and CRC-8 errors, frame errors, sequence errors, protocol error, etc.

- Connection timeout

The capability registers contain information regarding how the IP was generated. Most generics can be read back by reading the Codec General Capability Register and the Codec Internal Buffers Capability Register.

67.4 Virtual Channels

The core supports from 1 to 32 Virtual Channels. Each Virtual Channel has its own sets of registers for individual configuration, control and monitoring. The Quality of Service (QoS) in SpaceFibre is mostly configured in these registers. Additionally, transmission and reception of SpaceFibre packets are handled through descriptors; each channel has its own pair of TX and RX descriptor tables. The VC registers also include mechanisms to filter out and truncate packets based on their length and the first address byte.

67.4.1 Global configuration and status of the channel

Before transmitting and receiving packets over a specific Virtual Channel, the Quality of Service parameters shall be configured for the channel.

The VC control register contains 16 bits to establish the bandwidth allocated to the channel (VCCTRL.VBW). The expected bandwidth is expressed in 8.8 fixed point format and calculated as follows:

$$ExpectedBandwidth = \left| 1 - \frac{100}{Percentage} \right|$$

GRIP
Apr 2024, Version 2024.1
930
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

For example, the expected bandwidth value of 15% is expressed as: abs(1-(100/15)) = 5.6667. In 8.8 fixed point notation: 0x05ab. For convenience, typical integer values are shown in the table below, ranging from 1% to 95%:

Table 1090. Hexadecimal representation of bandwidth percentages for the Virtual Channels

BW	Hex	BW	Hex	BW	Hex	BW	Hex
1%	0x6300	25%	0x0300	49%	0x010a	73%	0x005f

The control register also has 4 bits for the priority of the channel (VCCTRL.PR), the lower values having higher priority (0 being the highest). On the other hand, since there are up to 64 different time-slots, two different registers are used for specifying when a Virtual Channel is allowed to transmit: VC Time-slot 1 Register (VCTS1) for time-slots 0-31 and VC Time-Slot 2 Register (VCTS2) for time-slots 32-63. Please refer to the SpaceFibre specification for further information regarding the QoS built into the protocol.

The status of a specific Virtual Channel can be obtained by reading the Virtual Channel Status Register. The register informs about bandwidth utilization (under-use and over-use flags). The FCT Overflow bit tells whether the FCT credit counter has overflowed; this indicates that the number of bits for the FCT counter (configured via the generic *remote_fct_cnt_max*) is too small. The Destination Credit bit indicates whether there is space in the virtual channel input buffer of the far end node. The Input Buffer Overflow bit informs about the VC input buffers being full.

67.4.2 TX descriptors

Transmission of SpaceFibre packets is handled by means of descriptors. In transmission, descriptors indicate where the packet is to be fetched from (both its header and its data segments) and control several aspects of the transmission process, such as interrupt generation and how the hardware pointers handling the descriptors shall be updated.

+46 31 7758650 | frontgrade.com/gaisler

The core reads descriptors from an area in memory pointed to by the Transmit Descriptor Table Address Register. The register consists of a base address and a descriptor selector. The base address points to the beginning of the area and must start on an address that is aligned to the size of the descriptor table. Each Virtual Channel has its own descriptor table.

The number of descriptors in the table can be configured by the generic *num_txdesc*. Accepted values are 64, 128, 256 and 512. The number of bits allocated to the base address and descriptor selector in the Transmit Descriptor Table Address Register depends on the value of this generic. A TX descriptor consists of four 32-bit words (16 bytes). Therefore, the size of the descriptor table can be determined as *num_txdesc * 16* bytes. The number of TX descriptors can also be obtained by reading the General Capabilities Register.

To transmit packets, one or more descriptors have to be initialized in memory. Each descriptor shall specify the number of bytes to transmit and the location of the data. There are two different length and address fields in the transmit descriptors because there are separate pointers for header and data. If a length field is zero the corresponding part of a packet is skipped and if both are zero no packet is sent. The maximum header length is 255 bytes and the maximum data length is 16 Mbyte - 1. When the pointer and length fields have been configured the descriptor enable bit should be set to validate the descriptor. This must always be done last. The other control bits must also be set before enabling the descriptor.

The figures below depict each word and describe the use of every field:

Table 1091. GRSPFI TX descriptor word 0 (offset 0x0)

31 20	19 18	17	16	15 12	11	10	9	8	7 0
RESERVED	CRCT	DC	HC	NONCRCLEN	R	IE	WR	EN	HEADERLEN

31: 20	RESERVED
19: 18	CRC Type (CRCT) - Defines the type of CRC or checksum to use for the data bytes. 00: RMAP CRC 01: CCSDS/CCITT CRC-16 10: 16-bit ISO Checksum (J.G. Fletcher, ISO 8473-1:1998) 11: Reserved
17	Append data CRC (DC) - Append CRC calculated according to the algorithm selected in the CRCT field (RMAP specification, CCSDS/CCITT CRC-16 or 16-bit ISO-checksum) after the data sent from the data pointer. The CRC covers all the bytes from this pointer. A null CRC will be sent if the length of the data field is zero.
16	Append header CRC (HC) - Append CRC calculated according to the RMAP specification after the data sent from the header pointer. The CRC covers all bytes from this pointer except a number of bytes in the beginning specified by the NONCRCLEN field. The CRC will not be sent if the header length field is zero.
15: 12	Non-CRC bytes (NONCRCLEN)- Sets the number of bytes in the beginning of the header which should not be included in the CRC calculation. This is necessary when using path addressing since one or more bytes in the beginning of the packet might be discarded before the packet reaches its destination.
11	RESERVED
10	Interrupt enable (IE) - If set, an interrupt will be generated once the packet has been transmitted as long as the transmitter interrupt enable bit in the DMA IRQ control register is also set.
9	Wrap (WR) - If set, the descriptor pointer will wrap and the next descriptor read will be the first one in the table (at the base address). Otherwise the pointer is increased with 0x10 to use the descriptor at the next higher memory location.
8	Enable (EN) - Enable transmitter descriptor. When all control fields (address, length, wrap) are set, this bit should be set. While the bit is set the descriptor should not be touched since this might corrupt the transmission. The core clears this bit when the transmission has finished.
7: 0	Header length (HEADERLEN) - Header Length in bytes. If set to zero, the header is skipped.

Table 1092. GRSPFI TX descriptor word 1 (offset 0x4)

31	0
HEADERADDRESS	

31: 0   Header address (HEADERADDRESS) - Address from where the packet header is fetched. No alignment restriction.

Table 1093. GRSPFI TX descriptor word 2 (offset 0x8)

31	24	23	0
RESERVED		DATALEN	

31: 24   RESERVED

23: 0   Data length (DATALEN) - Length in bytes of data part of packet. If set to zero, no data will be sent. If both data and header lengths are set to zero no packet will be sent.

Table 1094. GRSPFI TX descriptor word 3 (offset 0xC)

31	0
DATAADDRESS	

31: 0   Data address (DATAADDRESS) - Address from where data is read. No alignment restriction.

Once the TX descriptors have been written to the descriptor table, the TX descriptors available bit (TDA) in the corresponding VC descriptor control register must be set. The transmission process will not start until a DMA channel is assigned the current VC. The sequence to set up the DMA channels is explained later. New descriptors can be activated in the table on the fly (while transmission is active). Each time a set of descriptors is added the TDA bit shall be set again, as it is automatically cleared when the DMA channel finds a disabled descriptor.

The internal pointer which is used to keep the current position in the descriptor table can be read and written through the AHB interface. This pointer is set to zero during reset and is incremented each time a descriptor is used. It wraps automatically when the limit for the descriptor table is reached, or it can be set to wrap earlier by setting a bit in the current descriptor.

The descriptor table register can be updated with a new table anytime when the transmitter of the DMA channel handling the current VC channel is not active. A status bit is available in the DMA Channel Status Register (one register per DMA channel). A value of '0' in the TX Active bit (TA) shall be read to consider it safe to modify the TX descriptor table. Once that happens, the user may change the location of the descriptor table, the content of the current table or the pointer to the next descriptor to be fetched by the core.

67.4.3 RX descriptors

As in transmission, reception of SpaceFibre packets is handled by means of descriptors. In this case, descriptors indicate where the packet is to be stored. Some additional control bits are available as well to handle the interrupt generation and how the descriptor pointer shall be updated once the next reception finishes.

The core reads the descriptors from an area in memory pointed to by the RX Descriptor Table Address Register. The register consists of a base address and a descriptor selector. The base address points to the beginning of the area and must start on an address that is aligned to the size of the descriptor table. Each Virtual Channel has its own descriptor table.

The number of descriptors in the table can be configured by the generic *num_rxdesc*. Accepted values are 128, 256, 512 and 1024. The number of bits allocated to the base address and descriptor selector in the RX Descriptor Table Address Register depends on the value of this generic. An RX descriptor consists of two 32-bit words (8 bytes). Therefore, the size of the descriptor table can be determined as

GRIP

+46 31 7758650 | frontgrade.com/gaisler

*num_rxdesc * 8* bytes. The number of RX descriptors can also be obtained by reading the General Capabilities Register.

SpaceFibre packets are received by the codec regardless of which descriptors have been initialized. The packet is temporarily stored in the corresponding Virtual Channel buffer, waiting for a DMA channel to read it and store it in external memory. For the latter to happen, the descriptors corresponding to the selected VC shall be initialized.

Similarly to the transmitter, descriptors include a pointer to where the data shall be stored. In this case, however, the header and data are not discriminated, and the length of the packet is to be written by the core once the reception finishes. Once the pointer is set, and the control bits (wrap bit, interrupt enable) are also configured, the enable bit should be set to validate the descriptor. This must always be done last to avoid reading a corrupt descriptor.

The figures below depict each word of the RX descriptor and describe the meaning of every bit field:

Table 1095. GRSPFI RX descriptor word 0 (offset 0x0)

31	30	29	28	27	26	25	24		0
DC	HC	TR	EP	IE	WR	EN		PACKETLENGTH	

31	Data CRC Error (DC) - Set by the core if an RMAP CRC error was detected for the data. If the Protocol ID of the received packet is 0x02, the interpretation of this field changes: a 1 indicates that a CCSDS/CCITT CRC-16 error was detected.
30	Header CRC Error (HC) - Set by the core if an RMAP CRC error was detected for the header. If the Protocol ID of the received packet is 0x02, the interpretation of this field changes: a 1 indicates that a 16-bit ISO-Checksum error was detected.
29	Packet truncated (TR) - Set by the core when the reception has finished if the length of the packet exceeds the maximum length. The rest of the packet is spilled.
28	EEP termination (EP) - This packet ended with an Error End of Packet control character.
27	Interrupt enable (IE) - If set, an interrupt will be generated once a packet has been received as long as the receiver interrupt enable bit in the DMA IRQ control register is also set.
26	Wrap (WR) - If set, the descriptor pointer will wrap and the next descriptor read will be the first one in the table (at the base address). Otherwise the pointer is increased with 0x8 to use the descriptor at the next higher memory location.
25	Enable (EN) - Enable (EN) - Set to one to activate this descriptor. This means that the descriptor contains valid control values and the memory area pointed to by the packet address field can be used to store a packet. When all control fields are set, this bit should be set. While the bit is set the descriptor should not be touched since this might corrupt the reception. The core clears this bit when the reception has finished.
24: 0	Packet length (PACKETLENGTH) - The number of bytes received to this buffer. It is set by the IP, and is only valid after EN has been set to 0 by the GRSPFI core.

Table 1096. GRSPFI RX descriptor word 1 (offset 0x4)

31	0
PACKETADDRESS	

31: 0	Packet address (PACKETADDRESS) - The address pointing to the buffer which will be used to store the packet received.

Once the RX descriptors are written to the descriptor table, the RX descriptors available bit (RDA) in the corresponding VC descriptor control register must be set. The packet is not stored in external memory until a DMA channel is assigned the current VC. The sequence to set up the DMA channels is explained later. New descriptors can be activated in the table on the fly (while reception is active). Each time a set of descriptors is added the RDA bit shall be set again, as it is automatically cleared when the DMA channel finds a disabled descriptor.

The internal pointer which is used to keep the current position in the descriptor table can be read and written through the AHB interface. This pointer is set to zero during reset and is incremented each

GRIP

time a descriptor is used. It wraps automatically when the limit for the descriptor table is reached, or it can be set to wrap earlier by setting a bit in the current descriptor.

The descriptor table register can be updated with a new table anytime when the receiver of the DMA channel handling the current VC channel is not active. A status bit is available in the DMA Channel Status Register (one register per DMA channel). A value of 0b in the RX Active bit (RA) shall be read to consider it safe to modify the RX descriptor table. Once that happens, the user may change the location of the descriptor table, the content of the current table or the pointer to the next descriptor to be fetched by the core.

67.4.4 Packet maximum length filter (RX only)

GRSPFI features a mechanism to limit the size of the incoming packets that will be stored in memory. A separate maximum length filter exists per virtual channel.

The VC RX Maximum Length Register defines the maximum number of bytes that will be accepted by the core for a given SpaceFibre packet. If the length of a packet exceeds the value of the register, the Truncate bit in the RX descriptor is set and the rest of the packet is spilled, i.e. not stored in external memory. It is mandatory to configure this register prior to starting a reception, otherwise the default length is zero and no bytes are accepted.

67.4.5 Address filters (RX only)

GRSPFI features two address filters, one general and one specific to each VC. When a SpaceFibre packet is received over a Virtual Channel, the first byte is interpreted as the packet local address. An acceptance filter is applied to this address in order to decide whether the packet shall be accepted (stored in memory) or ignored (read from the SpaceFibre codec but never written to external memory). The Address Enable bit in the VC control register determines which filter to apply:

- Default filter. If the Address Enable bit is 0b, the default filter is used. The filter consists of 2 bytes: a default address and a default mask, which are configured in the GRSPFI Default Address Register. The SpaceFibre packet address is compared with the default address after applying the mask: those bits set to 1b in the corresponding position of the mask are ignored. The following condition must be fulfilled in order to accept a SpaceFibre packet when using the default filter:

$$PKTADDR \text{ and not } DEFMASK = DEFADDR \text{ and not } DEFMASK$$

- VC filter. If the Address Enable bit is 1b, the VC-specific filter is used. The filter consists of 2 bytes: a VC address and a VC mask, which are configured in the VC Address Register. The SpaceFibre packet address is compared with the VC address after applying the mask: those bits set to 1b in the corresponding position of the mask are ignored. The following condition must be fulfilled in order to accept a SpaceFibre packet when using the VC filter:

$$PKTADDR \text{ and not } VCMASK = VCADDR \text{ and not } VCMASK$$

Setting all bits of the corresponding mask to 1b disables the filter, and all packet addresses are therefore accepted.

67.5 Broadcast Channel

GRSPFI features a Broadcast Channel which can be controlled by any of the existing DMA channels. However, only one DMA channel can handle the Broadcast Channel at a time to avoid duplicity of transmission or reception of messages. In SpaceFibre, broadcast messages contain 3 main fields (8 bytes of data, broadcast type and broadcast channel number) and two flags (delayed and late). For further information please refer to the SpaceFibre standard.

GRIP
Apr 2024, Version 2024.1
935
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Unlike the Virtual Channels, communication through the Broadcast Channel is not based on descriptors. Since the length of the message is defined and much shorter than SpaceFibre packets may potentially be, the messages are stored in a circular buffer, externally to the IP. The content of those buffers is handled via hardware pointers. The following chapters describe how the Broadcast Channel is managed and how the messages are mapped in memory.

67.5.1 General

The Broadcast Channel Configuration Register can be used to configure the main parameters of the channel.

The transmission of broadcast messages is limited to the expected bandwidth of the Broadcast Channel. The user shall specify the expected bandwidth by writing the 16-bit BW field in the BC Configuration Register. The bandwidth is expressed in 0.16 format, and calculated as follows:

$$ExpectedBandwidth = \frac{Percentage}{400}$$

For example, the expected bandwidth value of 10% is expressed as: 10/400 = 0.025. In 0.16 fixed point notation: 0x0666. For convenience, the following table shows the most common bandwidth values, from 1% to 95%:

Table 1097. Hexadecimal representation of bandwidth percentages for the Broadcast Channel

BW	Hex	BW	Hex	BW	Hex	BW	Hex
1%	0x00a4	25%	0x1000	49%	0x1f5c	73%	0x2eb8

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

On the other hand, the broadcast channel number of the core shall also be configured in the same register by writing the corresponding 8-bit CHN field. The broadcast channel number is unique for a node in a SpaceFibre network, so all broadcast messages originated in the core will use this channel.

67.5.2 Setting up the transmission of broadcast messages

Broadcast messages to be transmitted are stored in a circular buffer external to the IP. The representation of the message is explained in 67.5.4. The content of the buffer is handled by means of two hardware pointers, which inform about any new available message and about the messages already transmitted. This section describes how to set up the transmitter of the Broadcast Channel. However, a transmission cannot start until a DMA channel is assigned the Broadcast Channel. This is discussed in a separate chapter corresponding to the DMA engine.

The Broadcast Channel TX Address Register shall be written in order to set the address of the circular buffer where messages are located. The address shall be aligned to 1kB boundary. The last valid position in the circular buffer is specified in the Broadcast Channel TX size register; in this case, the address is 16-byte aligned.

The hardware pointers are accessed via the Broadcast Channel TX Write Pointer Register and Broadcast Channel TX Read Pointer Register, respectively. The pointers are 16-byte aligned. The write pointer is handled by the user to indicate that there are new messages ready to be transmitted. It shall point to the position + 1 of the last broadcast message written to the buffer. On the contrary, the read pointer is normally modified by the core to inform about the messages already transmitted. It will point to the position + 1 of the last message read from the buffer. The user may modify the read pointer if a different starting point is desired; however, this may only be done when the DMA handling the Broadcast Channel is disabled and not active.

Once a pointer reaches the last valid position of the buffer, it will wrap around to zero. At least one position of the buffer must be left empty at any time to handle the content correctly. Otherwise, a full buffer would be simply interpreted as an empty buffer, so no transmission would happen.

67.5.3 Setting up the reception of broadcast messages

Received broadcast messages are stored in a circular buffer external to the IP. The representation of the message is explained in 67.5.4. The content of the buffer is handled by means of two hardware pointers, which inform about any new message received and about messages already read from the circular buffer by the user. This section describes how to handle the receiver of the Broadcast Channel. However, a message will not be stored in the circular buffer until a DMA channel is assigned the Broadcast Channel. This is discussed in a separate chapter corresponding to the DMA engine.

The Broadcast Channel RX Address Register shall be written in order to determine the location of the circular buffer where received messages are to be stored. The address shall be aligned to 1kB boundary. The last valid position in the circular buffer is specified in the Broadcast Channel RX size register; in this case, the address is 16-byte aligned.

The hardware pointers are accessed via the Broadcast Channel RX Write Pointer Register and Broadcast Channel RX Read Pointer Register, respectively. The pointers are 16-byte aligned. The write pointer is normally handled by the core to indicate that there are new received messages ready to be read by software. It shall point to the position + 1 of the last broadcast message written to the buffer. The user may modify the write pointer if a different starting point is desired; however, this may only be done when the DMA handling the Broadcast Channel is disabled and not active. On the contrary, the read pointer is modified by the user to inform about messages already read from the buffer, thus making room for new messages.

Once a pointer reaches the last valid position of the buffer, it will wrap around to zero. At least one position of the buffer will be left empty at any time to handle the content correctly. Otherwise, a full buffer would be simply interpreted as an empty buffer, so new messages would overwrite others yet pending to be read by the user.

67.5.4 Broadcast message memory mapping

Each broadcast message is represented by 16 bytes. This representation is common to both transmission and reception. The four words are described below:

Table 1098. Broadcast message word 0 (offset 0x0)

31	18	17	16	15	8	7	0
RESERVED		DL	LT	BCH		BTYPE	

31: 18	RESERVED
17	Delayed flag (DL) - This flag is set when a broadcast message is delayed in a routing switch because either a previous broadcast message was still in the process of being sent, or several broadcast messages arrived at the same time.
16	Late flag (LT). The LATE flag is set when a broadcast message has been delayed because of an error. The LATE flag is used in the broadcast mechanism to prevent duplication of a broadcast message when a copy of the broadcast message is delayed.
15: 8	Broadcast channel (BCH). Broadcast channel number from which the message is being sent. It is ignored in transmission (the channel number is configured via an AHB register instead).
7: 0	Broadcast type (BTYPE). This byte specifies the meaning of the data being transmitted in the current message.

Table 1099. Broadcast message word 1 (offset 0x4)

31	0
RESERVED	

31: 0	RESERVED

Table 1100. Broadcast message word 2 (offset 0x8)

31	0
DATA_H	

31: 0	DATA_H: 4 most significant bytes of the broadcast data (equivalent to data (63:32)).

Table 1101. Broadcast message word 3 (offset 0xC)

31	0
DATA_L	

31: 0	DATA_L: 4 least significant bytes of the broadcast data (equivalent to data (31:0)).

The broadcast channel number is unique for a node in a SpaceFibre network. Therefore, when transmitting a broadcast message, the BCH field in the first word is ignored; instead, the channel number is configured in the Broadcast Channel Configuration Register through the AHB slave interface.

67.6 DMA engine

67.6.1 Functional description

The DMA engine featured in GRSPFI is very flexible: the number of DMA channels is configurable through the generic *num_dmach*, whereas the Virtual or Broadcast channels assigned to each DMA channel can be selected in runtime through the AHB slave interface. Every DMA channel has its own set of registers: a DMA Control Register, a DMA Status Register, a DMA IRQ Control Register and a DMA VC Mapping Register. All implemented DMA channels operate in parallel.

There are no restrictions regarding how many channels (Virtual or Broadcast) can be assigned to a specific DMA channel. Likewise, a DMA does not have to be assigned any channel, in such a case the

channel would simply remain idle. Similarly, a Virtual Channel may not be assigned to any DMA channel: this effectively switches off that channel and no packets will be transmitted or received.

In any case, the user must ensure that a specific Virtual Channel is not assigned to more than one DMA channel simultaneously. Otherwise, a packet may be transmitted or stored twice, thus compromising the functionality of the IP.

The behavior is similar for both DMA transmitters and receivers. When idle, if a specific DMA channel is in charge of the Broadcast Channel, it will first check if there is any broadcast message pending to be fetched and transmitted (TX) or read and stored (RX). Otherwise, it will proceed to check if there is any descriptor available among the Virtual Channels assigned to it. The Virtual Channels are served in a Round-Robin fashion at DMA level, and the priority of the channel is later applied within the internal SpaceFibre codec, as part of the protocol built-in Quality of Service.

After the transmission or reception of a packet finishes, GRSPFI updates the corresponding AHB registers accordingly. For broadcast messages, the pointers to the circular buffers are updated; for Virtual Channels, the first word of the descriptor is overwritten with the updated information.

Once a DMA channel takes up a task, it will attempt to finish it before serving any other virtual / broadcast channel. For transmission, that means that a complete SpaceFibre packet will be sent; once this is done, the DMA channel will check again which channel is to be served next. The same applies to reception. If the transmitter or receiver are disabled while the DMA channel is still operating, it will still attempt to complete the operation before effectively switching off. This can be observed in the DMA Channel Status Register, by checking the bits TX Active and RX Active.

Every DMA channel comprises its own bus master interface, to be shared by its transmitter and receiver. The receiver has priority over the transmitter when it comes to accessing the bus, in order not to delay the reception of packets and thus preventing potential loss of data due to buffer overrun.

Optionally, GRSPFI can include a hardware RMAP target to decode incoming RMAP commands, perform the corresponding AMBA accesses and transmit the RMAP reply if applicable. Each DMA channel features its own RMAP target and verifies only the commands received over the virtual channels assigned to the channel. Even though the RMAP target is part of the DMA engine, it is described in a separate subsection of this manual.

67.6.2 Assigning Virtual / Broadcast channels to a DMA channel

In order to start fetching and storing messages from/to external memory, the DMA channel needs to be assigned any Virtual Channel or the Broadcast Channel. In the case of the Virtual Channels, this is done in the DMA Channel VC Mapping Register; each position represents a Virtual Channel. Setting a bit to 1b implies that the VC will be attended by that DMA channel.

Likewise, the Broadcast Channel is assigned to a DMA channel by writing the MAP bits in the Broadcast Channel Mapping Register. These bits are encoded as the DMA channel number (from 0 to 31). The user shall avoid assigning the BC to a non-implemented Virtual Channel, as the behavior is undefined. By default, the Virtual Channel 0 is in charge of handling the broadcast communication.

It is advisable to distribute the assignment of channels among all the available DMA channels in an efficient way. For instance, the Broadcast Channel and Virtual Channels only transmitting short packets could be assigned to a DMA channel. Another DMA channel would then be in charge of longer packets with lower priority, in order to avoid delaying high priority packets.

67.6.3 Receive DMA channel

Once Virtual and Broadcast Channels have been properly assigned, the receiver of the DMA channel can be enabled by setting the RE bit of the DMA Channel Control Register to 1b. After that, the DMA channel will automatically poll the channels assigned to it to determine if a packet processed, either from the Virtual or the Broadcast channels. Different tasks are given a different priority, as listed below (from top to lowest priority):

1. Store a broadcast message in memory.

2. Decode and process an incoming RMAP command.

3. Store a packet received over a virtual channel in memory if there are prefetched RX descriptors.

4. Prefetch a new RX descriptor.

Therefore, the receive channel will only perform a task if it does not have any higher priority task pending. For instance, a new RX descriptor can only be prefetched if there are no broadcast messages, RMAP commands to decode or packets ready to store in memory.

The receiver of the DMA channel needs to be enabled to perform any of the previous operations, so this requirement will not be listed in the subsequent paragraphs.

The Broadcast Channel has priority over any other Virtual Channel. If the Broadcast Channel is assigned to the DMA channel, the following conditions must be met in order to write a broadcast message to the circular buffer:

• BC mapped to the current DMA channel.

• The SpaceFibre codec has already received a valid broadcast message which is temporarily stored in a local FIFO in the DMA layer.

• There is space in the circular buffer (both hardware pointers are compared. At least 2 positions shall be free before storing the broadcast message, as the circular buffer must not be completely full at any time).

When the conditions above are met, the broadcast message is written to the circular buffer through the bus master interface. Once it finishes, the write pointer is updated, and an AMBA interrupt is generated if the BRE bit of the Interrupt Control Register is set.

The second highest priority task is the processing of incoming RMAP commands. The processing is autonomous and requires no software intervention, which implies that no descriptor is involved in the process. The conditions to start processing an RMAP command are listed below:

• RMAP target present (generic *rmap* set to 1) and enabled for a given virtual channel.

• The Virtual Channel is assigned to the current DMA channel.

• The packet has RMAP format: the first word of the packet contains no control characters, the second byte is set to 0x01 (RMAP Protocol ID) and the two most significant bits of the third byte (RMAP instruction) are set to 01b (RMAP command).

Processing an RMAP command means that the receiver decodes the fields of the command, parsing the data length and checking the header and data CRC. The address and key are checked and the transmitter is requested to send a reply if it was requested by the RMAP initiator, so long as the RMAP decoding was successful; otherwise the corresponding error code is returned. The RMAP target is explained later in a dedicated section.

If no broadcast or RMAP packets are available, standard packets received over the Virtual Channels assigned to the DMA channel are checked. The DMA engine must first prefetch the descriptors, regardless of whether data has been received over a virtual channel. Once the descriptor is prefetched and the codec has detected the beginning of the packet, the DMA engine can start storing the data in external memory via the bus master interface. The following conditions must be met in order for the DMA engine to start storing a SpaceFibre packet received over a given Virtual Channel in external memory:

• The Virtual Channel is assigned to the current DMA channel.

• The DMA engine had already prefetched and validated an RX descriptor for the Virtual Channel, i.e. the descriptor is enabled.

• The Virtual Channel in question shall have valid non-RMAP data in its output buffer, within the SpaceFibre codec.

GRIP
Apr 2024, Version 2024.1

940

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

If these conditions are satisfied, the entire SpaceFibre packet is stored in external memory through the bus master interface. Only if there are no Virtual Channels fulfilling the conditions above, the DMA engine may try to prefetch RX descriptors. In this case, the requirements for a given Virtual Channel are as follows:

- The Virtual Channel is assigned to the current DMA channel.

- There are descriptors available for the selected Virtual Channel. This is done by checking the RDA bit of the corresponding VC Descriptor Control Register.

- The DMA engine does not have an RX descriptor already prefetched for the Virtual Channel in question.

Once the reception ends and the packet is completely stored in memory, GRSPFI overwrites the RX descriptor with the corresponding status bits: length of the packet received, EEP detected and whether the packet was truncated due to maximum length violation. The enable bit is cleared to indicate that the descriptor has already been used. If the CRC logic is implemented, two fields indicate whether there were CRC or checksum errors. An AMBA interrupt will be generated if enabled both in the descriptor and in the DMA IRQ Control Register. A new RX descriptor can then be prefetched for that Virtual Channel.

The DMA Channel Status Register contains valuable information regarding the reception process. The RX Active bit indicates that the receive FSM is enabled and may be in a status other than idle: it may have started processing a SpaceFibre packet or a broadcast message. Disabling the receive channel will not have any effect until the ongoing operation ends (if there is any). The RX packet bit indicates that a SpaceFibre has been received and stored in external memory by this DMA channel, and the descriptor has been updated accordingly.

67.6.4 Transmit DMA channel

Once Virtual and Broadcast Channels have been properly assigned, the transmitter of the DMA channel can be enabled. This is done by setting the TE bit of the DMA Channel Control Register to 1b. After that, the DMA channel will automatically poll the channels assigned to it to determine if a packet can be fetched from external memory and transmitted. Different tasks are given a different priority, as listed below (from top to lowest priority):

1. Fetch and transmit a broadcast message.

2. Build and send an RMAP reply if requested by the receiver of the DMA channel.

3. Fetch and transmit a packet over a Virtual Channel.

Therefore, the transmit channel will only perform a task if it does not have any higher priority task pending. For instance, a new packet can only be fetched and transmitted if there are no broadcast messages or RMAP replies to transmit.

The transmitter of the DMA channel needs to be enabled to perform any of the previous operations, so this requirement will not be listed in the subsequent paragraphs.

The Broadcast Channel has priority over any other Virtual Channel. The following conditions must be met in order to transmit a broadcast message:

- BC mapped to the current DMA channel.

- There are new broadcast messages pending for transmission (both hardware pointers are compared. They shall not point to the same location).

When the conditions above are met, the broadcast message is fetched from the circular buffer through the bus master interface. Once the complete message is read, it is immediately written to the Broadcast Channel input buffer in the SpaceFibre codec. The codec then acknowledges the message, so the DMA engine can move on and deal with the next packet or broadcast message. The read pointer is updated, and an AMBA interrupt is generated if the BTE bit of the Interrupt Control Register is set.

GRIP
Apr 2024, Version 2024.1
941
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Please note that there may be a delay until the internal codec has finished the transmission of the message; the interrupt indicates that the DMA layer has passed the message to the SpFi codec.

If there are no pending broadcast messages, the transmitter checks if the receiver is requesting an RMAP reply to be sent. In this case, the conditions are as follows:

- RMAP target present (generic *rmap* set to 1) and enabled for a given virtual channel.

- Receive channel is requesting an RMAP reply.

The transmitter checks the current RMAP operation. For read commands the transmit performs AMBA read accesses to form the reply. For write and read-modify-write commands no further AMBA accesses are required and the reply can be sent immediately. The RMAP target is expanded in a dedicated section of this manual.

If any of the conditions above are not met, the Virtual Channels assigned to the DMA channel are checked. The following situations must be given prior to fetching a SpaceFibre packet from external memory:

- The Virtual Channel is assigned to the current DMA channel.

- There are descriptors available for the selected Virtual Channel. This is done by checking the TDA bit of the corresponding VC Descriptor Control Register.

If these conditions are satisfied, the TX descriptor is fetched. A packet will then be fetched as long as the descriptor determines that either (or both) the length of the header or the data is different from 0. If the length of the header or the data field is 0 (but not both), that part of the packet is skipped. However, if both are 0, no packet is transmitted, and the descriptor is overwritten with a 0b in the Descriptor Enabled bit.

When the packet is completely fetched, control characters (FILL, EOP or EEP) have been properly inserted and the last word is written to the Virtual Channel input buffer inside the codec, the transmission at DMA level is completed. GRSPFI overwrites the first word of the TX descriptor with the Descriptor Enabled bit set to 0b, since it has already been used by the IP. An AMBA interrupt will be generated if enabled.

It is important to realize that the AMBA interrupt does not imply that the packet has been transmitted over the SpaceFibre link. There may be delays in the link interface due to multiple packets from different Virtual Channels sharing the lane layer, as well as delays inherent to the codec itself. The codec will transmit the SpaceFibre packet as soon as possible, according to the SpaceFibre protocol. The interrupt does indicate that the DMA layer is done with the packet.

The DMA Channel Status Register contains valuable status information regarding the transmission. The TX Active bit indicates that the transmit FSM is enabled and may be in a state different from idle (processing a descriptor, passing a packet to the SpaceFibre codec or transmitting a broadcast message). If there is an ongoing operation, disabling the channel will not have any effect until the DMA engine finishes the transmission completely. The TX packet bit indicates that a SpaceFibre packet has been successfully fetched, aligned and passed to the codec ready for transmission, and the descriptor has been updated accordingly.

67.6.5 RMAP and CCSDS CRC logic

GRSPFI supports several algorithms to protect the content of the SpaceFibre packets. RMAP CRC logic is included in the implementation if the *rmapcrc* or *rmap* VHDL generics are set to 1. CCSDS/ CCITT CRC-16 and 16-bit ISO Checksum logic is included in the implementation when the VHDL generic *ccsdscrc* is set to 1, as long as the RMAP CRC logic is also instantiated.

In reception, the RMAP CRC calculation is always active for all received packets and covers all data bytes. The packet is by default assumed to be an RMAP packet and the length of the header is determined by checking the third byte, which should be the command field. The calculated CRC value is then checked when the entire header has been received (according to the calculated number of bytes) and if it is non-zero the HC bit is set to indicate a header CRC error.

The CRC value is not set to zero after the header has been received, instead the calculation continues in the same way until the complete packet has been received. When the header is not corrupted the CRC value will always be zero at the beginning of the data field and the behavior will be as if the CRC calculation was restarted. Then if the resulting CRC value is non-zero the DC bit is set to indicate a data CRC error. This means that the core can indicate a data CRC error even if the data field was correct when the header CRC was incorrect. However, the data should not be used when the header is corrupt and therefore the DC bit is unimportant in this case.

If the received packet is not of RMAP type the header CRC error indication bit cannot be used. It is still possible to use the DC bit if the complete packet is covered by a CRC calculated using the RMAP CRC definition. This is because the core does not restart the calculation after the header has been received but instead calculates a complete CRC over the packet. Therefore any packet format with one CRC at the end of the packet calculated according to RMAP standard can be checked using the DC bit.

When a packet is received with a protocol ID set to 0x02 (CCSDS), the CCSDS CRC-16 and ISO checksum will replace the RMAP CRC logic. The result is presented by the same status bits as for the RMAP head/data CRC error, but the interpretation of these bits is changed to ISO-checksum/CCSDS CRC error instead.

Note that the DC/HC bits are only updated if the packet is not handled by the RMAP target. Otherwise, the handling of the packet does not involve RX descriptors and the CRC logic is internally managed by the RMAP target when decoding the RMAP command.

It the received packet is not covered by either an RMAP CRC or CCSDS CRC/checksum, then both the HC and DC bits should be ignored.

In transmission, TX descriptors have several fields dedicated to setting up the CRC or checksum to be appended to the message. The core can calculate and insert the RMAP CRC of the header if the HC bit is set. Likewise, the data CRC can be calculated and inserted if the HC bit is set. However, in the case of the data field, three different algorithms are supported, selectable via the Data CRC Type field, *CRCT*: RMAP CRC, CCSDS/CCITT CRC-16 and 16-bit ISO checksum. When the CCSDS CRC/ISO-checksum logic is not available, the CRC-type field is assumed to be RMAP CRC.

The header CRC will be calculated from the data fetched from the header pointer and the data CRC is generated from data fetched from the data pointer. The CRCs are appended after the corresponding fields. The NON-CRC bytes field is set to the number of bytes in the beginning of the header field that should not be included in the CRC calculation, commonly used to exclude path addressing bytes that are discarded before reaching the destination.

When the RMAP target is sending an RMAP reply, it automatically configures the CRC logic so that the RMAP CRC is inserted for both the header and data fields.

67.7   RMAP target

67.7.1   Overview

The Remote Memory Access Protocol (RMAP) is used to implement access to resources in the node via the SpaceWire link. Some common operations are reading and writing to memory, registers and FIFOs. The GRSPFI core has an optional hardware RMAP target adapted to operate over SpaceFibre which can be instantiated by setting the VHDL generic *rmap* to 1. The DMA Capability Register can be read to determine whether the RMAP target is present in the design.

If RMAP is instantiated, every DMA channel has a dedicated RMAP target, and will only check commands received over virtual channels assigned to the DMA channel in question. This allows to enable or disable each RMAP target separately. Likewise, each virtual channel has dedicated configuration registers for the node address and destination key.

When enabled, the RMAP target processes all incoming packets with RMAP protocol ID (second byte set to 0x01) and type field in the instruction set to RMAP command (bits 7:6 of the third byte of

GRIP

+46 31 7758650 | frontgrade.com/gaisler

the packet set to 0b01). This is done autonomously without software intervention, meaning that no descriptors are needed. If the RMAP target is disabled or not present, RMAP commands are treated as any other SpaceFibre packet and are therefore stored in memory by using the hardware descriptors.

Once GRSPFI receives an RMAP command, it checks the header to determine if the command is valid or not. The header CRC is first checked; if valid, the command is processed, otherwise it is discarded and no reply is sent under any circumstances.

The next step is to apply the target address and destination key filters. The address filter is similar to the one applied to standard packets and described in 67.4.5; the only difference is that the packet is always passed to the DMA engine in case a reply is requested. If so, the invalid address code is returned in the RMAP status field. Likewise, the destination key of the command is compared with the key set in the Virtual Channel Destination Key register. In case of mismatch an invalid key code is returned if a reply has been requested.

If the header is accepted, the DMA processes the data field of the command. Depending on whether it is a verified or non-verified operation, the RMAP target will wait until the data length and CRC have been verified before initiating any AMBA access. A reply is formatted and sent if the ACK bit of the RMAP command is set.

When a failure occurs during a bus access the error code is set to 1 (General Error). There is predetermined order in which error-codes are set in the case of multiple errors in the core. It is shown in table 1102. Header CRC errors are not included as they do not result in an RMAP reply being sent.

Table 1102. The order of error detection in case of multiple errors. The error detected first has number 1.

Detection Order	Error Code	Error
1	12	Invalid destination logical address
2	3	Invalid destination key
3	2	Unused RMAP packet type or command code
4	9	Verify buffer overrun
5	11	RMW data length error
6	10	Authorization failure
7*	1	General Error (bus master errors during non-verified writes)
8	5/7	Early EOP / EEP (if early)
9	4	Invalid Data CRC
10	6	Cargo Too Large
11	7	EEP
12	1	General Error (bus master errors during verified writes or RMW)
*The bus master error is not guaranteed to be detected before Early EOP/EEP or Invalid Data CRC. For very long accesses the bus error detection might be delayed causing the other two errors to appear first.		

Read accesses are performed on the fly, that is they are not stored in a temporary buffer before transmitting. This means that the error code 1 will never be seen in a read reply since the header has already been sent when the data is read. If the bus master error occurs the packet will be truncated and ended with an EEP.

A verified command is not executed until the complete packet has been received. This means that all errors have been checked before performing any access to the bus, including EEP and cargo being too large.

The specific implementation of the different commands supported by the core is presented in the following subsections. Unsupported commands still defined in the RMAP standard will not be executed and the reply with error code 10 is returned, if requested.

GRIP

67.7.2 Write commands

The write commands are divided into two subcategories when examining their capabilities: verified writes and non-verified writes. Verified writes have a length restriction of 4 bytes and the address must be aligned to the size. That is 1 byte writes can be done to any address, 2 bytes must be halfword aligned, 3 bytes are not allowed and 4 bytes writes must be word aligned. Since there will always be only one AHB operation performed for each RMAP verified write command the incrementing address bit has no effect and can be set to any value.

Non-verified writes have no restrictions when the incrementing bit is set to 1. If it is set to 0 the number of bytes must be a multiple of 4 and the address word aligned. There is no guarantee how many words will be written when early EOP/EEP is detected for non-verified writes.

67.7.3 Read commands

Read commands are performed on the fly when the reply is sent. Thus if a bus error occurs the packet will be truncated and ended with an EEP, but no error code will reflect this as the header has already been sent. There are no restrictions for incrementing reads but non-incrementing reads have the same alignment restrictions as non-verified writes. Note that the "Authorization failure" error code will be sent in the reply if a violation was detected even if the length field was zero. Also note that no data is sent in the reply if an error was detected i.e. if the status field is non-zero.

67.7.4 RMW commands

All read-modify-write sizes are supported except 6 which would have caused 3 B being read and written on the bus. The RMW bus accesses have the same restrictions as the verified writes. The incrementing address bit shall be set, otherwise the command will not be authorized by the core. The packet is verified and all errors are checked before attempting any AMBA access, as in the case of verified write commands. No data is sent in a reply if an error is detected i.e. the status field is non-zero.

67.7.5 Control

The RMAP target mostly runs in the background without any external intervention, but there are a few control possibilities.

There is an enable bit in the Virtual Channel Control Registers that allows to enable RMAP decoding for a subset of the virtual channels in the system. If all virtual channels assigned to a given DMA channel have RMAP disabled, the RMAP target of that DMA channel will be effectively disabled as well. Any RMAP command received over a virtual channel with RMAP decoding disabled will result in the packet being processed as any other standard packet, i.e. stored via hardware descriptors.

The RMAP target makes use of the Virtual Channel Address Register and the Default Address Register to determine whether a command shall be accepted or not, similarly to the standard DMA channel. The selection between the address registers is done via the Virtual Channel Control Register.

The last control option for the target is the possibility to set the destination key which is found in the Virtual Channel Destination Key register. This allows to configure a different key for every virtual channel.

67.8 Time-slot generation

SpaceFibre has a built-in mechanism to divide transmission time into time-slots. Each Virtual Channel is only allowed to transmit during certain slots; this can be configured by writing the 2 VC Time-slot Registers (as explained in 67.4.1).

Additionally, the codec needs to be informed about the current time-slot. There are 2 broad approaches when it comes to managing the time-slot generation in GRSPFI:

- External generation. The time-slots are continuously updated by software every time that a change is required. In this case only the Time-Slot Register needs to be written with the value of

GRIP
Apr 2024, Version 2024.1

947

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

the current time-slot. This value is directly passed to the SpaceFibre codec without any further modification.

- Internal generation. The time-slot generation can be enabled, so that the core autonomously increments the time-slot on a periodic basis. The length (in clock cycles) of the time-slot is defined in the Time-slot Length Register; then the internal generation is enabled by setting the Enable Internal Generation bit in the Time-Slot Control Register. The current time-slot can be checked at any time by reading the Time-Slot Register, together with the current value of the internal hardware counter used to update the time-slots. Writing to this register overwrites the current time-slot, but the counter is read-only. Note that this is done in the SpaceFibre codec clock domain, so all calculations shall refer to this clock frequency.

When internal generation is enabled, there is an additional feature to correct drifts in the generation of the time-slots, configured via the Time-Slot Control Register. This is a one-time correction, applied to the next time-slot. The user shall indicate how many clock cycles are to be corrected, the sign (extend or shorten the time-slot) and assert the Valid Adjustment bit so that the adjustment may be applied. The core overwrites the Valid Adjustment bit with 0b when the adjustment has been applied.

67.9 External FIFO interfaces

67.9.1 Functional description

GRSPFI can implement external FIFO interfaces to directly expose the virtual and broadcast channel data to the ports of the IP. This functionality is enabled by two VHDL generics. The number of FIFO interfaces instantiated for virtual channel data is controlled by *numextvc*, whereas the generic *numextbc* determines if an additional FIFO interface is implemented for the broadcast messages. These generics can be configured separately, meaning that the IP may have external virtual channel interfaces without a broadcast channel FIFO port and vice-versa.

When implemented, these FIFO ports allow the user to directly access the data interfaces of the SpaceFibre codec inside GRSPFI, thus bypassing the DMA engine altogether. By default, this functionality is disabled and all virtual channels and the broadcast channel are handled by the DMA engine. To turn it on, the Bypass DMA bit shall be set: VCCTRL.BD for virtual channels, BCCONF.BD for the broadcast channel. For virtual channels, an additional field called VCCTRL.EFC exists to select which FIFO channel number shall be used to forward the data.

The user may dynamically configure these FIFO interfaces, meaning that the DMA bypass can be turned off and on in run time, and a virtual channel can be reassigned to a different FIFO channel. However, it is essential to avoid assigning a specific FIFO channel to more than one virtual channel simultaneously, otherwise the functionality may get compromised. Note that it is possible to expose only a subset of the virtual channels and/or the broadcast channel while still serving the remaining channels with the DMA engine.

To reconfigure this feature in run time it is always recommended to keep both DMA transmitter and receiver off while switching in order to guarantee that ongoing packets are handled properly. Moreover, if the user wants to switch from one FIFO interface to a different one, the IP will automatically forward the virtual channel data to the new FIFO port. It is up to the user to guarantee that the logic connected to GRSPFI is not attempting to write or read from the FIFO ports involved while the switch is taking place.

Please refer to the GRSPFI_CODEC section of this manual for further information regarding the timing of the signals in the external FIFO interfaces.

67.9.2 GRSPFI to GRSPWROUTER bridges

A potential application for the external FIFO interfaces of GRSPFI is the interconnection with other IPs or accelerators with FIFO-like interfaces. A relevant example is the SpaceWire router, thanks to

GRIP
Apr 2024, Version 2024.1

+46 31 7758650 | frontgrade.com/gaisler

its optional FIFO ports. The HSSL VHDL package includes 2 bridges for converting SpaceFibre data into SpaceWire and vice-versa: *grspfi_spwdatabr* and *grspfi_spwtcbr*.

The entity *grspfi_spwdatabr* is a bridge that transforms virtual channel data coming from the SpaceFibre codec into SpaceWire data. It instantiates an internal buffer to handle the clock-domain-crossing between the SpaceFibre and SpaceWire IPs and to adapt the bit width of the user data: from SpaceFibre 32-bit words plus 4 control flags to SpaceWire 8-bit characters plus 1 control flag. The bridge also inserts and extracts FILL characters in SpaceFibre traffic when the data length is not multiple of 4 bytes and adjusts the encoding of the EOP and EEP markers on either side.

The data bridge includes input clocks and resets for the SpaceWire/AMBA (*clk*, *rstn*) and SpaceFibre (*hssl_clk*, *hssl_rstn*) clock domains. The rest of signals are included in the records *bi* and *bo*. The bridge can be connected seamlessly to GRSPFI by tying *bi.spfi* and *bo.spfi* to *extvco(i)* and *extvci(i)*, where *i* is the desired external channel number. For the SpaceWire side, the *bi* and *bo* records also include signals with names matching those in the *ri* and *ro* records of the router (save for the *spw_* prefix) that should be connected together without any additional logic in between.

The second entity, *grspfi_spwtcbr*, provides a mechanism to convert SpaceFibre broadcast messages into SpaceWire time-codes. The bridge samples broadcast messages and extracts the relevant byte containing the time-code information, which is passed on to the FIFO port of the SpaceWire router. The IP can optionally filter broadcast messages based on the received broadcast type, in case only a subset of those correspond to time-code information. Likewise, time-codes received by the router are packetized in a broadcast message and forwarded to GRSPFI.

This bridge has the same input clocks and resets as the data bridge. The *bi* and *bo* records are obviously different: *bi.spfi* and *bo.spfi* should be coupled with the GRSPFI ports *extbco* and *extbci*, respectively, whereas *bi.spw_tickout*, *bi.spw_timeout*, *bo.spw_tickin* and *bo.spw_timein* can be directly connected to the FIFO ports of the router to drive the time-code interface.

Moreover, this bridge contains 3 configuration signals for mapping time-codes into broadcast messages:

- *bi.map_bctype[7:0]* and *bi.bcmask[7:0]* are used to filter broadcast messages out based on the broadcast type. The received broadcast type is compared with the value in the configuration register *bi.map_bctype*, except for those bits set to 1 in the filter mask, *bi.bcmask*. In the opposite direction, when a time-code is being converted into a broadcast message, the transmit broadcast type is set to *bi.map_bctype* and the mask is unused.

- *bi.map_bcsel[2:0]* allows to select which byte in the broadcast message contains time-code information. The LSB (bits 7 to 0) is selected when *bi.map_bcsel* is set to 0, while a value of 7 corresponds to the MSB (bits 63 to 56).

Both bridges have the VHDL generics *tech* and *ft* for their internal RAM blocks. The values allowed are the same as for GRSPFI and are therefore described in Table 1143.

67.10 AMBA interfaces

This section explains the AMBA interfaces present in the GRSPFI codec, as well as the AMBA interrupts that the IP may generate, and how to configure them.

67.10.1 Bus master interfaces

Every DMA channel has its own generic bus master interface to fetch and store descriptors, SpaceFibre packets and broadcast frames from/to external memory. The generic approach is chosen for maximum flexibility, so that the user can connect a wrapper adapting the bus master to any custom protocol. Frontgrade Gaisler provides wrapper for AHB 2.0 and AXI4.

The size of the read or write access depends on the operation being performed:

GRIP

Apr 2024, Version 2024.1

+46 31 7758650 | frontgrade.com/gaisler

- **Fetching a descriptor**: the descriptor size varies between TX and RX, as explained in 67.4.2 and 67.4.3. In particular, the size of the read access will be of 16 bytes for transmission and of 8 bytes for reception.

- **Storing a SpaceFibre packet** (RX): when the packet is being read from the codec by the DMA, a write access will be performed over the bus master interface as soon as there are at least 256 bytes available or the end of the packet has been detected. This means that the size of the write access may vary between 1 and 256 bytes.

- **Fetching the header of a SpaceFibre packet** (TX): once the descriptor is read and validated, GRSPFI will start fetching the header. This is done with a single burst read access with the size set to the length of the header (maximum 256 bytes).

- **Fetching the data of a SpaceFibre packet** (TX): the data is read with read burst accesses of up to 256 bytes. If there are less than 256 bytes pending, then the size is set to the remaining bytes. Therefore the read size may vary between 1 and 256 bytes.

- **Updating a descriptor**: once the transmission or reception finishes, the descriptor is updated with the status of the transaction. However, only the first word of the descriptor is overwritten: that implies a fixed write access of 4 bytes for both transmission and reception.

- **Storing or fetching a broadcast message**: since the size of a broadcast message is fixed to 16 bytes, as explained in 67.5.4, write and read accesses of broadcast messages will always consist of a burst of 16 bytes.

- **Access triggered by an RMAP command**: The size depends on the type of command and the data length. Verified operations will be completed in a single AMBA access, as the maximum is limited to 4 bytes.

In the particular case of the AHB master interface (i.e. the AHB wrapper is instantiated), the IP has the *hmindex* generic to set the index of the AHB master interface belonging to the first DMA channel. If there are multiple DMA channels, the remaining indexes are assigned consecutively: *hmindex* + 1, *hmindex* + 2, (...) *hmindex* + *num_dmach* - 1.

67.10.2 AHB slave interface

GRSPFI has a single AHB slave interface to access the registers of the core. These registers are used to configure and control the IP. The size of write and read accesses over the AHB interface is always 32 bits.

The IP has 2 major clock domains: the AMBA clock, used by the DMA engine and the AMBA interface, and the SpaceFibre clock, which involves the internal codec and its interface with the DMA FIFOs. Therefore, the internal registers are split into both clock domains. All accesses to registers implemented in the SpaceFibre clock domain are properly handled by means of cross domain crossing techniques.

The register address offsets can help determine if the register is implemented in the AMBA clock domain or in the SpaceFibre clock domain:

- 0x000 - 0x7FF: registers implemented in the SpaceFibre clock domain. These registers are closely related to the SpaceFibre codec and the Virtual Channels: control and status of the codec, configuration of the Virtual Channels and the Broadcast Channel, Quality of Service, timeslot generation, etc.

- 0x800 - 0xFFF: registers implemented in the AMBA clock domain. These registers are related to the DMA channels, interrupt handling and external memory management (i.e. descriptor tables and broadcast channel external buffers).

Due to the internal cross domain crossing techniques, there will be a delay when accessing registers implemented in the SpaceFibre clock domain; waitstates are inserted in order to delay the reply from the internal core to guarantee the integrity of the signals. The AHB interface waits for a maximum of 256 AMBA clock cycles to avoid locking up the AMBA bus if there is no clock running on the codec

side. After that time, the IP simply replies with zeros and sets the TO flag in the SpaceFibre Status Register.

67.10.3 AMBA interrupts

GRSPFI triggers AMBA interrupts upon certain events. The IP is highly configurable when it comes to selecting which events shall produce an interrupt. This section describes how the interrupts are handled and monitored.

The Interrupt Control Register shall be used to configure 3 types of interrupts:

- Broadcast message transmitted.

- Broadcast message received.

- SpaceFibre link events.

These interrupts can only be generated when the Interrupt Enable bit of the Interrupt Control Register is asserted. Additionally, they are individually controlled by means of the BC TX Interrupt bit, BC RX Interrupt bit and Link Interrupt bit. The General Interrupt Status Register provides information regarding the status of these interrupts.

Note that there are several reasons that may trigger a Link interrupt, such as CRC, sequence or protocol errors or a reset triggered by the far-end node. The specific event which has triggered the interrupt can be observed by reading the Lane Layer Status Register and Retry Layer Status Register.

Additionally, every DMA channel can trigger interrupts based on events solely associated to the specific channel. In this case, another 3 events are relevant:

- SpaceFibre packet transmitted by the DMA channel.

- SpaceFibre packet received by the DMA channel.

- Error while reading or writing over the bus master interface of the DMA channel.

- RMAP command received and processed.

These interrupts can be controlled via the DMA Channel IRQ Control Register (one per DMA channel), by writing the TX Interrupt, RX Interrupt, Bus Error Interrupt and RMAP Interrupt bits.

The user can read the DMA Channel Status Register to know which DMA-related event has caused an interrupt. In case it was a bus master error, further information is provided: which Virtual Channel and specific descriptor was being served (not applicable to broadcast messages), as well as a 4-bit code to identify when the bus error occurred (fetching the descriptor, storing the packet, etc.). Please refer to the chapter covering the Register definition to learn how these fields are encoded.

Since there may be multiple DMA channels coexisting in GRSPFI, a register is made available to quickly identify which DMA channels have provoked an interrupt: the DMA Interrupts Status Register, where each position corresponds to a DMA channel. This avoids the process of polling all the DMA channels one by one until finding out which one produced an interrupt.

67.11 Implementation

67.11.1 Reset

The core changes its reset behavior depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

GRSPFI will feature a synchronous reset if the parameter *grlib_async_reset_enable* is not set in the GRLIB configuration package. Otherwise, it will implement an asynchronous reset if *grlib_async_reset_enable* is set.

GRIP

Apr 2024, Version 2024.1

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

67.11.2 Endianness

The core automatically changes its endianness behavior depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for both big-endian and little-endian systems.

67.11.3 Clocking scheme

As explained throughout this section, there are up to 4 clock domains in the IP. These paragraphs describe their use and how they shall be generated and connected.

•   AMBA clock (clk): the DMA and AMBA layers of the IP operate in this clock domain. It shall be connected to the AMBA clock of the system where the IP is instantiated.

•   SpaceFibre clock (spfi_clk): used by the core logic, including the SpFi codec and the interface between the DMA FIFOs and the codec, the timeslot generation logic and the address filters. Some AHB registers are also implemented in this domain. This clock is normally generated from the SerDes output transmitter clock by using a Clock Conditioning Circuit. The target frequency shall be the SpaceFibre bit-rate divided by 40 (i.e. assuming a 40-bit SerDes interface). This is dependent on the specific SerDes device used. Example: if the link operates at 2.5 Gbps, the target frequency shall always be 62.5 MHz. If the SerDes transmitter clock is 125 MHz, then the multiplication factor of the CCC shall be 0.5.

•   SpaceFibre transmitter clock (spfi_txclk): this clock is used by the transmitter logic within the codec if using a narrow SerDes interface (16/20 bits; both generics *use_sep_txclk* and *sel_16_20_bit_mode* set to 1). The target frequency shall be the SpaceFibre bit-rate divided by 20 (i.e. a 20-bit SerDes interface, twice the frequency of the SpaceFibre clock). Is is normally generated from the SerDes output transmitter clock. In the example above, the frequency of this clock shall be 125 MHz and could be generated from the SerDes TX clock without multiplication factor.

•   SpaceFibre RX recovered clock (spfii.rx_clk): if the data received from the SerDes is not synchronous to the SpaceFibre clock, the SerDes recovered RX clock shall be connected to this input. If the data is already synchronous, for instance because the SerDes comprises its own elastic buffer, this clock shall be connected to the SpaceFibre clock directly.

Any exchange of signals between clock domains, especially between the AMBA and SpaceFibre clocks, is protected by clock domain crossing techniques in order to avoid metastability problems in the IP.

Please note that the SpaceFibre clock and the AMBA clock have separate reset signals; the user shall ensure that these resets are properly synchronized with their respective clocks if a synchronous reset scheme is chosen.

67.11.4 Relation between GRSPFI and GRHSSL

GRHSSL is a High Speed Serial Link controller providing support for both SpaceFibre and Wizard-Link. The IP can be configured to implement either or both codecs by means of VHDL generics. When both protocols are implemented, the user shall select which codec is active at a time via AHB registers. The selected core will be in charge of driving the SerDes and bus master interfaces.

GRSPFI internally uses the GRHSSL IP and configures it so that only SpaceFibre is instantiated. Generics relevant to SpaceFibre are exposed in the top-level entity, whereas those related to Wizard-Link are tied to predefined values in order to guarantee that the WizardLink layer is not present in the design.

67.12 Registers

The core is programmed through registers mapped into AHB address space. Only 32-bit single accesses to the registers are supported. Registers within the range 0x000-0x7FF are implemented in the SpaceFibre clock domain, whereas the range 0x800-0xFFF is related to the AMBA/DMA layer.

67.12.3 Codec Control Register

Table 1107. 0x008 - CCTRL - Codec Control Register

31									16
Reserved									
0x0000									
r									

15	14	13	12	11			4	3	2	1	0
Reserved		SCR	LB	SBR				AS	LS	LNR	LIR
00		0	0	0x00				0	0	0	0
r		rw	rw	rw				rw	rw	rw	rw

13	Scramble Enable (SCR). The retry layer comprises a data scrambler, which can be enabled/disabled with this bit. The data scrambler becomes directly active right after asserting this flag. This will lead to continuous data retries if the de-scrambler of the remote node is not activated. Therefore, a lane reset must be triggered after asserting/de-asserting this flag. By doing so, the remote node is informed during the subsequent handshake if the data is scrambled or not and will then switch on or off the de-scrambler accordingly.
12	Loop-back mode (LB). The SpaceFibre codec has an internal loop-back feature that can be enabled / disabled with this bit. The codec must be reset after asserting/de-asserting this flag.
11: 4	Standby Reason (SBR). Byte to be included in the SpaceFibre STANDBY control words with the reason why the STANDBY control was sent or any other status information.
3	Auto-Start (AS). When asserted, the lane layer will passively listen to incoming words from the far end and start the handshake procedure once INIT1 words are received.
2	Lane Start (LS). When asserted, the lane layer will actively try to build up a connection with the far end by sending out INIT1 words.
1	Lane Reset (LNR). The lane can be reset at any time by asserting this bit. In contrast to link resets, a lane reset is only reinitialising the lane. Therefore, ongoing transmissions are probably delayed but never cancelled.
0	Link Reset (LIR). The SpaceFibre link can be reset by asserting this bit. As a consequence, outbound packets are spilled up to and including the next EOP and inbound packets are terminated by an EEP.

67.12.4 Lane Layer Status Register

Table 1108. 0x00C - LLSTAT - Lane Layer Status Register

31	24	23	20	19

10	Retry Buffer Empty (RBE). Set when the error recovery buffer is empty, i.e. all data frames, broadcast frames and FCT words have been sent and acknowledged.
9	Protocol Error (PE). Set when an ACK / NACK error has been detected.
8	Too Many Errors (TME). Set when the RETRY counter has overflown (i.e. the link is automatically reset).
7: 4	Retry Count (RTC). 4-bit wide counter that increments for every RETRY event initiated. It is automatically reset when an ACK word is received from the far end. The SpaceFibre link is automatically reset when the counter reaches 16.
3	Sequence Error (SE). Set when a sequence number error occurred during the reception of data frames, broadcast frames, idle frames, FCT or FULL words.
2	Frame Error (FE). Set when an invalid data, broadcast, or idle frame is received.
1	CRC-8 Error (C8E). Set when a CRC error has occurred during the reception of a control word or broadcast frame.
0	CRC-16 Error (CE). Set when a CRC error has occurred during the reception of a data frame.

		Reserved		
		0x0000		
		r		

15	8	7		0
DEFMSK		DEFADDR		
0x00		0x00		
rw		rw		

15: 8   Default Mask (DEFMSK). Mask used in the default address filter. When a bit of the mask is set, the corresponding bit of the SpaceFibre address is not compared with the Default Address. The default address filter is applied to the first address byte received of a SpaceFibre packet when the VC-specific address filter is not enabled.

7: 0   Default Address (DEFADDR). Default address compared with the masked SpaceFibre address byte. The default address filter is applied when the VC-specific address filter is not enabled.

67.12.7 Time-slot Register

Table 1111. 0x020 - TS - Time-slot Register

31	30	29		
Reserved		CNT		
00		0x000000		
r		r

CNT		Reserved		TS	
0x000000		00		0x00	
r		r		rw	

29: 8   Time-slot internal counter (CNT). Hardware counter used to update the value of the current time-slot if the internal generation is enabled in the Time-slot Control Register. When it matches the nominal length plus/minus the adjustment programmed by the user, the time-slot is incremented and the internal counter resets to 0. It is expressed in number of SpaceFibre clock cycles. Read-only.

5: 0   Time-Slot (TS). Current time-slot used to schedule the transmission over the SpaceFibre link among the Virtual Channels. If the internal time-slot generation is enabled, this value is automatically incremented by the core. In this case, the register may still be written in order to modify the value of the current time-slot. If the internal generation is disabled, this register must be written periodically by software in order to update the time-slot.

15	14	13	4	3	2	1	0
Reserved		ADJ		AS	AV	Res	EG
00		0x000		0	0	0	0
r		rw		rw	rw	r	rw

13: 4	Adjustment (ADJ). Unsigned value of the adjustment to be applied to the length of the next time-slot. It represents the number of clock cycles that need to be corrected with respect to the nominal value defined in the Time-slot Length Register. The Adjustment Sign determines if the time-slot shall be extended (AS = 0b) or shortened (AS = 1b). This correction is applied only for the next time-slot if the Adjustment Valid bit is set (AV = 1b). When shortening the time-slot, this value must be smaller than the Time-slot Nominal Length.
3	Adjustment Sign (AS). Determines if the next time-slot shall be extended (0b) or shortened (1b).
2	Adjustment Valid (AV). If set, GRSPFI will apply the adjustment specified in ADJ and AS. This is only done once; after that, the core sets this bit to 0b, in order to indicate that the correction has already been applied.
0	Enable Internal Generation of Time-slots (EG). If set to 1b, GRSPFI will autonomously increment the value of the time-slot: a counter will be compared with the valued defined in the Time-slot Length Register; once it reaches that value, the time-slot is updated. If set to 0b, the value of the time-slot can only be updated by writing directly to the Time-slot Register.

67.12.9 Time-slot Length Register

Table 1113. 0x028 - TSLEN - Time-slot Length Register

67.12.10 Broadcast Channel Configuration Register

Table 1114. 0x030 - BCCONF - Broadcast Channel Configuration Register

31				16
BW				
0x0000				
rw				

15	9	8	7	0
Reserved		BD	CHN	
0x00		0	0x00	
r		rw	rw	

31: 16   Broadcast Channel Bandwidth (BW). For information regarding the encoding of this field, please refer to 67.5.1.

8   Bypass DMA Engine (BD). When this bit is set, broadcast messages are directly exposed via the external FIFO ports of the IP (EXTBCI, EXTBCO), thus bypassing the DMA engine. If not set, broadcast messages are handled by the DMA engine by means of circular buffers. This bit is only available if the generic *numextbc* is set to 1.

7: 0   Broadcast Channel Number (CHN). When a broadcast message is transmitted by GRSPFI, it will use the value defined in this field as the Broadcast Channel number.

67.12.11 Virtual Channel Control Register

Table 1115. 0x100, 0x120, 0x140... 0x4E0 - VCCTRL - Virtual Channel Control Register

PR		Reserved		EFC		BD	Res	RE	AE
0x0		000		0x0		0	0	0	0
rw		r		rw		rw	r	rw	rw

31: 16   Virtual Channel Bandwidth (VBW). Bandwidth allocated to this Virtual Channel. For information regarding the encoding of this field refer to 67.4.1.

15: 12   Priority (PR). Establishes the priority of the Virtual Channel from 0 to 15, 0 being the highest priority and 15 the lowest. Used by the codec to guarantee the QoS over the SpaceFibre link.

8: 4   External FIFO Channel (EFC). Select the FIFO channel, ranging from 0 to *numextvc* - 1, that will handle this virtual channel when the VCCTRL.BD bit is set. This field is only available if the generic *numextvc* is not 0.

3   Bypass DMA Engine (BD). When this bit is set, packets for this virtual channel are directly exposed via the external FIFO ports of the IP (EXTVCI, EXTVCO), thus bypassing the DMA engine. If not set, they are handled by the DMA engine by means of hardware descriptors. This bit is only available if the generic *numextvc* is not 0.

1   RMAP Enable (RE). If set to 1b, RMAP commands received over this virtual channel will be handled by the RMAP target, otherwise they will be stored in memory via descriptors. Only used when the generic *rmap* is set.

0   Virtual Channel Address Enable (AE). If set to 1b, SpaceFibre packets received over this Virtual Channel will be compared with the address (and mask) defined in the VC Address Register in order to accept or filtered them out. If set to 0b, the default address filter is applied instead.

Reserved			TO	BT	BR	LE
0x0000			0	0	0	0
r			wc	wc	wc	wc

x: 16	DMA Channel Interrupt (DCI). Set when the core has generated an interrupt associated with a DMA channel. There is one status bit per DMA channel. The specific cause can be obtained by reading the corresponding DMA Channel Status Register. The value of x is calculated as $num\_dmach + 15$.
3	AHB Register Timeout (TO). Set when the DMA engine has reached the internal timeout (256 AMBA clock cycles) while waiting for a reply when accessing the AHB registers implemented on the codec clock domain.
2	Broadcast Transmission (BT). Set when a broadcast message has been transmitted successfully. This implies that the message has been fetched from external memory and passed on to the internal codec.
1	Broadcast Reception (BR). Set when a broadcast message has been received successfully. This implies that the message has been received by the codec, passed to the DMA layer and stored in external memory.
0	Link event (LE). Set when an event has occurred in the SpaceFibre Link. The specific event can be checked by reading the Lane Layer Status Register and especially the Retry Layer Status Register.

x		3	2	1	0
RXDESCSEL			Reserved		
All 0b			0x0		
rw			r		

31: x+1	RX Descriptor Table Address (RXADDR). Sets the base address of the descriptor table. The number of bits of this field depends on the size of the DMA receive descriptor table, determined by the generic *num_rxdesc*. The value of x is calculated as follows: $x = log_2(num\_rxdesc) + 2$.
x: 3	RX Descriptor Selector (RXDESCSEL). Offset within the descriptor table. Shows which descriptor is currently used by the core. For each new descriptor read, the selector will increase by 8 and eventually wrap to zero again. The number of bits of this field depends on the size of the DMA receive descriptor table, determined by the generic *num_rxdesc*. The value of x is calculated as follows: $x = log_2(num\_rxdesc) + 2$.

67.12.33 Virtual Channel Descriptor Control Register

Table 1137. 0x908, 0x918, 0x928... 0xAF8 - VCDCTRL - Virtual Channel Descriptor Control Register

31	30	29	16
TDA	RDA	Reserved	
0	0	0x0000	
r	r	r	

15		4	3	2	1	0
Reserved			CTD	CRD	NTD	NRD
0x000			0	0	0	0
r			w	w	w	w

31	Transmit Descriptor Available (TDA). Read-only bit indicating whether the TX descriptor table contains descriptors yet to be fetched and processed. Cleared when the core finds a disabled descriptor (Descriptor Enable bit set to 0b inside the descriptor) or when a bus master error occurs during transmission.
30	Receive Descriptor Available (RDA). Read-only bit indicating whether the RX descriptor table contains descriptors yet to be fetched and processed. Cleared when the core finds a disabled descriptor (Descriptor Enable bit set to 0b inside the descriptor) or when a bus master error occurs during reception.
3	Clear Transmit Descriptor Table (CTD). Write-only bit that, when set, clears the content of the TX Descriptor Table. It takes effect only when the DMA channel handling the current Virtual Channel is in IDLE state.
2	Clear Receive Descriptor Table (CRD). Write-only bit that, when set, clears the content of the RX Descriptor Table. It takes effect only when the DMA channel handling the current Virtual Channel is in IDLE state.
1	New Transmit Descriptor Available (NTD). Write-only bit that indicates to GRSPFI that new descriptors have been added to the TX Descriptor table. It takes effect only when the DMA channel handling the current Virtual Channel is in IDLE state.
0	New Receive Descriptor Available (NRD). Write-only bit that indicates to GRSPFI that new descriptors have been added to the RX Descriptor table. It takes effect only when the DMA channel handling the current Virtual Channel is in IDLE state.

BMEDSC			BMECD			TX	RX	TA	RA
0x000			0x0			0	0	0	0
wc			wc			wc	wc	r	r

25	RMAP done (RD). Set when the RMAP target has completed the processing of an RMAP command, including the transmission of a reply, if applicable. Only used when the VHDL generic *rmap* is set.
24: 20	Bus Master Error - Virtual Channel (BMEVC). This field identifies which Virtual Channel was being served when an error occurred during an access through the bus master interface. If no Virtual Channels are involved (i.e. Broadcast Channel) then this field returns 0x00. Cleared to 0x00 when the Bus Master Error Code field is written.
17: 8	Bus Master Error - Descriptor (BMEDSC). This field identifies which descriptor was being used when an error occurred during an access through the bus master interface. If no descriptors are involved (i.e. Broadcast Channel) then this field returns 0x000. Cleared to 0x000 when the Bus Master Error Code field is written.
7: 4	Bus Master Error - Code (BMECD). This field specifies what type of error occurred when accessing the bus. Writing to this field clears the content of all the bus master error-related fields: BMEVC, BMEDSC and BMECD. Encoding:
	0x0: No errors
	0x1: Fetching RX descriptor
	0x2: Storing received SpaceFibre packet
	0x3: Updating RX descriptor
	0x4: Storing received broadcast message
	0x5: Fetching TX descriptor
	0x6: Fetching the header of a SpaceFibre packet for transmission
	0x7: Fetching the data of a SpaceFibre packet for transmission
	0x8: Updating TX descriptor
	0x9: Fetching broadcast message for transmission
	0xA: Write access to the bus while processing an RMAP command

0xB: Read access to the bus while processing an RMAP command

3	Packet transmitted (TX). If set to 1b, this DMA channel has fetched and passed a complete SpaceFibre packet on to the codec, and the associated descriptor has been updated. Cleared to 0b when written.
2	Packet received (RX). If set to 1b, this DMA channel has read a complete SpaceFibre packet from the codec and written it to external memory, and the associated descriptor has been updated. Cleared to 0b when written.
1	Transmitter Active (TA). If set to 1b, the transmitter of this DMA channel is active. It may imply that the Transmitter Enable bit in the DMA Channel Control Register is set, or that the DMA channel is still completing an ongoing operation before being disabled.
0	Receiver Active (RA). If set to 1b, the receiver of this DMA channel is active. It may imply that the Receiver Enable bit in the DMA Channel Control Register is set, or that the DMA channel is still completing an ongoing operation before being disabled.

67.12.36 DMA Channel VC Mapping Register

Table 1140. 0xB08, 0xB18, 0xB28... 0xB78 - DCMAP - DMA Channel VC Mapping Register

31
VCMAP
0x00000000
rw

0
VCMAP
0x00000000
rw

31: 0	DMA channel - Virtual Channel Mapping (VCMAP). This register configures which Virtual Channels are served by the current DMA channel. A specific Virtual Channel may only be handled by a single DMA channel at a time. Each bit (from 0 to 31) represents a different Virtual Channel; positions for Virtual Channels not implemented are reserved and will always return 0b.

67.12.37 DMA Channel IRQ Control Register

Table 1141. 0xB0C, 0xB1C, 0xB2C... 0xB7C - DCICTRL - DMA Channel IRQ Control Register

31	16
Reserved	
0x0000

15				4	3	2	1	0
Reserved					RMI	BEI	TI	RI
0x000					0	0	0	0
r					rw	rw	rw	rw

3	RMAP Interrupt Enable (RMI). If set to 1b, GRSPFI will generate an AMBA interrupt when an RMAP command has been processed, including the transmission of a reply when applicable. Only used if the VHDL generic *rmap* is set.
2	Bus Master Error Interrupt Enable (BEI). If set to 1b, GRSPFI will generate an AMBA interrupt when an error is detected during an access over the bus master interface of this DMA channel.
1	Transmit Interrupt Enable (TI). If set to 1b, GRSPFI will generate AMBA interrupts when this DMA channel has completely fetched a SpaceFibre packet and passed it on to the codec for transmission, and the corresponding descriptor has been updated. Note that the Interrupt Enable bit in the descriptor associated with the packet shall also be set to 1b.
0	Receive Interrupt Enable (RI). If set to 1b, GRSPFI will generate AMBA interrupts when this DMA channel has completely read a SpaceFibre from the codec and stored it in external memory, and the corresponding descriptor has also been updated. Note that the Interrupt Enable bit in the descriptor associated with the packet shall also be set to 1b.

67.12.38 DMA Channel Extended Status Register

Table 1142. 0xB80, 0xB90, 0xBA0... 0xBF0 - DCSTAT2 - DMA Channel Extended Status Register

31								16
RC								
0x0000								
wc								

15	14	13	12	8	7	6	5	4	0
TAF	TF	TS	TFS		RAE	RE	RS	RFS	
0	0	0	0x01		1	1	0	0x01	
r	r	r	r		r	r	r	r	

31: 16   RMAP counter (RC). Number of RMAP commands successfully processed by the core. Cleared when written to a value other than 0. Only used if the VHDL generic *rmap* is set.

15   TX FIFO Almost Full (TAF). Read-only flag generated by the local TX FIFO indicating that it is almost full, i.e., its available space is lower than 256 bytes.

14   TX FIFO Full (TF). Read-only flag generated by the local TX FIFO indicating that it is full.

13   TX Start (TS). Read-only signal generated by the DMA FSM to indicate an ongoing transmission.

12: 8   TX FSM State (TFS). Read-only field containing the current state of the TX FSM. Encoding:
0x01 Idle | 0x02 Select next Virtual Channel | 0x03 Fetch TX descriptor | 0x04 Read TX descriptor |
0x05 Start TX | 0x06 Fetch header bytes | 0x07 Burst access for header bytes | 0x08 Fetch data bytes |
0x09 Burst access for data bytes | 0x0A Wait for TX end | 0x0B Update TX descriptor | 0x0C End of TX |
0x0D Fetch broadcast message | 0x0E Read broadcast message | 0x0F Transmit broadcast message |
0x10 Form RMAP reply header | 0x11 RMAP read operation | 0x12 RMAP single read access |
0x13 RMAP incremental read access | 0x14 RMAP RMW data | 0x15 End of RMAP reply.

7   RX FIFO Almost Empty (RAE). Read-only flag generated by the local RX FIFO indicating that it is almost empty, i.e., it contains less than 256 bytes of data.

6   RX FIFO Empty (RE). Read-only flag generated by the local RX FIFO indicating that it is empty.

5   RX Start (RS). Read-only signal generated by the DMA FSM to indicate an ongoing reception.

4: 0   RX FSM State (RFS). Read-only field containing the current state of the RX FSM. Encoding:
0x01 Idle | 0x02 Select next Virtual Channel (descriptor prefetching) | 0x03 Prefetch descriptor |
0x04 Read descriptor | 0x05 Select next virtual channel (data storage) | 0x06 Store packet |
0x07 Write burst stage 1 | 0x08 Write burst stage 2 | 0x09 Write burst stage 3 | 0x0A Update RX descriptor |
0x0B End of RX | 0x0C Store broadcast message | 0x0D Broadcast message RX end |
0x0E Select next virtual channel (RMAP) | 0x0F Read RMAP header | 0x10 Decode RMAP header |
0x11 RMAP non-verified command | 0x12 RMAP single write access | 0x13 RMAP incremental write stage 0 |
0x14 RMAP incremental write stage 1 | 0x15 RMAP verified command | 0x16 RMAP verified read (RMW) |
0x17 RMAP verified write | 0x18 RMAP read | 0x19 Discard RMAP packet | 0x1A Waiting on RMAP reply.

67.13   Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0BC (GRSPFI). For description of vendor and device identifiers see GRLIB IP Library User's Manual.

67.14   Configuration options

Table 1143 shows the configuration options of the core (VHDL generics).

Table 1143. Configuration options

Generic name	Function	Allowed range	Default
tech	Technology for the internal memories.	0 - NTECH	inferred (0)
hmindex	AHB master index of the first DMA channel. The rest of the DMA channels are assigned an index depending on the settings of the generic *incr_hmindex*. Only present in the AHB wrapper.	0 - NAHBMST-1	0
hsindex	AHB slave index.	0 - NAHBSLV-1	0

*Table 1143.*Configuration options

Generic name	Function	Allowed range	Default
haddr	Addr field of the AHB bar.	0 - 16#FFF#	0
hmask	Mask field of the AHB bar.	0 - 16#FFF#	16#FF0#
hirq	Interrupt line used by GRSPFI.	0 - NAHBIRQ-1	0
use_8b10b	If set, internal 8B10B encoding and decoding is activated.	0 - 1	1
use_sep_txclk	If set, the SerDes transmission clock is decoupled from the SpaceFibre port clock. An additional transmit buffer is instantiated for this reason.	0 - 1	0
sel_16_20_bit_-mode	If set, the SerDes interface is 16+2 bit (without 8B10B) or 20 bit (with 8B10B) wide instead of 36/40 bit. If set, *use_sep_txclk* must also be set.	0 - 1	0
ticks_2us	Clock ticks corresponding to 2 us.	1 - 8192	125
tx_skip_freq	Frequency of SKIP word transmission in clock cycles.	1 - 8192	5000
prbs_init1	If set, the INIT1 sequence during lane initialization is embedded into a stream of pseudo-random numbers.	0 - 1	1
depth_rbuf_data	Log(Depth) of the data retry buffer.	1 - 32	8
depth_rbuf_fct	Log(Depth) of the FCT retry buffer.	1 - 32	4
depth_rbuf_bc	Log(Depth) of the broadcast retry buffer.	1 - 32	8
num_vc	Number of virtual channels.	1 - 32	4
fct_multiplier	Multiplier used in the internal FCT logic. The value of the FCT counter is compared with 64*fct_multiplier to decide if the far end can receive new words.	1 - 8	1
depth_vc_rx_buf	Log(Depth) of virtual channel input buffer.	1 - 32	10
depth_vc_tx_buf	Log(Depth) of virtual channel output buffer.	1 - 32	10
remote_fct_cnt_-max	Width of the remote FCT counter.	1 - 32	9
width_bw_credit	Width of the bandwidth credit counter.	0 - 16#FFFFFFFF#	20
min_bw_credit	Minimum bandwidth credit threshold limit.	0 - 16#FFFFFFFF#	52428
idle_time_limit	Bandwidth idle time limit in clock cycles.	0 - 65535	62500
num_dmach	Number of DMA channels.	1 - 8	1
num_txdesc	Size of the TX descriptor table in number of descriptors.	64, 128, 256, 512	64
num_rxdesc	Size of the RX descriptor table in number of descriptors.	128, 256, 512, 1024	128
depth_dma_fifo	Depth of the DMA FIFOs. Sets the number of entries in the 128-bit transmitter and receiver FIFOs (2 FIFOs per DMA channel).	16 - 256	32
depth_bc_fifo	Depth of the BC FIFO. Sets the number of entries in the 82-bit receiver FIFO.	1 - 32	4
incr_hmindex	If set, the AHB master indices of the DMA channels are assigned incrementally, starting with hmindex. Otherwise, all AHB master indices are set to hmindex. Only present in the AHB wrapper.	0 - 1	1
use_async_rxrst	Force asynchronous reset in the recovered clock domain, regardless of the general GRLIB settings.	0 - 1	0
ft_core_vc	Enable fault-tolerance against SEU errors for the FIFOs in the Virtual Channel Layer. Possible options are byte parity protection (ft = 1), TMR registers (ft = 2), SECDED BCH (ft = 4) or technology specific protection (ft = 5). If set to 0, no protection is implemented.	0 - 2, 4 - 5	0

*Table 1143.*Configuration options

Generic name	Function	Allowed range	Default
ft_core_rt1	Enable fault-tolerance against SEU errors for the large FIFOs in the Retry Layer (Data and Broadcast). The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_core_rt2	Enable fault-tolerance against SEU errors for the small FIFOs in the Retry Layer (FCT and pointers). The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_core_if	Enable fault-tolerance against SEU errors for the FIFOs in the Interface Layer. The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_dma_data	Enable fault-tolerance against SEU errors for the TX/RX FIFOs in the DMA layer. The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_dma_bc	Enable fault-tolerance against SEU errors for the Broadcast Channel FIFOs in the DMA layer. The core supports the same configurations as above.	0 - 2, 4 - 5	0
scantest	Enable Scan Test support.	0 - 1	0
ahbbits	Width of AHB read/write data buses and maximum access size. Only present in the AHB wrapper.	32, 64, 128	AHBDW
lendian	Select endianness of the system: 0 for big-endian, 1 for little-endian. Only present in the AXI wrapper.	0 - 1	1
rmap	If set, every DMA channel will feature a hardware RMAP target and RMAP CRC logic.	0 - 1	0
rmapcrc	Include RMAP CRC logic in every DMA channel without implementing a full RMAP target.	0 - 1	0
ccsdscrc	Enable CCSDS/CCITT CRC-16 and 16-bit ISO-checksum (J.G. Fletcher, ISO 8473-1:1998) logic in every DMA channel. It requires that either *rmap* or *rmapcrc* is also set to 1.	0 - 1	0
nodeaddr	When set to 0 - 254: this generic specifies the reset value for the DEFADDR.DEFADDR field. When set to 255: Reset value for the node address is taken from the CFG.NODEADDR input signal.	0 - 255	254
destkey	Reset value for the core destination key.	0 - 255	0
numextvc	Number of external FIFO interfaces that can be used to bypass the DMA engine when transmitting and receiving packets over a specific virtual channel.	0 - 32	0
numextbc	If set, implement an external FIFO interface that can be used to bypass the DMA engine when transmitting and receiving broadcast messages.	0 - 1	0

67.15 Signal descriptions

Table 1144 shows the interface signals of the core when using the wrapper for AMBA AHB 2.0 (VHDL ports).

Table 1144. Signal descriptions

Signal name	Field	Type	Function	Active
RSTN	N/A	Input	System reset	Low
CLK	N/A	Input	AMBA clock	-
SPFI_RSTN	N/A	Input	SpaceFibre reset	Low

68   GRSPFI_CODEC - SpaceFibre encoder/decoder

68.1   Overview

SpaceFibre is a high-speed serial link mainly designed for payload data processing applications on board spacecraft. Like many other modern network architectures, SpaceFibre utilises a Serialiser/ Deserialiser (SerDes) circuit at its physical layer, allowing data rates of 2 Gbit/s and more. The SerDes can either be part of the chip design or a standalone device can be used.

Interfacing a SpaceFibre port from the user application is simple as it closely follows the procedure known from SpaceWire. A SpaceFibre port has one or more pairs of transmit and receive buffers, referred to as virtual channels, and each virtual channel acts like a single SpaceWire interface, i.e. several SpaceWire network streams can be multiplexed into one SpaceFibre network stream. The multiplexer is called medium access controller and is choosing the active virtual channel according to a number of Quality-of-Service (QoS) rules.

Data is always transferred in frames with a size of 256 bytes or less. While such a data frame is passed to the physical link, it is also stored in an error recovery buffer. It remains in this buffer until the far end node acknowledges the correct reception of the frame, which is detected by checking a CRC checksum at the end of the frame. However, if the far end node sends a negative-acknowledgement (NACK) word instead, the frame is re-transmitted from the error-recovery buffer.

Aside from data frames, SpaceFibre also supports broadcast frames, which are multi-purpose high-priority messages. These messages are comparable to SpaceWire time-codes but in addition to a simple sequence number they also transmit a data payload of 8 bytes. Broadcast frames are stored in the replay buffer just like the data frames, i.e. they are automatically retransmitted after a link error.

On the receive side, incoming data from the physical link is processed continuously, i.e. one 32-bit word is processed every clock cycle. To avoid buffer overruns in the virtual channel receive buffers, the communication between a virtual channel transmit buffer in the local node and the virtual channel receive buffer in the far end node is flow-controlled by means of Flow Control Token (FCT) words. Just like the data and broadcast frames, the FCT words are stored in the error-recovery buffer and are therefore retransmitted in case of errors.

A simplified block diagram of the SpaceFibre IP core can be seen in Figure 166. The SpaceFibre IP port comprises a data link layer and lane layer. Internally, the data link layer is further divided into the so-called broadcast layer, virtual channel layer and retry layer, which are responsible for the transmission and reception of broadcast frames, for the transmission and reception of data frames and for the error recovery mechanism, respectively.

Signals related to the broadcast interface have the prefix 'bc', signals related to the virtual channel interface the prefix 'vc', and signals related to the SerDes the prefix 'se'. Furthermore, the prefix 'cf' describes a configuration parameter signal whereas the prefix 'sr' describes a status register signal.

68.2 Operation

68.2.1 Configuration

All soft configuration parameters are synchronous to clock *clk* and should be stored in registers external to the SpaceFibre IP core.

Global configuration

The SpaceFibre link can be reset by asserting *cf_link_rst*. As a consequence, outbound packets are spilled up to and including the next EOP and inbound packets are terminated by an EEP.

Lane Layer

The lane initialization state machine is controlled with the signals *cf_lane_start* and *cf_auto_start*. When *cf_lane_start* is asserted, the lane layer will actively try to build up a connection with the far end by sending out INIT1 words. When *cf_auto_start* is asserted, the lane layer will passively listen to incoming words from the far end and start the handshake procedure once INIT1 words are received. *cf_lane_start* has higher precedence than *cf_lane_auto_start*. To shut down the lane, both *cf_lane_auto_start* and *cf_lane_start* must be de-asserted. When shut down, the transmitter and receiver parts of the SerDes are disabled as well.

The lane can be reset at any time by asserting *cf_lane_rst*. In contrast to link resets, a lane reset is only reinitialising the lane. Therefore, ongoing transmissions are probably delayed but never canceled.

The SpaceFibre IP core has an internal loop-back feature that can be enabled/ disabled with *cf_la_loopback*. The SpaceFibre IP core must be reset after asserting/de-asserting this flag.

Retry Layer

The retry layer comprises a data scrambler, which can be enabled/disabled with *cf_data_scr_en*. The data scrambler becomes directly active after asserting this flag. This will lead to continuous data retries if the de-scrambler of the remote node is not activated. Therefore, a lane reset must be triggered after asserting/de-asserting this flag. By doing so, the remote node is informed during the subsequent handshake if the data is scrambled or not and will then switch on or off the de-scrambler accordingly.

Broadcast Layer

The transmission of broadcasts is limited in bandwidth depending on an expected bandwidth value defined by the 16-bit wide port *cf_bc_expected_bw*. Typical values are between 1% and 95%. If the user application tries to send more broadcasts than allowed, the bandwidth limitation becomes automatically active. *cf_bc_expected_bw* is expressed in 0.16 fixed point format and is calculated as follows:

$$ExpectedBandwidth = \frac{Percentage}{400}$$

For example, the expected bandwidth value of 10% is expressed as: 10/400 = 0.025. In 0.16 fixed point notation: 0x0666. For convenience, these values are pre-calculated for 1% to 95% and stored in a constant array in the package file spfi_pkg.vhd. The transmission of broadcasts can also be completely switched off by setting the expected bandwidth value to 0x0000.

Virtual Channel Layer

The transmission of data frames is bandwidth-limited for each virtual channel. The expected bandwidth values for all virtual channels are concatenated in port vector *cf_vc_expected_bw*. Each expected bandwidth value is 16-bit wide. For instance, the value for virtual channel 0 is stored at bit positions 15:0 and the value for virtual channel 1 is stored at bit positions 31:16. The expected bandwidth values are expressed in 8.8 fixed point format and are calculated as follows:

GRIP
Apr 2024, Version 2024.1

980

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

$$ExpectedBandwidth = \left| 1 - \frac{100}{Percentage} \right|$$

For example, the expected bandwidth value of 15% is expressed as: abs(1-(100/15)) = 5.6667. In 8.8 fixed point notation: 0x05ab. For convenience, these values are pre-calculated for 1% to 95% and stored in a constant array in the package file spfi_pkg.vhd. A virtual channel can also be completely switched off by setting its expected bandwidth value to 0x0000.

The timeslot vectors for all virtual channels are concatenated in port vector *cf_vc_tslot_vecs*. Since SpaceFibre offers 64 timeslots per virtual channel, the timeslot vector for virtual channel 0 is stored at bit positions 63:0, the timeslot vector for virtual channel 1 at bit positions 127:0 and so on. Each bit enables or disables the transmission of data frames in the timeslot with the number of the bit position. For instance, to allow virtual channel 0 to send data in timeslot 0, timeslot 3 and timeslot 7, one can set its timeslot vector to: 0b10001001 = 0x89.

The priority values for all virtual channels are concatenated in port vector *cf_vc_priorities*. Each priority value is 4-bit wide, i.e. the priority levels 0 to 15 are supported. For instance, the value for virtual channel 0 is stored at bit positions 3:0 and the value for virtual channel 1 is stored at bit positions 7:4. Priority level 15 has the lowest precedence and priority level 0 has the highest precedence.

68.2.2 Status signaling

Lane Layer

The status flag *sr_far_end_lrst* is pulsed high if a link reset was triggered due to a system reset in the far end node. *sr_far_end_los* is pulsed if a new handshake is started due to a loss of signal at the SerDes receiver. *sr_rxerr_count* is an 8-bit wide counter for received RXERR words. The counter is automatically decreased by one every time 16,384 more words have been received. *sr_rxerr_count_of* is pulsed when the RXERR word counter overflows. *sr_rx_polarity* is set when the lane layer detects inverted receive polarity during handshake. If internal 8B10B decoding is activated, the polarity of the incoming bitstream is automatically inverted.

sr_far_end_standby is pulsed when STANDBY words are received. This is always the case when the link initialization state machine in the far end node is deactivated. *sr_timeout* is set when a connection timeout occurs during lane initialization. *sr_lane_state* is a 4-bit wide unsigned value encoding the current lane initialization state as follows:

Table 1146. Lane initialization state encoding

1	Clear Line
2	Disabled
3	Wait
4	Started
5	Invert Rx Polarity
6	Connecting
7	Connected
8	Active
9	Loss Of Signal
10	Prepare Standby

GRIP

Apr 2024, Version 2024.1

981

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

Retry Layer

sr_crc16_err is pulsed when a CRC error has occurred during the reception of a data frame. *sr_crc8_err* is pulsed when a CRC error has occurred during the reception of a control word or broadcast frame. *sr_seq_err* is pulsed when a sequence number error occurred during the reception of data frames, broadcast frames, idle frames, FCT or FULL words. *sr_frame_err* is pulsed when an invalid data, broadcast, or idle frame is received.

sr_rbuf_empty is set when the error recovery buffer is empty, i.e. all data frames, broadcast frames and FCT words have been sent and acknowledged. *sr_retry_cnt* is an 4-bit wide counter that increments for every RETRY event initiated. It is automatically reset when an ACK word is received from the far end. The SpaceFibre link is automatically reset when the counter reaches 16.

Virtual Channel Layer

sr_fct_cnt_ov is a bit vector where each bit position corresponds to a virtual channel number. The bit is pulsed when the corresponding FCT credit counter has overflowed. This indicates that the width of the FCT counter, defined by *remote_fct_cnt_max*, is too small. *sr_input_buf_ov* is a bit vector where each bit position corresponds to a virtual channel number. The bit is set when a virtual channel input buffer is receiving data when it is full. This indicates a fatal protocol error. *sr_dest_has_credit* is a bit vector where each bit position corresponds to a virtual channel number. The bit is set when there is space in the virtual channel input buffer of the far end node. *sr_bw_over_use* is a bit vector where each bit position corresponds to a virtual channel number. The bit is set when the virtual channel uses more bandwidth than expected, i.e. when the bandwidth overuse mechanism is active. In contrast, *sr_bw_under_use* indicates that a virtual channel uses less bandwidth than expected. Note that this flag is also set when a virtual channel is deactivated due to an expected bandwidth value of 0, even if the user application tries to transmit data over this virtual channel.

68.2.3 Virtual channel interface

Transmit side

On port *vc_tx_data*, data is fed into the virtual channel transmit buffers. The input vectors are 32-bit wide and concatenated, i.e. the data word for virtual channel 0 is stored at bit positions 31:0, the data word for virtual channel 1 is stored at bit positions 63:32 and so on. The lowest byte is transmitted first. On port *vc_tx_kflags*, a 4-bit vector for each virtual channel defines which bytes of the data transmit word are k-codes. The vectors are concatenated as well, i.e. the k-flags vector for virtual channel 0 is stored at bit positions 3:0, the k-flags vector for virtual channel 1 is stored at bit positions 7:4 and so on. The lowest bit in the k-flags vector corresponds to the lowest byte of the data word. The following k-codes are allowed:

Table 1147. SpaceFibre k-codes

SpaceFibre Character	K-Code	Corresponding data byte
EOP – End of packet	K29.7	0xFD
EEP – Error end of packet	K30.7	0xFE
FILL – Fill character	K27.7	0xFB

An example of how to use the k-codes correctly is shown in figure 167. The first four lines are normal data words, which are part of the payload of a SpaceWire packet. The k-flags vector must be set to 0b0000. In line 5, the SpaceWire packet is terminated by an EOP. Due to the byte-order, the k-code for the EOP is transmitted as least significant byte. The EOP is followed by three FILL characters for achieving word alignment. The k-flags vector must be set to 0b1111 because all bytes of the word are k-codes. In line 6, a new SpaceWire packet begins, starting with physical address 0x08. The address is transmitted as most significant byte since three FILL characters must be transmitted first. Here, the k-flags vector must be set to 0b0111 because only the FILL characters are k-codes.

GRIP
Apr 2024, Version 2024.1

982

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Usage of any other k-codes than the aforementioned ones for EOP, EEP an FILL characters must be avoided. SpaceFibre uses k-codes for control words on lower protocol layers. Injecting the wrong combination of k-codes through the virtual channel interface can compromise the correct functionality of the SpaceFibre protocol.

TX Data Word **K-Flags**

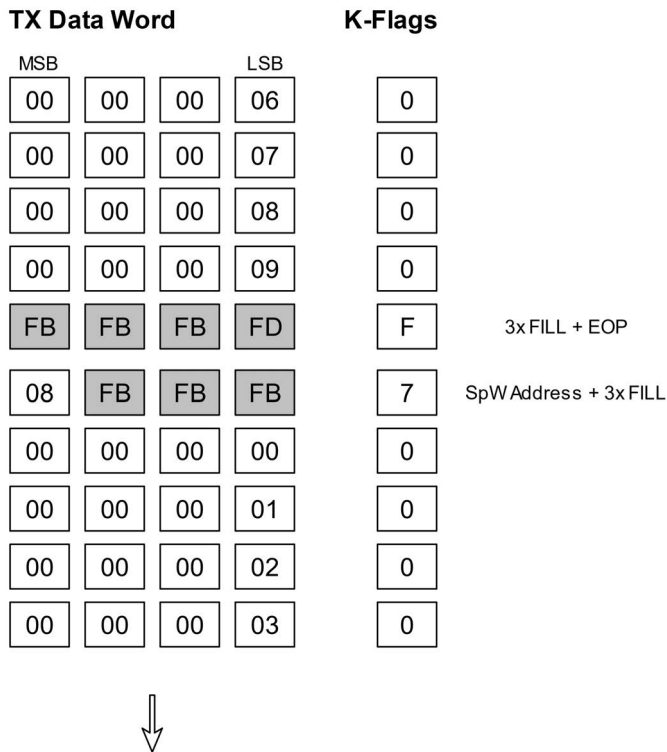
MSB			LSB		
00	00	00	06	0	
00	00	00	07	0	
00	00	00	08	0	
00	00	00	09	0	
FB	FB	FB	FD	F	3x FILL + EOP
08	FB	FB	FB	7	SpW Address + 3x FILL
00	00	00	00	0	
00	00	00	01	0	
00	00	00	02	0	
00	00	00	03	0	


Figure 167. Example of k-code usage

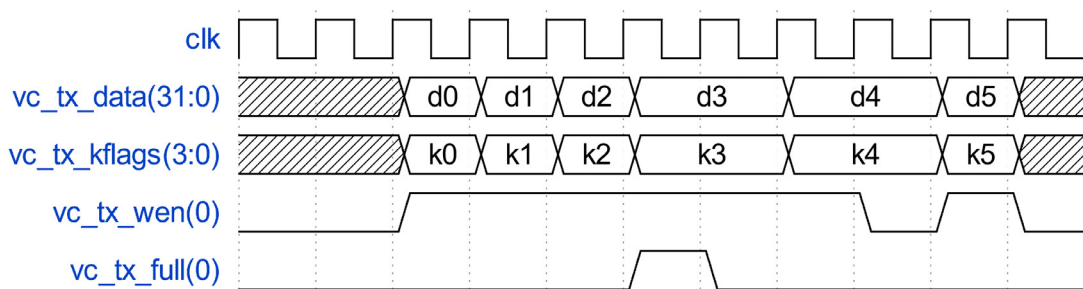
To write into a virtual channel transmit buffer, the write enable flag for the virtual channel in bit vector *vc_tx_wen* must be asserted. The bit position corresponds to the virtual channel number. If the transmit buffer is full, the full flag for the virtual channel in bit vector *vc_tx_full* is asserted. Again, the bit position of the flag corresponds to the virtual channel number. If the transmit buffer is full, any further write attempts are ignored. An example timing diagram for virtual channel 0 is shown in figure 168.


Figure 168. Example timing diagram - virtual channel 0 transmit side

The medium access controller allows the assignment of virtual channels to specific timeslots. *vc_tx_timeslot* is a 6-bit wide unsigned value defining the current timeslot number between 0 and 63.

Receive side

On port *vc_rx_data*, data is read out from the virtual channel input buffers. The output vectors are 32-bit wide and concatenated, i.e. the data word for virtual channel 0 is stored at bit positions 31:0, the

GRIP
Apr 2024, Version 2024.1

983

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

data word for virtual channel 1 is stored at bit positions 63:32 and so on. The lowest byte is the one received first. On port *vc_rx_kflags*, a 4-bit vector for each virtual channel defines which bytes of the received data word are k-codes. The vectors are concatenated as well, i.e. the k-flags vector for virtual channel 0 is stored at bit positions 3:0, the k-flags vector for virtual channel 1 is stored at bit positions 7:4 and so on. The lowest bit in the k-flags vector corresponds to the lowest byte of the data word. The same k-codes as described in table 1147 can occur, i.e. EOP, EEP and FILL characters.

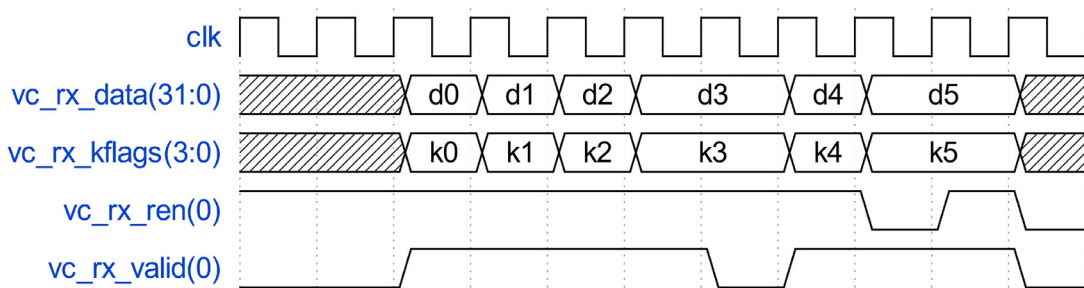
To read from a virtual channel receive buffer, the read enable flag for the virtual channel in bit vector *vc_rx_ren* must be asserted. The bit position corresponds to the virtual channel number. Data on *vc_rx_data* is only valid if the corresponding valid flag in bit vector *vc_rx_valid* is asserted. Again, the bit position corresponds to the virtual channel number. This FIFO scheme makes it particularly easy to interface other FIFO-like interfaces in the user logic. For instance, one could loopback the received data to the transmit side by simply connecting *vc_tx_data* to *vc_rx_data*, *vc_tx_kflags* to *vc_rx_kflags*, *vc_tx_wen* to *vc_rx_valid* and *vc_rx_ren* to not(*vc_tx_full*). An example timing diagram is shown in figure 169.


Figure 169. Example timing diagram - virtual channel 0 receive side

68.2.4 Broadcast interface

Transmit side

A broadcast delivers 8 bytes of payload, which are fed into the SpaceFibre IP core on port *bc_tx_data*. The lowest byte is transmitted first. Each broadcast has a channel and sequence number, which can be fed in at port *bc_tx_channel* and *bc_tx_seq* respectively. The write enable flag *bc_tx_wen* must be asserted to write the broadcast. Once the flag is set, an internal state machine prepares and executes the transmission of the broadcast frame. During this process the broadcast data, channel and sequence number must be kept stable. The SpaceFibre IP core signals the end of the transmission by pulsing the active-high flag bc_tx_ack for one clock cycle. An example timing diagram is shown in figure 170.
Figure 170. Example timing diagram - broadcast channel transmit side

Receive side

On the receive side, broadcast payload data is available on port *bc_rx_data*, the broadcast channel number on port *bc_rx_channel* and the broadcast sequence number on port *bc_rx_seq*. If the broadcast was sent during a retry, i.e. if the broadcast is unusually delayed, the flag *bc_rx_late* is high. Data

GRIP
Apr 2024, Version 2024.1

984

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

on the aforementioned ports is only valid when the active-high flag *bc_rx_valid* is pulsed for one clock-cycle. From a user's perspective, this flag can be used as a write enable signal for some sort of memory to store the broadcast data for further processing.
Figure 171. Example timing diagram - broadcast channel receive side

68.2.5 Serdes interface

Transmit

The internal data path width of the SpaceFibre IP core is 32 bits. The SpaceFibre IP core allows several different configurations:

- Large SerDes interface (*sel_16_20_bit_mode* is false), internal 8B10B encoding is activated (*use_8b10b* is true): In this configuration, 8B10B encoded 40-bit wide transmit data is outputted at *se_tx_data*(39:0). *se_tx_kflags*(3:0) is unused and can be left open.

- Large SerDes interface (*sel_16_20_bit_mode* is false), internal 8B10B encoding is deactivated (*use_8b10b* is false): In this configuration, unencoded 32-bit wide transmit data is outputted at *se_tx_data*(31:0). *se_tx_kflags*(3:0) is active and must be connected to the external 8B10B encoder, e.g. within the SerDes device.

- Small SerDes interface (*sel_16_20_bit_mode* is true), internal 8B10B encoding is activated (*use_8b10b* is true): In this configuration, 8B10B encoded 20-bit wide transmit data is outputted at *se_tx_data*(19:0). *se_tx_kflags*(3:0) is unused and can be left open.

- Small SerDes interface (*sel_16_20_bit_mode* is true), internal 8B10B encoding is deactivated (*use_8b10b* is false): In this configuration, unencoded 16-bit wide transmit data is outputted at *se_tx_data*(15:0). *se_tx_kflags*(1:0) is active and must be connected to the external 8B10B encoder, e.g. within the SerDes device.

If the lane layer of the SpaceFibre IP core is deactivated, the flag *se_tx_en* is low. It can be used to switch off the transmit side of the SerDes to save power during idle times.

For debug purposes, the transmit data and k-flags before any possible data path width conversion and 8B10B encoding can be monitored at *se_tx_data_dbg* and *se_tx_kflags_dbg*.

Receive

Similarly to the transmit side, the SerDes interface is used differently depending on the configuration:

- Large SerDes interface (*sel_16_20_bit_mode* is false), internal 8B10B decoding is activated (*use_8b10b* is true): In this configuration, 8B10B encoded 40-bit wide receive data is fed in on port *se_rx_data*(39:0). *se_rx_kflags*(3:0) is unused and can be tied to ground.

- Large SerDes interface (*sel_16_20_bit_mode* is false), internal 8B10B encoding is deactivated (*use_8b10b* is false): In this configuration, unencoded 32-bit wide receive data is fed in on port *se_rx_data*(31:0). *se_rx_kflags*(3:0) is active and must be connected to the external 8B10B decoder, e.g. within the SerDes device.

GRIP
Apr 2024, Version 2024.1

985

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Small SerDes interface (*sel_16_20_bit_mode* is true), internal 8B10B encoding is activated (*use_8b10b* is true): In this configuration, 8B10B encoded 20-bit wide receive data is fed in on port *se_rx_data*(19:0). *se_rx_data*(39:20) should be tied to ground. *se_rx_kflags*(3:0) is unused and can be tied to ground as well.

- Small SerDes interface (*sel_16_20_bit_mode* is true), internal 8B10B encoding is deactivated (*use_8b10b* is false): In this configuration, unencoded 16-bit wide receive data is fed in on port *se_rx_data*(15:0). *se_rx_kflags*(1:0) is active and must be connected to the external 8B10B encoder, e.g. within the SerDes device. *se_rx_data*(39:16) and *se_rx_kflags*(3:2) are unused and can be tied to ground.

If internal 8B10B decoding is not activated and the SerDes provides byte related error flags, for instance for disparity errors, these can be connected to the *se_rx_serror* port, with the lowest bit corresponding to the lowest byte of the receive data. If this is not the case, this port should be tied to ground. If the received data from the SerDes device is not synchronous to the SpaceFibre clock clk, the recovered SerDes receive clock must be connected to port *se_rx_clk*. If the data is already synchronous, for instance because the SerDes comprises its own elastic buffer, the SpaceFibre clock clk must be connected to *se_rx_clk*. If the lane layer of the SpaceFibre IP core is deactivated, the flag *se_rx_en* is low. It can be used to switch off the receive side of the SerDes to save power during idle times. If the SerDes provides a "No Signal" flag, it should be connected to port *se_no_signal*, otherwise this port must be tied to ground. If internal 8B10 decoding is not activated and the SerDes provides the capability to invert incoming bits, port *se_inv_pol* can be connected to the corresponding control port of the SerDes. If not, this port can be left unconnected.

For debug purposes, the receive data and k-flags after any possible data path width conversion and 8B10B decoding can be monitored at *se_rx_data_dbg* and *se_rx_kflags_dbg*.

68.3 Registers

There are no user accessible registers in the core. It is suggested to connect the configuration input signals (CF_*) and the status output signals (ST_*) to registers outside the core.

68.4 Vendor and device identifier

The vendor and device identifiers are only applicable for cores with AHB interfaces.

68.5 Implementation

68.5.1 Reset

The core changes reset behavior depending on settings in the GRLIB configuration package (see GRLIB User's Manual). By default, the core makes use of synchronous reset and resets all its internal registers.

The core will use asynchronous reset for all registers if the GRLIB config package setting *grlib_async_reset_enable* is set.

68.6 Configuration options

Table 1148 shows the configuration options of the core (VHDL generics).

Table 1148. Configuration options

Generic name	Function	Allowed range	Default
tech	This generic can be used for technology-specific internal components such as memories.	0 - NTECH	inferred
use_8b10b	If set, internal 8B10B encoding and decoding is activated.	0 - 1	1
use_sep_txclk	If set, the SerDes transmission clock is decoupled from the SpaceFibre port clock. An additional transmit buffer is instantiated for this reason.	0 - 1	0
sel_16_20_bit_-mode	If set, the SerDes interface is 16+2 bit (without 8B10B) or 20 bit (with 8B10B) wide instead of 36/40 bit. If set, use_sep_txclk must also be set.	0 - 1	0
ticks_2us	Clock ticks corresponding to 2 µs.	1 - 8192	125
tx_skip_freq	Frequency of SKIP word transmission in clock cycles.	1 - 8192	5000
prbs_init1	If set, the INIT1 sequence during lane initialisation is embedded into a stream of pseudo-random numbers.	0 - 1	1
depth_rbuf_data	Log(Depth) of the data retry buffer.	1 - 32	8
depth_rbuf_fct	Log(Depth) of the FCT retry buffer.	1 - 32	4
depth_rbuf_bc	Log(Depth) of the broadcast retry buffer.	1 - 32	8
num_vc	Number of virtual channels.	1 - 32	4
fct_multiplier	Multiplier used in the internal FCT logic. The value of the FCT counter is compared with 64*$fct\_multiplier$ to decide if the far end can receive new words.	1 - 8	1
depth_vc_rx_buf	Log(Depth) of virtual channel input buffer.	1 - 32	10
depth_vc_tx_buf	Log(Depth) of virtual channel output buffer.	1 - 32	10
remote_fct_cnt_-max	Width of the remote FCT counter.	0 - 32	9
width_bw_credit	Width of the bandwidth credit counter.	0 - 16#FFFFFFFF#	20
min_bw_credit	Minimum bandwidth credit threshold limit.	0 - 16#FFFFFFFF#	52428
idle_time_limit	Bandwidth idle time limit in clock cycles.	0 - 65535	62500
use_async_rxrst	Force asynchronous reset in the recovered clock domain, regardless of the general GRLIB settings	0 - 1	0
ft_vc	Enable fault-tolerance against SEU errors for the FIFOs in the Virtual Channel Layer. Possible options are byte parity protection (ft = 1), TMR registers (ft = 2), SECDED BCH (ft = 4) or technology specific protection (ft = 5). If set to 0, no protection is implemented.	0 - 2, 4 - 5	0
ft_rt1	Enable fault-tolerance against SEU errors for the large FIFOs in the Retry Layer (Data and Broadcast). The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_rt2	Enable fault-tolerance against SEU errors for the small FIFOs in the Retry Layer (FCT and pointers). The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_if	Enable fault-tolerance against SEU errors for the FIFOs in the Interface Layer. The core supports the same configurations as above.	0 - 2, 4 - 5	0
scantest	Enable Scan Test support	0 - 1	0

69 GRSPW - SpaceWire codec with AHB host Interface and RMAP target

69.1 Overview

The SpaceWire core provides an interface between the AHB bus and a SpaceWire network. It implements the SpaceWire standard (ECSS-E-ST-50-12C) with the protocol identification extension (ECSS-E-ST-50-51C). The optional Remote Memory Access Protocol (RMAP) target implements the ECSS standard (ECSS-E-ST-50-52C).

The core is configured through a set of registers accessed through an APB interface. Data is transferred through DMA channels using an AHB master interface.

Currently, there is one DMA channel but the core can easily be extended to use separate DMA channels for specific protocols. The core can also be configured to have either one or two ports.

There can be up to four clock domains: one for the AHB interface (system clock), one for the transmitter and one or two for the receiver depending on the number of configured ports. The receiver clock can be twice as fast and the transmitter clock four times as fast as the system clock whose frequency should be at least 10 MHz.

The core only supports byte addressed 32-bit big-endian host systems.

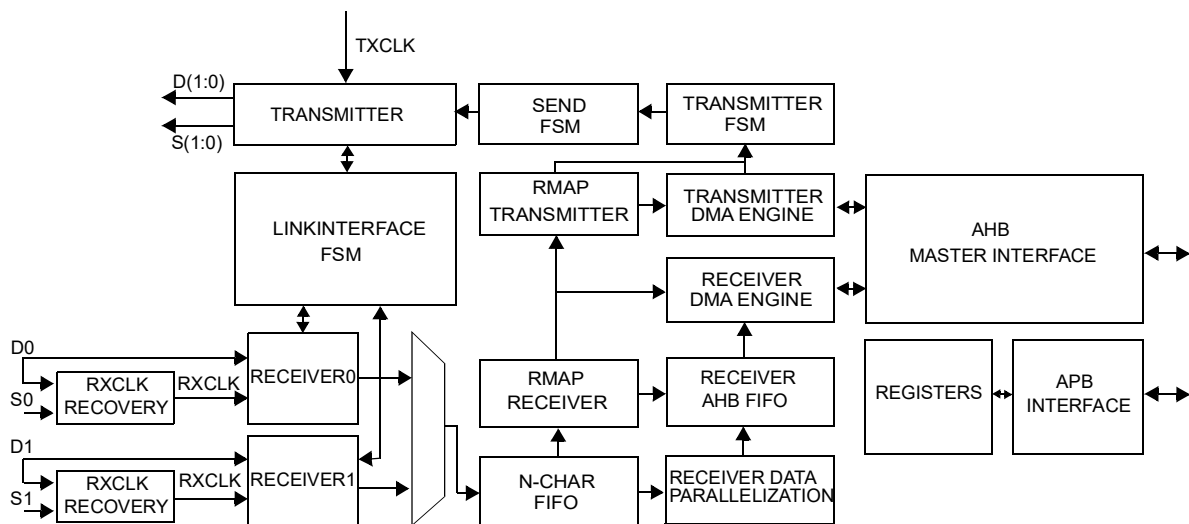
Note: This IP core is deprecated and should not be used for new designs. Please see the GRSPW2 IP core instead.


Figure 172. Block diagram

69.2 Operation

69.2.1 Overview

The main sub-blocks of the core are the link-interface, the RMAP target and the AMBA interface. A block diagram of the internal structure can be found in figure 172.

The link interface consists of the receiver, transmitter and the link interface FSM. They handle communication on the SpaceWire network. The AMBA interface consists of the DMA engines, the AHB master interface and the APB interface. The link interface provides FIFO interfaces to the DMA engines. These FIFOs are used to transfer N-Chars between the AMBA and SpaceWire domains during reception and transmission.

The RMAP target is an optional part of the core which can be enabled with a VHDL generic. The RMAP target handles incoming packets which are determined to be RMAP commands instead of the

GRIP
Apr 2024, Version 2024.1
993
Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

receiver DMA engine. The RMAP command is decoded and if it is valid, the operation is performed on the AHB bus. If a reply was requested it is automatically transmitted back to the source by the RMAP transmitter.

The core is controlled by writing to a set of user registers through the APB interface and three signals: tick-in, rmapen and clkdiv10. The controlled parts are clock-generation, DMA engines, RMAP target and the link interface.

The link interface, DMA engines, RMAP target and AMBA interface are described in section 69.3, 69.4, 69.5 and 69.7 respectively.

69.2.2 Protocol support

The core only accepts packets with a destination address corresponding to the one set in the node address register. Packets with address mismatch will be silently discarded (except in promiscuous mode which is covered in section 69.4.10). The node address register is initialized to the default address 254 during reset. It can then be changed to other values by writing to the register.

The core has support for the protocol ID specified in ECSS-E-ST-50-51C. It is used for identifying RMAP commands that should be received by the RMAP target. Other packets are stored to the DMA channel. This is only applicable if the RMAP target is present and enabled. When the RMAP target is not present or disabled all the bytes after the address are treated as normal cargo.

RMAP commands are identified using the protocol ID (0x01) and the instruction field. They are handled separately from other packets if the hardware RMAP target is enabled. When enabled, all RMAP commands are processed, executed and replied in hardware. RMAP replies received are always stored to the DMA channel. If the RMAP target is disabled, all packets are stored to the DMA channel. More information on the RMAP protocol support is found in section 69.7.

RMAP packets arriving with the extended protocol ID (0x000001) are stored to the DMA channel which means that the hardware RMAP target will not work if the incoming RMAP packets use the extended protocol ID. Note also that packets with the reserved extended protocol identifier (ID = 0x000000) are not ignored by the core. It is up to the client receiving the packets to ignore them.

When transmitting packets, the address and protocol-ID fields must be included in the buffers from where data is fetched. They are *not* automatically added by the core.

Figure 173 shows the packet types supported by the core. The core also allows reception and transmission with extended protocol identifiers but without support for RMAP CRC calculations and the RMAP target.
Figure 173. The SpaceWire packet types supported by the GRSPW.

69.3 Link interface

The link interface handles the communication on the SpaceWire network and consists of a transmitter, receiver, a FSM and FIFO interfaces. An overview of the architecture is found in figure 172.

69.3.1 Link interface FSM

The FSM controls the link interface (a more detailed description is found in the SpaceWire standard). The low-level protocol handling (the signal and character level of the SpaceWire standard) is handled by the transmitter and receiver while the FSM in the host domain handles the exchange level.

The link interface FSM is controlled through the control register. The link can be disabled through the link disable bit, which depending on the current state, either prevents the link interface from reaching the started state or forces it to the error-reset state. When the link is not disabled, the link interface FSM is allowed to enter the started state when either the link start bit is set or when a NULL character has been received and the autostart bit is set.

The current state of the link interface determines which type of characters are allowed to be transmitted which together with the requests made from the host interfaces determine what character will be sent.

Time-codes are sent when the FSM is in the run-state and a request is made through the time-interface (described in section 69.3.5).

When the link interface is in the connecting- or run-state it is allowed to send FCTs. FCTs are sent automatically by the link interface when possible. This is done based on the maximum value of 56 for the outstanding credit counter and the currently free space in the receiver N-Char FIFO. FCTs are sent as long as the outstanding counter is less than or equal to 48 and there are at least 8 more empty FIFO entries than the counter value.

N-Chars are sent in the run-state when they are available from the transmitter FIFO and there are credits available. NULLs are sent when no other character transmission is requested or the FSM is in a state where no other transmissions are allowed.

The credit counter (incoming credits) is automatically increased when FCTs are received and decreased when N-Chars are transmitted. Received N-Chars are stored to the receiver N-Char FIFO for further handling by the DMA interface. Received Time-codes are handled by the time-interface.

69.3.2 Transmitter

The state of the FSM, credit counters, requests from the time-interface and requests from the DMA-interface are used to decide the next character to be transmitted. The type of character and the character itself (for N-Chars and Time-codes) to be transmitted are presented to the low-level transmitter which is located in a separate clock-domain.

This is done because one usually wants to run the SpaceWire link on a different frequency than the host system clock. The core has a separate clock input which is used to generate the transmitter clock. More information on transmitter clock generation is found in section 69.8.2. Since the transmitter often runs on high frequency clocks (> 100 MHz) as much logic as possible has been placed in the system clock domain to minimize power consumption and timing issues.

The transmitter logic in the host clock domain decides what character to send next and sets the proper control signal and presents any needed character to the low-level transmitter as shown in figure 174. The transmitter sends the requested characters and generates parity and control bits as needed. If no requests are made from the host domain, NULLs are sent as long as the transmitter is enabled. Most of the signal and character levels of the SpaceWire standard is handled in the transmitter. External LVDS drivers are needed for the data and strobe signals.

A transmission FSM reads N-Chars for transmission from the transmitter FIFO. It is given packet lengths from the DMA interface and appends EOPs/EEPs and RMAP CRC values if requested. When it is finished with a packet the DMA interface is notified and a new packet length value is given.

69.3.3 Receiver

The receiver detects connections from other nodes and receives characters as a bit stream on the data and strobe signals. It is also located in a separate clock domain which runs on a clock generated from the received data and strobe signals. More information on the clock-generation can be found in section 69.8.2.

The receiver is activated as soon as the link interface leaves the error reset state. Then after a NULL is received it can start receiving any characters. It detects parity, escape and credit errors which causes the link interface to enter the error reset state. Disconnections are handled in the link interface part in the system clock domain because no receiver clock is available when disconnected.

Received Characters are flagged to the host domain and the data is presented in parallel form. The interface to the host domain is shown in figure 175. L-Chars are the handled automatically by the host domain link interface part while all N-Chars are stored in the receiver FIFO for further handling. If two or more consecutive EOPs/EEPs are received all but the first are discarded.

There are no signals going directly from the transmitter clock domain to the receiver clock domain and vice versa. All the synchronization is done to the system clock.
Figure 175. Schematic of the link interface receiver.

69.3.4 Dual port support

The core can be configured to include an additional SpaceWire port. With dual ports the transmitter drives an additional pair of data/strobe output signals and one extra receiver is added to handle a second pair of data/strobe input signals.

One of the ports is set as active (how the active port is selected is explained below) and the transmitter drives the data/strobe signals of the active port with the actual output values as explained in section 69.3.2. The inactive port is driven with zero on both data and strobe.

Both receivers will always be active but only the active port's interface signals (see figure 175) will be propagated to the link interface FSM. Each time the active port is changed, the link will be reset so that the new link is started in a controlled manner.

When the noportforce register is zero the portsel register bit selects the active link and when set to one it is determined by the current link activity. In the latter mode the port is changed when no activity is seen on the currently active link while there is activity on the deselected receive port. Activity is defined as a detected null. This definition is selected so that glitches (e.g. port unconnected) do not cause unwanted port switches.

69.3.5 Time interface

The time interface is used for sending Time-codes over the SpaceWire network and consists of a time-counter register, time-ctrl register, tick-in signal, tick-out signal, tick-in register field and a tick-out

GRIP

Apr 2024, Version 2024.1

996

Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

register field. There are also two control register bits which enable the time receiver and transmitter respectively.

Each Time-code sent from the core is a concatenation of the time-ctrl and the time-counter register. There is a timetxen bit which is used to enable Time-code transmissions. It is not possible to send time-codes if this bit is zero.

Received Time-codes are stored to the same time-ctrl and time-counter registers which are used for transmission. The timerxen bit in the control register is used for enabling time-code reception. No time-codes will be received if this bit is zero.

The two enable bits are used for ensuring that a node will not (accidentally) both transmit and receive time-codes which violates the SpaceWire standard. It also ensures that a the master sending time-codes on a network will not have its time-counter overwritten if another (faulty) node starts sending time-codes.

The time-counter register is set to 0 after reset and is incremented each time the tick-in signal is asserted for one clock-period and the timetxen bit is set. This also causes the link interface to send the new value on the network. Tick-in can be generated either by writing a one to the register field or by asserting the tick-in signal. A Tick-in should not be generated too often since if the time-code after the previous Tick-in has not been sent the register will not be incremented and no new value will be sent. The tick-in field is automatically cleared when the value has been sent and thus no new ticks should be generated until this field is zero. If the tick-in signal is used there should be at least 4 system-clock and 25 transmit-clock cycles between each assertion.

A tick-out is generated each time a valid time-code is received and the timerxen bit is set. When the tick-out is generated the tick-out signal will be asserted one clock-cycle and the tick-out register field is asserted until it is cleared by writing a one to it.

The current time counter value can be read from the time register. It is updated each time a Time-code is received and the timerxen bit is set. The same register is used for transmissions and can also be written directly from the APB interface.

The control bits of the Time-code are always stored to the time-ctrl register when a Time-code is received whose time-count is one more than the nodes current time-counter register. The time-ctrl register can be read through the APB interface. The same register is used during time-code transmissions.

It is possible to have both the time-transmission and reception functions enabled at the same time.

69.4   Receiver DMA engine

The receiver DMA engine handles reception of data from the SpaceWire network to different DMA channels. Currently there is only one receive DMA channel available but the core has been written so that additional channels can be easily added if needed.

69.4.1   Basic functionality

The receiver DMA engine reads N-Chars from the N-Char FIFO and stores them to a DMA channel. Reception is based on descriptors located in a consecutive area in memory that hold pointers to buffers where packets should be stored. When a packet arrives at the core it reads a descriptor from memory and stores the packet to the memory area pointed to by the descriptor. Then it stores status to the same descriptor and increments the descriptor pointer to the next one.

69.4.2   Setting up the core for reception

A few registers need to be initialized before reception can take place. First the link interface need to be put in the run state before any data can be sent. The DMA channel has a maximum length register which sets the maximum size of packet that can be received to this channel. Larger packets are truncated and the excessive part is spilled. If this happens an indication will be given in the status field of the descriptor. The minimum value for the receiver maximum length field is 4 and the value can only

GRIP
Apr 2024, Version 2024.1
997
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

be incremented in steps of four bytes. If the maximum length is set to zero the receiver will *not* function correctly.

The node address register needs to be set to hold the address of this SpaceWire node. Packets received with the incorrect address are discarded. Finally, the descriptor table and control register must be initialized. This will be described in the two following sections.

69.4.3 Setting up the descriptor table address

The core reads descriptors from an area in memory pointed to by the receiver descriptor table address register. The register consists of a base address and a descriptor selector. The base address points to the beginning of the area and must start on a 1 kbytes aligned address. It is also limited to be 1 kbytes in size which means the maximum number of descriptors is 128.

The descriptor selector points to individual descriptors and is increased by 1 when a descriptor has been used. When the selector reaches the upper limit of the area it wraps to the beginning automatically. It can also be set to wrap automatically by setting a bit in the descriptors. The idea is that the selector should be initialized to 0 (start of the descriptor area) but it can also be written with another 8 bytes aligned value to start somewhere in the middle of the area. It will still wrap to the beginning of the area.

If one wants to use a new descriptor table the receiver enable bit has to be cleared first. When the rxactive bit for the channel is cleared it is safe to update the descriptor table register. When this is finished and descriptors are enabled the receiver enable bit can be set again.

69.4.4 Enabling descriptors

As mentioned earlier one or more descriptors must be enabled before reception can take place. Each descriptor is 8 byte in size and the layout can be found in the tables below. The descriptors should be written to the memory area pointed to by the receiver descriptor table address register. When new descriptors are added they must always be placed after the previous one written to the area. Otherwise they will not be noticed.

A descriptor is enabled by setting the address pointer to point at a location where data can be stored and then setting the enable bit. The WR bit can be set to cause the selector to be set to zero when reception has finished to this descriptor. IE should be set if an interrupt is wanted when the reception has finished. The DMA control register interrupt enable bit must also be set for this to happen.

The descriptor packet address should be word aligned. All accesses on the bus are word accesses so complete words will always be overwritten regardless of whether all 32-bit contain received data. Also if the packet does not end on a word boundary the complete word containing the last data byte will be overwritten. If the *rxunaligned* or *rmap* VHDL generic is set to 1 this restriction is removed

GRIP

and any number of bytes can be received to any packet address without excessive bytes being over-written.

Table 1151. GRSPW receive descriptor word 0 (address offset 0x0)

31	30	29	28	27	26	25	24		0
TR	DC	HC	EP	IE	WR	EN	PACKETLENGTH		

31	Truncated (TR) - Packet was truncated due to maximum length violation.
30	Data CRC (DC) - 1 if a CRC error was detected for the data and 0 otherwise.
29	Header CRC (HC) - 1 if a CRC error was detected for the header and 0 otherwise.
28	EEP termination (EP) - This packet ended with an Error End of Packet character.
27	Interrupt enable (IE) - If set, an interrupt will be generated when a packet has been received if the receive interrupt enable bit in the DMA channel control register is set.
26	Wrap (WR) - If set, the next descriptor used by the GRSPW will be the first one in the descriptor table (at the base address). Otherwise the descriptor pointer will be increased with 0x8 to use the descriptor at the next higher memory location. The descriptor table is limited to 1 kbytes in size and the pointer will be automatically wrap back to the base address when it reaches the 1 kbytes boundary.
25	Enable (EN) - Set to one to activate this descriptor. This means that the descriptor contains valid control values and the memory area pointed to by the packet address field can be used to store a packet.
24: 0	Packet length (PACKETLENGTH) - The number of bytes received to this buffer. Only valid after EN has been set to 0 by the GRSPW.

Table 1152. GRSPW receive descriptor word 1 (address offset 0x4)

31	0
PACKETADDRESS	

31: 0	Packet address (PACKETADDRESS) - The address pointing at the buffer which will be used to store the received packet. If the rxunaligned and rmap VHDL generics are both set to zero only bit 31 to 2 are used.

69.4.5 Setting up the DMA control register

The final step to receive packets is to set the control register in the following steps: The receiver must be enabled by setting the rxen bit in the DMA control register (see section 69.9). This can be done anytime and before this bit is set nothing will happen. The rxdescav bit in the DMA control register is then set to indicate that there are new active descriptors. This must always be done after the descriptors have been enabled or the core might not notice the new descriptors. More descriptors can be activated when reception has already started by enabling the descriptors and writing the rxdescav bit. When these bits are set reception will start immediately when data is arriving.

69.4.6 The effect to the control bits during reception

When the receiver is disabled all packets going to the DMA-channel are discarded. If the receiver is enabled the next state is entered where the rxdescav bit is checked. This bit indicates whether there are active descriptors or not and should be set by the external application using the DMA channel each time descriptors are enabled as mentioned above. If the rxdescav bit is '0' and the nospill bit is '0' the packets will be discarded. If nospill is one the core waits until rxdescav is set.

When rxdescav is set the next descriptor is read and if enabled the packet is received to the buffer. If the read descriptor is not enabled, rxdescav is set to '0' and the packet is spilled depending on the value of nospill.

The receiver can be disabled at any time and will cause all packets received afterwards to be discarded. If a packet is currently received when the receiver is disabled the reception will still be finished. The rxdescav bit can also be cleared at any time. It will not affect any ongoing receptions but

GRIP

Apr 2024, Version 2024.1

999

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

no more descriptors will be read until it is set again. Rxdescav is also cleared by the core when it reads a disabled descriptor.

69.4.7 Address recognition and packet handling

When the receiver N-Char FIFO is not empty, N-Chars are read by the receiver DMA engine. The first character is interpreted as the logical address which is compared to the node address register. If it does not match, the complete packet is discarded (up to and including the next EOP/EEP).

If the address matches the next action taken depends on whether RMAP is enabled or not. If RMAP is disabled all packets are stored to the DMA channel and depending on the conditions mentioned in the previous section, the packet will be received or not. If the packet is received the complete packet including address and protocol ID but excluding EOP/EEP is stored to the address indicated in the descriptor, otherwise the complete packet is discarded.

If RMAP is enabled the protocol ID and 3rd byte in the packet is first checked before any decisions are made. If incoming packet is an RMAP packet (ID = 0x01) and the command type field is 01b the packet is processed by the RMAP command handler which is described in section 69.6. Otherwise the packet is processed by the DMA engine as when RMAP is disabled.

At least 2 non EOP/EEP N-Chars need to be received for a packet to be stored to the DMA channel. If it is an RMAP packet 3 N-Chars are needed since the command byte determines where the packet is processed. Packets smaller than the minimum size are discarded.

69.4.8 Status bits

When the reception of a packet is finished the enable bit in the current descriptor is set to zero. When enable is zero, the status bits are also valid and the number of received bytes is indicated in the length field. The DMA control register contains a status bit which is set each time a packet has been received. The core can also be made to generate an interrupt for this event as mentioned in section 69.4.4.

RMAP CRC logic is included in the implementation if the *rmapcrc* or *rmap* VHDL generic set to 1. The RMAP CRC calculation is always active for all received packets and all bytes except the EOP/EEP are included. The packet is always assumed to be a RMAP packet and the length of the header is determined by checking byte 3 which should be the command field. The calculated CRC value is then checked when the header has been received (according to the calculated number of bytes) and if it is non-zero the HC bit is set indicating a header CRC error.

The CRC value is not set to zero after the header has been received, instead the calculation continues in the same way until the complete packet has been received. Then if the CRC value is non-zero the DC bit is set indicating a data CRC error. This means that the core can indicate a data CRC error even if the data field was correct when the header CRC was incorrect. However, the data should not be used when the header is corrupt and therefore the DC bit is unimportant in this case. When the header is not corrupted the CRC value will always be zero when the calculation continues with the data field and the behaviour will be as if the CRC calculation was restarted

If the received packet is not of RMAP type the header CRC error indication bit cannot be used. It is still possible to use the DC bit if the complete packet is covered by a CRC calculated using the RMAP CRC definition. This is because the core does not restart the calculation after the header has been received but instead calculates a complete CRC over the packet. Thus any packet format with one CRC at the end of the packet calculated according to RMAP standard can be checked using the DC bit.

If the packet is neither of RMAP type nor of the type above with RMAP CRC at the end, then both the HC and DC bits should be ignored.

69.4.9   Error handling

If a packet reception needs to be aborted because of congestion on the network, the suggested solution is to set link disable to '1'. Unfortunately, this will also cause the packet currently being transmitted to be truncated but this is the only safe solution since packet reception is a passive operation depending on the transmitter at the other end. A channel reset bit could be provided but is not a satisfactory solution since the untransmitted characters would still be in the transmitter node. The next character (somewhere in the middle of the packet) would be interpreted as the node address which would probably cause the packet to be discarded but not with 100% certainty. Usually this action is performed when a reception has stuck because of the transmitter not providing more data. The channel reset would not resolve this congestion.

If an AHB error occurs during reception the current packet is spilled up to and including the next EEP/EOP and then the currently active channel is disabled and the receiver enters the idle state. A bit in the channels control/status register is set to indicate this condition.

69.4.10 Promiscuous mode

The core supports a promiscuous mode where all the data received is stored to the DMA channel regardless of the node address and possible early EOPs/EEPs. This means that all non-eop/eep N-Chars received will be stored to the DMA channel. The rxmaxlength register is still checked and packets exceeding this size will be truncated.

RMAP commands will still be handled by the RMAP target when promiscuous mode is enabled if the rmapen bit is set. If it is cleared, RMAP commands will also be stored to the DMA channel.

69.5   Transmitter DMA engine

The transmitter DMA engine handles transmission of data from the DMA channel to the SpaceWire network. There is one DMA channel available but the core has been written so that additional DMA channels can be easily added if needed.

69.5.1   Basic functionality

The transmit DMA engine reads data from the AHB bus and stores them in the transmitter FIFO for transmission on the SpaceWire network. Transmission is based on the same type of descriptors as for the receiver and the descriptor table has the same alignment and size restrictions. When there are new descriptors enabled the core reads them and transfer the amount data indicated.

69.5.2   Setting up the core for transmission

Four steps need to be performed before transmissions can be done with the core. First the link interface must be enabled and started by writing the appropriate value to the ctrl register. Then the address to the descriptor table needs to be written to the transmitter descriptor table address register and one or more descriptors must also be enabled in the table. Finally, the txen bit in the DMA control register should be written with a one which triggers the transmission. These steps will be covered in more detail in the next sections.

69.5.3   Enabling descriptors

The descriptor table address register works in the same way as the receiver's corresponding register which was covered in section 69.4.

To transmit packets one or more descriptors have to be initialized in memory which is done in the following way: The number of bytes to be transmitted and a pointer to the data has to be set. There are two different length and address fields in the transmit descriptors because there are separate pointers for header and data. If a length field is zero the corresponding part of a packet is skipped and if both are zero no packet is sent. The maximum header length is 255 bytes and the maximum data length is

16 Mbyte - 1. When the pointer and length fields have been set the enable bit should be set to enable the descriptor. This must always be done last. The other control bits must also be set before enabling the descriptor.

The transmit descriptors are 16 bytes in size so the maximum number in a single table is 64. The different fields of the descriptor together with the memory offsets are shown in the tables below.

The HC bit should be set if RMAP CRC should be calculated and inserted for the header field and correspondingly the DC bit should be set for the data field. This field is only used by the core when the CRC logic is available (*rmap* or *rmapcrc* VHDL generic set to 1). The header CRC will be calculated from the data fetched from the header pointer and the data CRC is generated from data fetched from the data pointer. The CRCs are appended after the corresponding fields. The NON-CRC bytes field is set to the number of bytes in the beginning of the header field that should not be included in the CRC calculation. The CRCs are sent even if the corresponding length is zero.

When both header and data length are zero no packet is sent not even an EOP.

69.5.4   Starting transmissions

When the descriptors have been initialized, the transmit enable bit in the DMA control register has to be set to tell the core to start transmitting. New descriptors can be activated in the table on the fly (while transmission is active). Each time a set of descriptors is added the transmit enable register bit should be set. This has to be done because each time the core encounters a disabled descriptor this register bit is set to 0.

Table 1153. GRSPW transmit descriptor word 0 (address offset 0x0)

31 18	17	16	15	14	13	12	11 8	7 0
RESERVED	DC	HC	LE	IE	WR	EN	NONCRCLEN	HEADERLEN

31: 18	RESERVED
17	Append data CRC (DC) - Append CRC calculated according to the RMAP specification after the data sent from the data pointer. The CRC covers all the bytes from this pointer. A null CRC will be sent if the length of the data field is zero.
16	Append header CRC (HC) - Append CRC calculated according to the RMAP specification after the data sent from the header pointer. The CRC covers all bytes from this pointer except a number of bytes in the beginning specified by the non-crc bytes field. The CRC will not be sent if the header length field is zero.
15	Link error (LE) - A Link error occurred during the transmission of this packet.
14	Interrupt enable (IE) - If set, an interrupt will be generated when the packet has been transmitted and the transmitter interrupt enable bit in the DMA control register is set.
13	Wrap (WR) - If set, the descriptor pointer will wrap and the next descriptor read will be the first one in the table (at the base address). Otherwise the pointer is increased with 0x10 to use the descriptor at the next higher memory location.
12	Enable (EN) - Enable transmitter descriptor. When all control fields (address, length, wrap and crc) are set, this bit should be set. While the bit is set the descriptor should not be touched since this might corrupt the transmission. The GRSPW clears this bit when the transmission has finished.
11: 8	Non-CRC bytes (NONCRCLEN)- Sets the number of bytes in the beginning of the header which should not be included in the CRC calculation. This is necessary when using path addressing since one or more bytes in the beginning of the packet might be discarded before the packet reaches its destination.
7: 0	Header length (HEADERLEN) - Header Length in bytes. If set to zero, the header is skipped.

Table 1154. GRSPW transmit descriptor word 1 (address offset 0x4)

31   0
HEADERADDRESS

31: 0	Header address (HEADERADDRESS) - Address from where the packet header is fetched. Does not need to be word aligned.

31	24	23	0
RESERVED		DATALEN	

31: 24	RESERVED
23: 0	Data length (DATALEN) - Length of data part of packet. If set to zero, no data will be sent. If both data- and header-lengths are set to zero no packet will be sent.

Table 1156. GRSPW transmit descriptor word 3(address offset 0xC)

31	0
DATAADDRESS	

31: 0	Data address (DATAADDRESS) - Address from where data is read. Does not need to be word aligned.

69.5.5 The transmission process

When the txen bit is set the core starts reading descriptors immediately. The number of bytes indicated are read and transmitted. When a transmission has finished, status will be written to the first field of the descriptor and a packet sent bit is set in the DMA control register. If an interrupt was requested it will also be generated. Then a new descriptor is read and if enabled a new transmission starts, otherwise the transmit enable bit is cleared and nothing will happen until it is enabled again.

69.5.6 The descriptor table address register

The internal pointer which is used to keep the current position in the descriptor table can be read and written through the APB interface. This pointer is set to zero during reset and is incremented each time a descriptor is used. It wraps automatically when the 1 kbytes limit for the descriptor table is reached or it can be set to wrap earlier by setting a bit in the current descriptor.

The descriptor table register can be updated with a new table anytime when no transmission is active. No transmission is active if the transmit enable bit is zero and the complete table has been sent or if the table is aborted (explained below). If the table is aborted one has to wait until the transmit enable bit is zero before updating the table pointer.

69.5.7 Error handling

Abort Tx

The DMA control register contains a bit called Abort TX which if set causes the current transmission to be aborted, the packet is truncated and an EEP is inserted. This is only useful if the packet needs to be aborted because of congestion on the SpaceWire network. If the congestion is on the AHB bus this will not help (This should not be a problem since AHB slaves should have a maximum of 16 wait-states). The aborted packet will have its LE bit set in the descriptor. The transmit enable register bit is also cleared and no new transmissions will be done until the transmitter is enabled again.

AHB error

When an AHB error is encountered during transmission the currently active DMA channel is disabled and the transmitter goes to the idle mode. A bit in the DMA channel's control/status register is set to indicate this error condition and, if enabled, an interrupt will also be generated. Further error handling depends on what state the transmitter DMA engine was in when the AHB error occurred. If the descriptor was being read the packet transmission had not been started yet and no more actions need to be taken.

If the AHB error occurs during packet transmission the packet is truncated and an EEP is inserted. Lastly, if it occurs when status is written to the descriptor the packet has been successfully transmitted but the descriptor is not written and will continue to be enabled (this also means that no error bits are set in the descriptor for AHB errors).

GRIP

Apr 2024, Version 2024.1

1003

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The client using the channel has to correct the AHB error condition and enable the channel again. No more AHB transfers are done again from the same unit (receiver or transmitter) which was active during the AHB error until the error state is cleared and the unit is enabled again.

Link error

When a link error occurs during the transmission the remaining part of the packet is discarded up to and including the next EOP/EEP. When this is done status is immediately written (with the LE bit set) and the descriptor pointer is incremented. The link will be disconnected when the link error occurs but the core will automatically try to connect again provided that the link-start bit is asserted and the link-disabled bit is deasserted. If the LE bit in the DMA channel's control register is not set the transmitter DMA engine will wait for the link to enter run-state and start a new transmission immediately when possible if packets are pending. Otherwise the transmitter will be disabled when a link error occurs during the transmission of the current packet and no more packets will be transmitted until it is enabled again.

69.6   RMAP

The Remote Memory Access Protocol (RMAP) is used to implement access to resources in the node via the SpaceWire Link. Some common operations are reading and writing to memory, registers and FIFOs. The core has an optional hardware RMAP target which is enabled with a VHDL generic. This section describes the basics of the RMAP protocol and the target implementation.

69.6.1   Fundamentals of the protocol

RMAP is a protocol which is designed to provide remote access via a SpaceWire network to memory mapped resources on a SpaceWire node. It has been assigned protocol ID 0x01. It provides three operations write, read and read-modify-write. These operations are posted operations which means that a source does not wait for an acknowledge or reply. It also implies that any number of operations can be outstanding at any time and that no timeout mechanism is implemented in the protocol. Time-outs must be implemented in the user application which sends the commands. Data payloads of up to 16 Mb - 1 is supported in the protocol. A destination can be requested to send replies and to verify data before executing an operation. A complete description of the protocol is found in the RMAP standard.

69.6.2   Implementation

The core includes a taget for RMAP commands which processes all incoming packets with protocol ID = 0x01 and type field (bit 7 and 6 of the 3rd byte in the packet) equal to 01b. When such a packet is detected it is not stored to the DMA channel, instead it is passed to the RMAP receiver.

The core implements all three commands defined in the standard with some restrictions. First of all the optional error code 12 is not implemented and support is only provided for 32-bit big-endian systems. This means that the first byte received is the msb in a word. The command handler will not receive RMAP packets using the extended protocol ID which are always dumped to the DMA channel.

The RMAP receiver processes commands. If they are correct and accepted the operation is performed on the AHB bus and a reply is formatted. If an acknowledge is requested the RMAP transmitter automatically send the reply. RMAP transmissions have priority over DMA channel transmissions.

Packets with a mismatching destination logical address are never passed to the RMAP target. There is a user accessible destination key register which is compared to destination key field in incoming packets. If there is a mismatch and a reply has been requested the error code in the reply is set to 3. Replies are sent if and only if the ack field is set to '1'.

Detection of all error codes except code 12 is supported. When a failure occurs during a bus access the error code is set to 1 (General Error). There is predetermined order in which error-codes are set in the case of multiple errors in the core. It is shown in table 1157.

Table 1157. The order of error detection in case of multiple errors in the GRSPW. The error detected first has number 1.

Detection Order	Error Code	Error
1	2	Unused RMAP packet type or command code
2	3	Invalid destination key
3	9	Verify buffer overrun
4	11	RMW data length error
5	10	Authorization failure
6*	1	General Error (AHB errors during non-verified writes)
7	5/7	Early EOP / EEP (if early)
8	4	Invalid Data CRC
9	1	General Error (AHB errors during verified writes or RMW)
10	7	EEP
11	6	Cargo Too Large
*The AHB error is not guaranteed to be detected before Early EOP/EEP or Invalid Data CRC. For very long accesses the AHB error detection might be delayed causing the other two errors to appear first.		

Read accesses are performed on the fly, that is they are not stored in a temporary buffer before transmission. This means that the error code 1 will never be seen in a read reply since the header has already been sent when the data is read. If the AHB error occurs the packet will be truncated and ended with an EEP.

Errors up to and including Invalid Data CRC (number 8) are checked before verified commands. The other errors do not prevent verified operations from being performed.

The details of the support for the different commands are now presented. All defined commands which are received but have an option set which is not supported in this specific implementation will not be executed and a possible reply is sent with error code 10.

69.6.3 Write commands

The write commands are divided into two subcategories when examining their capabilities: verified writes and non-verified writes. Verified writes have a length restriction of 4 B and the address must be aligned to the size. That is 1 B writes can be done to any address, 2 B must be halfword aligned, 3 B are not allowed and 4 B writes must be word aligned. Since there will always be only one AHB operation performed for each RMAP verified write command the incrementing address bit can be set to any value.

Non-verified writes have no restrictions when the incrementing bit is set to 1. If it is set to 0 the number of bytes must be a multiple of 4 and the address word aligned. There is no guarantee how many words will be written when early EOP/EEP is detected for non-verified writes.

69.6.4 Read commands

Read commands are performed on the fly when the reply is sent. Thus if an AHB error occurs the packet will be truncated and ended with an EEP. There are no restrictions for incrementing reads but non-incrementing reads have the same alignment restrictions as non-verified writes. Note that the "Authorization failure" error code will be sent in the reply if a violation was detected even if the length field was zero. Also note that no data is sent in the reply if an error was detected i.e. if the status field is non-zero.

1005
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

69.6.5 RMW commands

All read-modify-write sizes are supported except 6 which would have caused 3 B being read and written on the bus. The RMW bus accesses have the same restrictions as the verified writes. As in the verified write case, the incrementing bit can be set to any value since only one AHB bus operation will be performed for each RMW command. Cargo too large is detected after the bus accesses so this error will not prevent the operation from being performed. No data is sent in a reply if an error is detected i.e. the status field is non-zero.

69.6.6 Control

The RMAP command handler mostly runs in the background without any external intervention, but there are a few control possibilities.

There is an enable bit in the control register of the core which can be used to completely disable the RMAP command handler. When it is set to '0' no RMAP packets will be handled in hardware, instead they are all stored to the DMA channel.

There is a possibility that RMAP commands will not be performed in the order they arrive. This can happen if a read arrives before one or more writes. Since the command handler stores replies in a buffer with more than one entry several commands can be processed even if no replies are sent. Data for read replies is read when the reply is sent and thus writes coming after the read might have been performed already if there was congestion in the transmitter. To avoid this the RMAP buffer disable bit can be set to force the command handler to only use one buffer which prevents this situation.

The last control option for the command handler is the possibility to set the destination key which is found in a separate register.

69.7   AMBA interface

The AMBA interface consists of an APB interface, an AHB master interface and DMA FIFOs. The APB interface provides access to the user registers which are described in section 69.9. The DMA engines have 32-bit wide FIFOs to the AHB master interface which are used when reading and writing to the bus.

The transmitter DMA engine reads data from the bus in bursts which are half the FIFO size in length. A burst is always started when the FIFO is half-empty or if it can hold the last data for the packet. The burst containing the last data might have shorter length if the packet is not an even number of bursts in size.

GRIP
Apr 2024, Version 2024.1

1008

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The receiver DMA works in the same way except that it checks if the FIFO is half-full and then performs a burst write to the bus which is half the fifo size in length. The last burst might be shorter. If the *rmap* or *rxunaligned* VHDL generics are set to 1 the interface also handles byte accesses. Byte accesses are used for non word-aligned buffers and/or packet lengths that are not a multiple of four bytes. There might be 1 to 3 single byte writes when writing the beginning and end of the received packets.

69.7.1 APB slave interface

As mentioned above, the APB interface provides access to the user registers which are 32-bits in width. The accesses to this interface are required to be aligned word accesses. The result is undefined if this restriction is violated.

69.7.2 AHB master interface

The core contains a single master interface which is used by both the transmitter and receiver DMA engines. The arbitration algorithm between the channels is done so that if the current owner requests the interface again it will always acquire it. This will not lead to starvation problems since the DMA engines always deassert their requests between accesses.

The AHB accesses are always word accesses (HSIZE = 0x010) of type incremental burst with unspecified length (HBURST = 0x001) if VHDL generics rmap and rxunaligned are disabled. The AHB accesses can be of size byte, halfword and word (HSIZE = 0x000, 0x001, 0x010) otherwise. Byte and halfword accesses are always NONSEQ. Note that read accesses are always word accesses (HSIZE = 0x010), which can result in destructive read.

The burst length will be half the AHB FIFO size except for the last transfer for a packet which might be smaller. Shorter accesses are also done during descriptor reads and status writes.

The AHB master also supports non-incrementing accesses where the address will be constant for several consecutive accesses. HTRANS will always be NONSEQ in this case while for incrementing accesses it is set to SEQ after the first access. This feature is included to support non-incrementing reads and writes for RMAP.

If the core does not need the bus after a burst has finished there will be one wasted cycle (HTRANS = IDLE).

BUSY transfer types are never requested and the core provides full support for ERROR, RETRY and SPLIT responses.

69.8 Implementation

69.8.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

69.8.2 Clock-generation

Figure 176 shows the clock recovery scheme for the receiver. Data and strobe are coupled directly from their pads to an xor gate which generates the clock. The output from the xor is then connected to a clock network. The specific type of clock network depends on the technology used. The xor gate is actually all that logically belongs to the Rx clock recovery module in figure 176.

The clock output drives all flip-flops in the receiver module found in figure 172. The data signal which is used for generating the clock is also coupled to the data inputs of several flip-flops clocked

GRIP

1009

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

by the Rx clock as seen in figure 176. Care must be taken so that the delay from the data and strobe signals through the clock network are longer than the delay to the data input + setup time.
Figure 176. The clocking scheme for the receiver. The clock is

The transmitter clock is generated from the txclk input. A separate clock input is used to allow the transmitter to be run at much higher frequencies than the system clock. The SpaceWire node contains a clock-divider which divides the txclk signal to the wanted frequency. The transmitter clock should be 10 MHz during initialization and any frequency above 2 MHz in the run-state.

There is an input signal called clkdiv10 which sets the clock divisor value during initialization and the reset value for the user accessible clock divisor register. The user register value will be used in run-state. The resulting tx clock frequency will be txclk/(clock divisor value+1). So if no clock division is wanted, the clock divisor should be set to 0.

Since only integer values are allowed for the clock division and the required init-frequency is 10 Mhz the frequency of the txclk input must be a multiple of 10 MHz. The clock divisor value is 8-bits wide so the maximum txclk frequency supported is 2.56 GHz (note that there is also a restriction on the relation between the system and transmit clock frequencies).

69.8.3 Timers

There are two timers in the core: one for generating the 6.4/12.8 us periods and one for disconnect timing. They run on the system (AMBA) clock and the frequency must be at least 10 MHz to guarantee disconnect timing limits.

There are two user accessible registers which are used to the set the number of clock cycles used for the timeout periods. These registers are described in section 69.9.

The reset value for the timer registers can be set in two different ways selected by the usegen VHDL generic. If usegen is set to 1, the sysfreq VHDL generic is used to generate reset values for the disconnect, 6.4 us and 12.8 us timers. Otherwise, the input signals dcrstval and timerrstval will be used as reset values. If the system clock frequency is 10 MHz or above the disconnect time will be within the limits specified in the SpaceWire standard.

69.8.4 Synchronization

The VHDL generic nsync selects how many synchronization registers are used between clock domains. The default is one and should be used when maximum performance is needed. It allows the transmitter to be clocked 4 times faster than the system clock and the receiver 2 times faster. These are theoretical values without consideration for clock skew and jitter. Note also that the receiver clocks data at both negative and positive edges. Thus, the bitrate is twice as high as the clock-rate.

The synchronization limits the Tx and Rx clocks to be at most 4 and 2 times faster than the system clock. But it might not be possible to achieve such high clock rates for the Tx and Rx clocks for all technologies.

The asynchronous reset to the receiver clock domain has to have a maximum delay of one receiver clock cycle to ensure correct operation. This is needed because the receiver uses has a completely

GRIP

+46 31 7758650 | frontgrade.com/gaisler

asynchronous reset. To make sure that nothing bad happens the is a synchronous reset guard which prevents any signals from being assigned before all registers have their reset signals released.

69.8.5 Fault-tolerance

The core can optionally be implemented with fault-tolerance against SEU errors in the FIFO memories. The fault-tolerance is enabled through the *ft* VHDL generic. Possible options are byte parity protection (*ft = 1*) or TMR registers (*ft = 2*). Note: the GPL version of GRLIB does not include fault-tolerance, and the core will not work unless the *ft* VHDL generic is 0.

69.8.6 Synthesis

Since the receiver and transmitter may run on very high frequency clocks their clock signals have been coupled through a clock buffer with a technology wrapper. This clock buffer will utilize a low skew net available in the selected technology for the clock.

The clock buffer will also enable most synthesis tools to recognize the clocks and it is thus easier to find them and place constraints on them. The fact there are three clock domains in the GRSPW of which all are possibly high frequency clocks makes it necessary to declare all paths between the clock domains as false paths.

In Synplify this is most easily done by declaring all the clocks to be in different clockgroups in the sdc file (if Synplify does not automatically put them in different groups). This will disable any timing considerations between the clock domains and these constraints will also propagate to the place and route tool.

The type of clock buffer is selectable with a VHDL generic and the value zero provides a normal feed through which lets the synthesis tool infer the type of net used.

69.8.7 Technology mapping

The core has three generics for technology mapping: *tech*, *techfifo* and *memtech*. *Tech* selects the technology used for the clock buffers and also adds reset to some registers for technologies where they would otherwise cause problems with gate-level simulations. *Techfifo* selects whether *memtech* should be used to select the technology for the FIFO memories (the RMAP buffer is not affected by the this generic) or if they should be inferred. *Tech* and *memtech* can be set to any value from 0 to NTECH as defined in the GRLIB.TECH package.

69.8.8 RAM usage

The core maps all RAM memories on the syncram_2p component if the *ft* generic is 0 and to the syncram_2pft component for other values. The syncrams are located in the technology mapping library (TECHMAP). The organization of the different memories are described below. If techfifo and/or memtech is set to 0 the synthesis tool will infer the memories. Either RAM blocks or flip-flops will be used depending on the tool and technology. The number of flip-flops used is *syncram depth x syncram width* for all the different memories. The receiver AHB FIFO with fifosize 32 will for example use 1024 flips-flops.

Receiver ahb FIFO

The receiver AHB fifo consists of one syncram_2p block with a width of 32-bits. The depth is determined by the configured FIFO depth. Table 1159 shows the syncram organization for the allowed configurations.

31	RMAP available (RA) - Set to one if the RMAP command handler is available. Only readable.
30	RX unaligned access (RX) - Set to one if unaligned writes are available for the receiver. Only readable.
29	RMAP CRC available (RC) - Set to one if RMAP CRC is enabled in the core. Only readable.
28: 27	RESERVED
26	Number of ports (PO) - The number of available SpaceWire ports minus one. Only readable.
25: 22	RESERVED
21	Port select (PS) - Selects the active port when the no port force bit is zero. '0' selects the port connected to data and strobe on index 0 while '1' selects index 1. Only available if the ports VHDL generic is set to 2. Reset value: '0'.
20	No port force (NP) - Disable port force. When disabled the port select bit cannot be used to select the active port. Instead, it is automatically selected by checking the activity on the respective receive links. Only available if the ports VHDL generic is set to 2. Reset value: '0' if the RMAP command handler is not available. If available the reset value is set to the value of the rmapen input signal.
19: 18	RESERVED
17	RMAP buffer disable (RD) - If set only one RMAP buffer is used. This ensures that all RMAP commands will be executed consecutively. Only available if the rmap VHDL generic is set to 1. Reset value: '0'.
16	RMAP Enable (RE) - Enable RMAP command handler. Only available if rmap VHDL generic is set to 1. Reset value: '1'.
15: 12	RESERVED
11	Time Rx Enable (TR) - Enable time-code receptions. Reset value: '0'.
10	Time Tx Enable (TT) - Enable time-code transmissions. Reset value: '0'.
9	Link error IRQ (LI) - Generate interrupt when a link error occurs. Not reset.
8	Tick-out IRQ (TQ) - Generate interrupt when a valid time-code is received. Not reset.
7	RESERVED
6	Reset (RS) - Make complete reset of the SpaceWire node. Self clearing. Reset value: '0'.
5	Promiscuous Mode (PM) - Enable Promiscuous mode. Reset value: '0'.
4	Tick In (TI) - The host can generate a tick by writing a one to this field. This will increment the timer counter and the new value is transmitted after the current character is transferred. A tick can also be generated by asserting the tick_in signal. Reset value: '0'.
3	Interrupt Enable (IE) - If set, an interrupt is generated when one or both of bit 8 to 9 is set and its corresponding event occurs. Reset value: '0'.
2	Autostart (AS) - Automatically start the link when a NULL has been received. Reset value: '0' if the RMAP command handler is not available. If available the reset value is set to the value of the rmapen input signal.
1	Link Start (LS) - Start the link, i.e. allow a transition from ready to started state. Reset value: '0'.
0	Link Disable (LD) - Disable the SpaceWire codec. Reset value: '0'.

*Table 1167.*0x0C - CLKDIV - clock divisor register

31 16	15 8	7 0
RESERVED	CLKDIVSTART	CLKDIVRUN
0	*	*
r	rw	rw

31: 16	RESERVED
15: 8	Clock divisor startup (CLKDIVSTART) - 8-bit Clock divisor value used for the clock-divider during startup (link-interface is in other states than run). The actual divisor value is Clock Divisor register + 1. Reset value: clkdiv10 input signal.
7: 0	Clock divisor run (CLKDIVRUN) - 8-bit Clock divisor value used for the clock-divider when the link-interface is in the run-state. The actual divisor value is Clock Divisor register + 1. Reset value: clkdiv10 input signal.

69.10.5 Destination Key

*Table 1168.*0x10 - DKEY - destination key

31 8	7 0
RESERVED	DESTKEY
0	*
r	rw

31: 8	RESERVED
7: 0	Destination key (DESTKEY) - RMAP destination key. Only available if the rmap VHDL generic is set to 1. Reset value: 0 (taken from the deskey VHDL generic)

69.10.6 Time Register

*Table 1169.*0x14 - TIME - time register

31 8	7 6	5 0
RESERVED	TCTRL	TIMECNT
0	0	0
r	rw	rw

31: 8	RESERVED
7: 6	Time control flags (TCTRL) - The current value of the time control flags. Sent with time-code resulting from a tick-in. Received control flags are also stored in this register. Reset value: '0'.
5: 0	Time counter (TIMECNT) - The current value of the system time counter. It is incremented for each tick-in and the incremented value is transmitted. The register can also be written directly but the written value will not be transmitted. Received time-counter values are also stored in this register. Reset value: '0'.

69.10.7 Timer and Disconnect Register

*Table 1170.*0x18 - TDR - timer and disconnect register.

31 22	21 12	11 0
RESERVED	DISCONNECT	TIMER64

31: 22	RESERVED
21: 12	Disconnect (DISCONNECT) - Used to generate the 850 ns disconnect time period. The disconnect period is the number is the number of clock cycles in the disconnect register + 3. So to get a 850 ns period, the smallest number of clock cycles that is greater than or equal to 850 ns should be calculated and this values - 3 should be stored in the register. Reset value is set with VHDL generics or with input signals depending on the value of the usegen VHDL generic.
11: 0	6.4 us timer (TIMER64) - Used to generate the 6.4 and 12.8 us time periods. Should be set to the smallest number of clock cycles that is greater than or equal to 6.4 us. Reset value is set with VHDL generics or with input signals depending on the value of the usegen VHDL generic.

69.10.8 DMA Control Register

*Table 1171.*0x20 - DMACTRL - dma control register

31 17	16	15 13	12	11	10	9	8	7	6	5	4	3	2	1	0

r	rw	r	rw	rw	r	r	wc	wc	wc	wc	rw	rw	rw	rw	rw

31: 17	RESERVED
16	Link error disable (LE) - Disable transmitter when a link error occurs. No more packets will be transmitted until the transmitter is enabled again. Reset value: '0'.
15: 13	RESERVED
12	No spill (NS) - If cleared, packets will be discarded when a packet is arriving and there are no active descriptors. If set, the GRSPW will wait for a descriptor to be activated.
11	Rx descriptors available (RD) - Set to one, to indicate to the GRSPW that there are enabled descriptors in the descriptor table. Cleared by the GRSPW when it encounters a disabled descriptor: Reset value: '0'.
10	RX active (RX) - Is set to '1' if a reception to the DMA channel is currently active otherwise it is '0'. Only readable.
9	Abort TX (AT) - Set to one to abort the currently transmitting packet and disable transmissions. If no transmission is active the only effect is to disable transmissions. Self clearing. Reset value: '0'.
8	RX AHB error (RA) - An error response was detected on the AHB bus while this receive DMA channel was accessing the bus. Cleared when written with a one. Reset value: '0'.
7	TX AHB error (TA) - An error response was detected on the AHB bus while this transmit DMA channel was accessing the bus. Cleared when written with a one. Reset value: '0'.
6	Packet received (PR) - This bit is set each time a packet has been received. never cleared by the SW-node. Cleared when written with a one. Reset value: '0'.
5	Packet sent (PS) - This bit is set each time a packet has been sent. Never cleared by the SW-node. Cleared when written with a one. Reset value: '0'.
4	AHB error interrupt (AI) - If set, an interrupt will be generated each time an AHB error occurs when this DMA channel is accessing the bus. Not reset.
3	Receive interrupt (RI) - If set, an interrupt will be generated each time a packet has been received. This happens both if the packet is terminated by an EEP or EOP. Not reset.
2	Transmit interrupt (TI) - If set, an interrupt will be generated each time a packet is transmitted. The interrupt is generated regardless of whether the transmission was successful or not. Not reset.

69.12   Implementation

69.12.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

69.13   Configuration options

Table 1175 shows the configuration options of the core (VHDL generics).

*Table 1175.*Configuration options

Generic	Function	Allowed range	Default
tech	Technology for clock buffers	0 - NTECH	inferred
hindex	AHB master index.	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar.	0 - 16#FFF#	0
pmask	Mask field of the APB bar.	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by GRSPW.	0 - NAHBIRQ-1	0
sysfreq	Frequency of clock input "clk" in kHz.	-	10000
usegen	Use values calculated from sysfreq generic as reset values for 6.4 us timer and disconnect timer.	0 - 1	1
nsync	Number of synchronization registers. Warning: Value 2 only to be used when bit rate is equal or less than the system clock frequency.	1 - 2	1
rmap	Include hardware RMAP target. RMAP CRC logic will also be added. If set to 2 the core will only implement the RMAP target, provide a limited APB interface, enable time code reception and its interrupt.	0 - 2	0
rmapcrc	Enable RMAP CRC logic.	0 - 1	0
fifosize1	Sets the number of entries in the 32-bit receiver and transmitter AHB fifos.	4 - 32	32
fifosize2	Sets the number of entries in the 9-bit receiver fifo (N-Char fifo).	16 - 64	64
rxclkbuftype	Select clock buffer type for receiver clock. 0 does not select a buffer, instead i connects the input directly to the output (synthesis tools may still infer a buffer). 1 selects hardwired clock while 2 selects routed clock.	0 - 2	0
rxunaligned	Receiver unaligned write support. If set, the receiver can write any number of bytes to any start address without writing any excessive bytes.	0 - 1	0
rmapbufs	Sets the number of buffers to hold RMAP replies.	2 - 8	4
ft	Enable fault-tolerance against SEU errors	0 - 2	0
scantest	Enable support for scan test	0 - 1	0
techfifo	Implement FIFO with RAM cells (1) or flip-flops (0)	0 - 1	1
netlist	Use netlist rather then RTL code	0 - 1	0
ports	Sets the number of ports	1 - 2	1
memtech	Technology for RAM blocks	0 - NTECH	inferred
nodeaddr	Sets the reset value for the core's node address. Value 255 enables rmapnodeaddr input instead.	0 - 254 255	254
destkey	Sets the reset value for the core's destination key.	0 - 255	0

69.14   Signal descriptions

Table 1176 shows the interface signals of the core (VHDL ports). As indicated in the table the core consists of two different entities, called GRSPW and GRSPW_PHY. The GRSPW entity is the main part and includes most core's functionality, while the GRSPW_PHY only handles the receiver clock generation and the lower parts of the PHY layer. One GRSPW_PHY entity is used per port. See section 69.18 for information on how to interface GRSPW with GRSPW_PHY.

Table 1176. Signal descriptions

Entity	Signal name	Field	Type	Function	Active
GRSPW	RST	N/A	Input	Reset	Low
	CLK	N/A	Input	Clock	-
	RXCLK[1:0]	N/A	Input	Receiver clock. One clock per port.	-
	TXCLK	N/A	Input	Transmitter default run-state clock	-
	AHBMI	*	Input	AHB master input signals	-
	AHBMO	*	Output	AHB master output signals	-
	APBI	*	Input	APB slave input signals	-
	APBO	*	Output	APB slave output signals	-
	SWNI	D[1:0]	Input	Data input synchronous to RXCLK (rising edge). One bit per port.	-
		ND[9:0]	Input	Data input synchronous to RXCLK (falling edge). Five bits per port.	
		TICKIN	Input	Time counter tick input	High
		CLKDIV10	Input	Clock divisor value used during initialization and as reset value for the clock divisor register	-
		RMAPEN	Input	Reset value for the rmapen control register bit	-
		RMAPNODEADDR	Input	Reset value for nodeaddr register bits when nodeaddr VHDL generic /= 255	-
		DCRSTVAL	Input	Reset value for disconnect timer. Used if usegen VHDL generic is set to 0.	-
		TIMERRSTVAL	Input	Reset value for 6.4 us timer. Used if usegen VHDL generic is set to 0.	-
		DCONNECT[3:0]	Input	Disconnect strobes. Two bits per port.	
	SWNO	D[1:0]	Output	SpaceWire data output. One bit per port.	-
		S[1:0]	Output	SpaceWire strobe output. One bit per port.	-
		TICKOUT	Output	Time counter tick output	High
		LINKDIS	Output	Linkdisabled status	High
		RMAPACT	Output	RMAP command processing active	High
		RXRST	Output	Receiver reset.	Low

Table 1176. Signal descriptions

Entity	Signal name	Field	Type	Function	Active
GRSPW_PHY	RXRST	N/A	Input	Receiver reset.	Low
	DI	N/A	Input	SpaceWire data input.	-
	SI	N/A	Input	SpaceWire strobe input.	-
	RXCLKO	N/A	Output	Receiver clock recovered from data and strobe input.	-
	DO	N/A	Ouput	Recovered data, synchronous to RXCLKO (rising edge).	-
	NDO[4:0]	N/A	Output	Recovered data, synchronous to RXCLKO (falling edge)	-
	DCON-NECT[1:0]	N/A	Ouput	Disconnect strobe signals.	-
	TESTEN	N/A	Input	Scan test enable	High
	TESTCLK	N/A	Input	Scan test clock. Used inside the GRSP-W_PHY entity instead of recovered RXCLK when TESTEN is active.	-
	* see GRLIB IP Library User's Manual				

69.15 Signal definitions and reset values

The signals and their reset values are described in table 1177.

Table 1177. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
spw_clk	Input	Transmitter default run-state clock	Rising edge	-
spw_rxd	Input, LVDS	Data input, positive	High	-
spw_rxdn	Input, LVDS	Data input, negative	Low	-
spw_rxs	Input, LVDS	Strobe input, positive	High	-
spw_rxsn	Input, LVDS	Strobe input, negative	Low	-
spw_txd	Output, LVDS	Data output, positive	High	Logical 0
spw_txdn	Output, LVDS	Data output, negative	Low	Logical 1
spw_txs	Output, LVDS	Strobe output, positive	High	Logical 0
spw_txsn	Output, LVDS	Strobe output, negative	Low	Logical 1

69.16 Timing

The timing waveforms and timing parameters are shown in figure 177 and are defined in table 1178.

The SpaceWire jitter and skew timing waveforms and timing parameters are shown in figure 178 and are defined in table 1179.

69.17 Library dependencies

Table 1180 shows libraries used when instantiating the core (VHDL libraries).

Table 1180. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions
GAISLER	SPACEWIRE	Signals, component	Component and record declarations.

69.18 Instantiation

This example shows how the core can be instantiated.

Normally di, si, do and so should be connected to input and output pads configured with LVDS drivers. How this is done is technology dependent.

The GRSPW in the example is a 2-port core configured with non-ft memories of size 4, 64 and 8 entries for AHB FIFOs, N-Char FIFO and RMAP buffers respectively. The system frequency (clk) is 40 MHz and the transmitter frequency (txclk) is 20 MHz.

The memory technology is inferred which means that the synthesis tool will select the appropriate components. The rx clk buffer uses a hardwired clock.

The hardware RMAP command handler is enabled which also automatically enables rxunaligned and rmapcrc. Finally, the DMA channel interrupt line is 2 and the number of synchronization registers is 1.

69.19 API

A simple Application Programming Interface (API) is provided together with the GRSPW. The API is located in $(GRLIB)/software/spw. The files are rmapapi.c, spwapi.c, rmapapi.h, spwapi.h. The spwapi.h file contains the declarations of the functions used for configuring the GRSPW and transferring data. The corresponding definitions are located in spwapi.c. The rmapapi is structured in the same manner and contains a function for building RMAP packets.

These functions could be used as a simple starting point for developing drivers for the GRSPW. The different functions are described in this section.

69.19.1 GRSPW Basic API

The basic GRSPW API is based on a struct spwvars which stores all the information for a single GRSPW core. The information includes its address on the AMBA bus as well as SpaceWire parameters such as node address and clock divisor. A pointer to this struct is used as a input parameter to all the functions. If several cores are used, a separate struct for each core is created and used when the specific core is accessed.

*Table 1181.*The spwvars struct

Field	Description	Allowed range
regs	Pointer to the GRSPW	-
nospill	The nospill value used for the core.	0 - 1
rmap	Indicates whether the core is configured with RMAP. Set by spw_init.	0 - 1
rxunaligned	Indicates whether the core is configured with rxunaligned support. Set by spw_init.	0 - 1
rmapcrc	Indicates whether the core is configured with RMAPCRC support. Set by spw_init.	0 - 1
clkdiv	The clock divisor value used for the core.	0 - 255
nodeaddr	The node address value used for the core.	0 - 255
destkey	The destination key value used for the core.	0 - 255
rxmaxlen	The Receiver maximum length value used for the core.	0 - 33554431
rxpnt	Pointer to the next receiver descriptor.	0 - 127
rxchkpnt	Pointer to the next receiver descriptor that will be polled.	0 - 127
txpnt	Pointer to the next transmitter descriptor.	0 - 63
txchkpnt	Pointer to the next transmitter descriptor that will be polled.	0 - 63
timetxen	The timetxen value used for this core.	0 - 1
timerxen	The timerxen value used for this core.	0 - 1
txd	Pointer to the transmitter descriptor table.	-
rxd	Pointer to the receiver descriptor table	-

The following functions are available in the basic API:

```
int spw_setparam(int nodeaddr, int clkdiv, int destkey, int nospill, int timetxen, int
timerxen, int rxmaxlen, int spwadr, struct spwvars *spw);
```

Used for setting the different parameters in the spwvars struct. Should always be run first after creating a spwvars struct. This function only initializes the struct. Does not write anything to the Space-Wire core.

*Table 1182.*Return values for spw_setparam

Value	Description
0	The function completed successfully
1	One or more of the parameters had an illegal value

*Table 1183.*Parameters for spw_setparam

Parameter	Description	Allowed range
nodeaddr	Sets the node address value of the struct spw passed to the function.	0-255
clkdiv	Sets the clock divisor value of the struct spw passed to the function.	0-255
destkey	Sets the destination key of the struct spw passed to the function.	0-255
nospill	Sets the nospill value of the struct spw passed to the function.	0 - 1
timetxen	Sets the timetxen value of the struct spw passed to the function.	0 - 1
timerxen	Sets the timerxen value of the struct spw passed to the function.	0 - 1
rxmaxlen	Sets the receiver maximum length field of the struct spw passed to the function.	$0 - 2^{25}-1$
spwadr	Sets the address to the GRSPW core which will be associated with the struct passed to the function.	$0 - 2^{32}-1$

```
int spw_init(struct spwvars *spw);
```

Initializes the GRSPW core located at the address set in the struct spw. Sets the following registers: node address, destination key, clock divisor, receiver maximum length, transmitter descriptor table address, receiver descriptor table address, ctrl and dmactrl. All bits are set to the values found in the spwvars struct. If a register bit is not present in the struct it will be set to zero. The descriptor tables are allocated to an aligned area using malloc. The status register is cleared and lastly the link interface is enabled. The run state frequency will be set according to the value in clkdiv.

*Table 1184.*Return values for spw_init

Value	Description
0	The function completed successfully
1	One or more of the parameters could not be set correctly or the link failed to initialize.

*Table 1185.*Parameters for spw_init

Parameter	Description	Allowed range
spw	The spwvars struct associated with the GRSPW core that should be initialized.	-

```
int set_txdesc(int pnt, struct spwvars *spw);
```

1	The new address could not be written correctly

Table 1187. Parameters for spw_txdesc

Parameter	Description	Allowed range
pnt	The new address to the descriptor table area	$0 - 2^{32}-1$
spw	Pointer to the spwvars struct associated with GRSPW core that should be configured	-

```
int set_rxdesc(int pnt, struct spwvars *spw);
```

Sets a new address to the Receiver descriptor table address register. Should only be used when no transmission is active. Also resets the pointers for spw_rx and spw_checkrx (Explained in the section for those functions).

Table 1188. Return values for spw_rxdesc

Value	Description
0	The function completed successfully
1	The new address could not be written correctly

Table 1189. Parameters for spw_rxdesc

Parameter	Description	Allowed range
pnt	The new address to the descriptor table area	$0 - 2^{32}-1$
spw	Pointer to the spwvars struct associated with GRSPW core that should be configured	-

```
void spw_disable(struct spwvars *spw);
```

Disables the GRSPW core (the link disable bit is set to '1').

69.20   Appendix A Clarifications of the GRSPW implementation of the standard

6.3.1 page 9 RMAP draft F

"The user application at destination will be informed that there was an error

in the data transferred. The source will be informed of the data error if the

acknowledge bit in the command has been set."

We view the RMAP command handler as both protocol parser and user application. All commands are parsed in the first stage and various (internal) status bits are set. The next step (which can be viewed as the user application) will make the decision of how to act upon the received command from these bits. Therefore, the various errors that can occur are not externally observable.

If an error occurs when the command handler is accessing the AHB bus through the DMA interface errors will be externally observable using the AHB status register in GRLIB.

6.3.6 page 13 RMAP draft F

"The Write Command packet arrives at the destination and its header is found to be in error. This fact is added to the error statistics in the destination node."

This text does not state how and if these statistics should be observable. At the moment the error handling is internal to the RMAP command handler and therefore no statistics are internally observable. A counter for this particular error might be added in the future.

6.3.6 page 15 RMAP draft F

"These various errors will be reported to the user application running on the

destination node (Write Data Error Indication)."

Again the RMAP command handler is the user application and all these errors are handled internally.

6.5.6 page 31 RMAP draft F

"The source user application, in fact immediately rejects this as an authorisation

failure as the command is trying to RMW an area of protected memory."

It should probably be destination user application instead of source. It is unclear what immediately means. Should it be rejected before any accesses are done on the bus and thus requiring the RMAP command handler to include a complete bus decoding. The GRSPW does (probably) not comply to this paragraph at the moment. If a bus error occurs a general error code will be returned.

6.5.6 page 32

"If the header of the RMW reply packet is received intact but the data field is

corrupted as indicated by an incorrect data field length (too long or too short)

or by a CRC error, then an error can be flagged to the application immediately

(RMW Data Failure) without having to wait for an application timeout."

This is not applicable to the GRSPW since it does not handle replies. However this is practically an unnecessary comment since it is not specified in the standard in which manner received replies are indicated to the higher layers.

70 GRSPW2 - SpaceWire codec with AHB host Interface and RMAP target

70.1 Overview

The SpaceWire core provides an interface between the AHB bus and a SpaceWire network. It implements the SpaceWire standard (ECSS-E-ST-50-12C) with the protocol identification extension (ECSS-E-ST-50-51C). The optional Remote Memory Access Protocol (RMAP) target implements the ECSS standard (ECSS-E-ST-50-52C).

The SpaceWire interface is configured through a set of registers accessed through an APB interface. Data is transferred through DMA channels using an AHB master interface. The number of DMA channels is configurable from one to four.

The core can also be configured with two SpaceWire ports with manual or automatic switching between them.

There can be up to four clock domains: one for the AHB interface (system clock), one for the transmitter and one or two for the receiver depending on the number of configured ports.

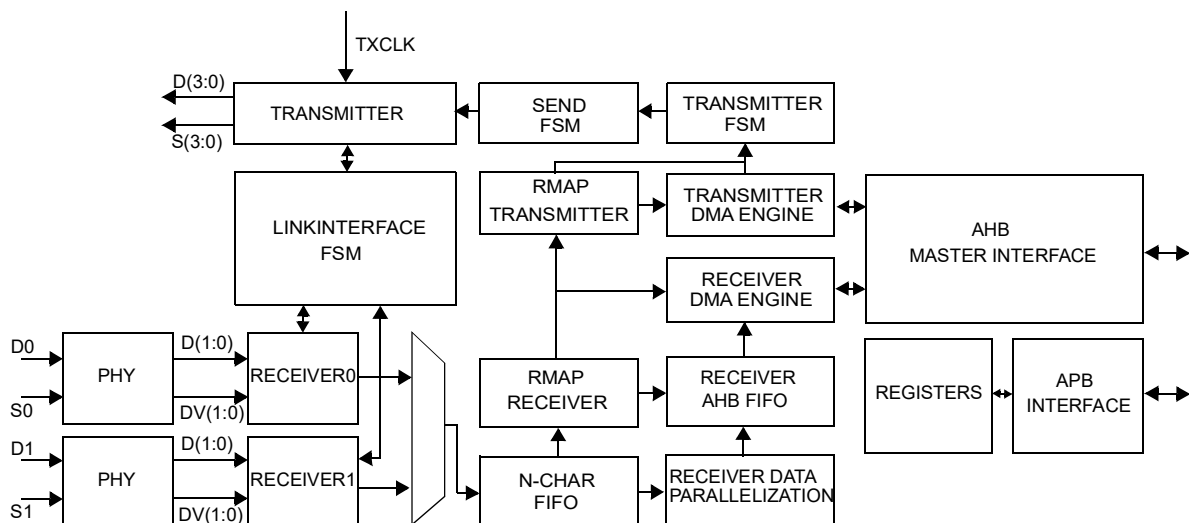
The core supports byte addressed 32-bit big-endian and little-endian host systems. Transmitter outputs can be either Single Data Rate (SDR) or Double Data Rate (DDR). The receiver can be connected either to an Frontgrade SpaceWire transceiver or recover the data itself using a self-clocking scheme or sampling (SDR or DDR).


Figure 179. Block diagram

70.2 Operation

70.2.1 Overview

The main sub-blocks of the core are the link interface, the RMAP target and the AMBA interface. A block diagram of the internal structure can be found in figure 179.

The link interface consists of the receiver, transmitter, and the link interface FSM. They handle communication on the SpaceWire network. The PHY block provides a common interface for the receiver to the four different data recovery schemes and is external to this core. A short description is found in section 70.3.5. The complete documentation is found in the GRSPW2_PHY section of GRLIB IP Core User's Manual. The AMBA interface consists of the DMA engines, the AHB master interface and the APB interface. The link interface provides FIFO interfaces to the DMA engines. These FIFOs

GRIP

Apr 2024, Version 2024.1

1037

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

are used to transfer N-Chars between the AMBA and SpaceWire domains during reception and transmission.

The RMAP target is an optional part of the core which can be enabled with a VHDL generic. The RMAP target handles incoming packets which are determined to be RMAP commands instead of the receiver DMA engine. The RMAP command is decoded and if it is valid, the operation is performed on the AHB bus. If a reply was requested it is automatically transmitted back to the source by the RMAP transmitter.

The link interface, DMA engines, RMAP target and AMBA interface are described in section 70.3, 70.6, 70.8 and 70.9 respectively.

70.2.2 Protocol support

The core only accepts packets with a valid destination address in the first received byte. Packets with address mismatch will be silently discarded (except in promiscuous mode, which is covered in section 70.6.10).

The second byte is sometimes interpreted as a protocol ID a described hereafter. The RMAP protocol (ID=0x1) is the only protocol handled separately in hardware while other packets are stored to a DMA channel. If the RMAP target is present and enabled all RMAP commands will be processed, executed and replied automatically in hardware. Otherwise RMAP commands are stored to a DMA channel in the same way as other packets. RMAP replies are always stored to a DMA channel. More information on the RMAP protocol support is found in section 70.8. When the RMAP target is not present or disabled, there is no need to include a protocol ID in the packets and the data can start immediately after the address.

All packets arriving with the extended protocol ID (0x00) are stored to a DMA channel. This means that the hardware RMAP target will not work if the incoming RMAP packets use the extended protocol ID. Note also that packets with the reserved extended protocol identifier (ID = 0x000000) are not ignored by the core. It is up to the client receiving the packets to ignore them.

When transmitting packets, the address and protocol-ID fields must be included in the buffers from where data is fetched. They are *not* automatically added by the core.

Figure 180 shows the packet types accepted by the core. The core also allows reception and transmission with extended protocol identifiers but without support for RMAP CRC calculations and the RMAP target.

Addr	ProtID	D0	D1	D2	D3	..	Dn-2	Dn-1	EOP

Addr	D0	D1	D2	D3	D4	..	Dm-2	Dm-1	EOP
Figure 180. The SpaceWire packet types supported by the core.

When a package is received with a protocol ID = 0x02 (CCSDS) the core can, if enabled, automatically calculate and check the CCSDS/CCITT CRC-16 and 16-bit ISO-checksum (J.G. Fletcher, ISO 8473-1:1998) assuming this is included in the package.

70.2.3 Endianness

The core is designed for big-endian and little-endian systems.

GRSPW2 automatically detects the endianness of the system by reading a dedicated sideband signal included in the AMBA records. When accessing the AHB bus, the data may be swapped, depending on the selected endianness and the type of data involved in the transfer:

GRIP
Apr 2024, Version 2024.1

1038

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Words belonging to TX and RX descriptors are never swapped and shall be read and written using 32-bit accesses. These words shall be located at the same address offsets (0x0, 0x4, 0x8 and 0xC) regardless of the endianness.

- Data in standard SpaceWire packets is treated as a stream of bytes, i.e. the bytes will be located in the same memory positions in both big- and little-endian systems. If *addr* is the address configured in the corresponding field of a descriptor, the first byte shall be located at *addr*, the second byte at *addr+1*, and so on. This implies that GRSPW2 will internally swap the AHB words in little-endian configurations when accessing the AMBA bus.

- Data in RMAP packets is also treated as a stream of bytes for all commands (Read, Write and Read-Modify-Write). The first data byte of an RMAP packet is associated with the address in the packet. GRSPW2 will swap the data bytes in little-endian configurations. Note: the user shall take the endianness of the host system into account. This means that, when accessing APB registers and 32-bit descriptors via RMAP, the user shall swap the bytes of the command in little-endian host systems.

70.3   Link interface

The link interface handles the communication on the SpaceWire network and consists of a transmitter, receiver, a FSM and FIFO interfaces. An overview of the architecture is found in figure 179.

70.3.1   Link interface FSM

The FSM controls the link interface (a more detailed description is found in the SpaceWire standard). The low-level protocol handling (the signal and character level of the SpaceWire standard) is handled by the transmitter and receiver while the FSM handles the exchange level.

The link interface FSM is controlled through the Control register (CTRL). The link can be disabled through the CTRL.LD bit, which depending on the current state, either prevents the link interface from reaching the started state or forces it to the error-reset state. When the link is not disabled, the link interface FSM is allowed to enter the started-state when either the CTRL.LS bit is set or when a NULL character has been received and the CTRL.AS bit is set.

The state of the link interface determines which type of characters that are allowed to be transmitted, which together with the requests made from the host interfaces determine what character will be sent.

Time-codes are sent when the FSM is in the run-state and a request is made through the time-interface (described in section 70.4).

When the link interface is in the connecting- or run-state it is allowed to send FCTs. FCTs are sent automatically by the link interface when possible. This is done based on the maximum value of 56 for the outstanding credit counter and the currently free space in the receiver N-Char FIFO. FCTs are sent as long as the outstanding counter is less than or equal to 48 and there are at least 8 more empty FIFO entries than the counter value.

N-Chars are sent in the run-state when they are available from the transmitter FIFO and there are credits available. NULLs are sent when no other character transmission is requested, or when the FSM is in a state where no other transmissions are allowed.

The credit counter (incoming credits) is automatically increased when a FCTs is received, and decreased when N-Chars are transmitted. Received N-Chars are stored to the receiver N-Char FIFO for further handling by the DMA interface. Received Time-codes are handled by the time-interface.

70.3.2   Transmitter

The state of the FSM, credit counters, requests from the time-interface and requests from the DMA-interface are used to decide the next character to be transmitted. The type of character and the character itself (for N-Chars and Time-codes) to be transmitted are presented to the low-level transmitter which is located in a separate clock-domain.

This is done because one usually wants to run the SpaceWire link on a different frequency than the host system clock. The core has a separate clock input which is used to generate the transmitter clock. More information on transmitter clock generation is found in section 70.11.2. Since the transmitter often runs on high frequency clocks (> 100 MHz) as much logic as possible has been placed in the system clock domain to minimize power consumption and timing issues.

The transmitter logic in the host clock domain decides what character to send next and sets the proper control signal and presents any needed character to the low-level transmitter as shown in figure 181. The transmitter sends the requested characters and generates parity and control bits as needed. If no requests are made from the host domain, NULLs are sent as long as the transmitter is enabled. Most of the signal and character levels of the SpaceWire standard is handled in the transmitter. External LVDS drivers are needed for the data and strobe signals. The outputs can be configured as either single- or double data rate. The latter increases maximum bitrate significantly but is not available for all technologies.
Figure 181. Schematic of the link interface transmitter. Some bits in D[3:0] and S[3:0] may be unused, depending on the values of the *output_type*, and *ports* VHDL generics (see section 70.15).

A transmission FSM reads N-Chars for transmission from the transmitter FIFO. It is given packet lengths from the DMA interface and appends EOPs/EEPs and RMAP/CCSDS-CRC (or ISO-checksum) values if requested. When it is finished with a packet the DMA interface is notified and a new packet length value is given.

70.3.3 Receiver

The receiver detects connections from other nodes and receives characters as a bit stream recovered from the data and strobe signals by the GRSPW2_PHY module, which presents it as a data and data-valid signal. The receiver and GRSPW2_PHY are located in a separate clock domain which runs on a clock driven by the GRSPW2_PHY. More information on the clock-generation can be found in section 70.11.2.

The receiver is activated as soon as the link interface leaves the error reset state. Then after a NULL is received it can start receiving any characters. It detects parity, escape and credit errors which causes the link interface to enter the error reset state. Disconnections are handled in the link interface part in the tx clock domain because no receiver clock is available when disconnected.

Received Characters are flagged to the host domain and the data is presented in parallel form. The interface to the host domain is shown in figure 182. L-Chars are the handled automatically by the host domain link interface part while all N-Chars are stored in the receiver FIFO for further handling. If two or more consecutive EOPs/EEPs are received all but the first one are discarded.

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler
Figure 182. Schematic of the link interface receiver.

70.3.4 Dual port support

The core can be configured to include an additional SpaceWire port. With dual ports the transmitter drives an additional pair of data/strobe output signals and one extra receiver is added to handle a second pair of data/strobe input signals.

One of the ports is set as active (how the active port is selected is explained below) and the transmitter drives the data/strobe signals of the active port with the actual output values as explained in section 70.3.2. The inactive port is driven with zero on both data and strobe.

Both receivers will always be active but only the active port's interface signals (see figure 182) will be propagated to the link interface FSM. Each time the active port is changed, the link will be reset so that the new link is started in a controlled manner.

When the CTRL.NP bit is zero, the CTRL.PS bit selects the active port. When the CTRL.NP bit is set to one, the active port is automatically selected during initialization. For the latter mode, the port on which the first bit is received will be selected as the active port. If the initialization attempt fails on that port the link is reset and the active port is again sected based on which port the first bit is received.

70.3.5 Receiver PHY

The receiver supports four different input data recovery schemes: self-clocking (xor), sampling SDR, sampling DDR and the Frontgrade SpaceWire transceiver. These four recovery types are handled in the PHY module and data is presented to the receiver as a data (D) and data-valid (DV) signal. This part of the receiver must often be constrained and placing it in a separate module makes this process easier with the most common synthesis tools. The input type is selected using the VHDL generic *input_type*. More information about the PHY can be found in the GRSPW2_PHY section of the GRLIP IP Core User's Manual.

70.3.6 Setting link-rate

The register field CLKDIV.CLKDIVSTART determines the link-rate during initialization (all states up to and including the connecting-state). The register is also used to calculate the link interface FSM timeouts (6.4 µs and 12.8 µs, as defined in the SpaceWire standard). The CLKDIV.CLKDIVSTART field should always be set so that a 10 Mbit/s link-rate is achieved during initialization. In that case the timeout values will also be calculated correctly.

To achieve a 10 Mbit/s link-rate, the CLKDIV.CLKDIVSTART field should be set according to the following formulas:

With single data rate (SDR) outputs:

CLKDIV.CLKDIVSTART = (<frequency in MHz of TXCLK> / 10) - 1

With double data rate (DDR) outputs, or when connected to Frontgrade SpaceWire transceiver:

CLKDIV.CLKDIVSTART = (2 x <frequency in MHz of TXCLK> / 10) - 1

GRIP

+46 31 7758650 | frontgrade.com/gaisler

The link-rate in run-state is controlled with the run-state divisor, the CLKDIV.CLKDIVRUN register field. The link-rate in run-state is calculated according to the following formulas:

With SDR outputs:

<link-rate in Mbits/s> = <frequency in MHz of TXCLK> / (CLKDIV.CLKDIVRUN+1)

With DDR outputs / Frontgrade SpaceWire transceiver:

<link-rate in Mbits/s> = 2 x <frequency in MHz of TXCLK> / (CLKDIV.CLKDIVRUN+1)

The value of CLKDIV.CLKDIVRUN only affects the link-rate in run-state, and does not affect the 6.4 µs or 12.8 µs timeouts values.

Note that when using DDR ouputs, or when connected to Frontgrade SpaceWire transceiver, there is a limitation in the usable clock divisor values. All even values (except 0) will result in the same bitrate as the one higher odd number.

An example of clock divisor and resulting link-rate, with a TXCLK frequency of 50 MHz, is shown in the table 1222. Also see 70.11.2 for information on clock requirements.

Table 1222. SpaceWire link-rate example with 50 MHz TXCLK

	Link-rate in Mbit/s	
Clock divisor value	SDR outputs	DDR outputs / Frontgrade SpaceWire transceiver
0	50	100
1	25	50
2	16.67	25
3	12.5	25
4	10	16.67
5	8.33	16.67
6	7.14	12.5
7	6.25	12.5
8	5.56	10
9	5	10

70.4   Time-code distribution

Time-codes are control codes that consists of two control flags (bits 7:6) and a time value (bits 5:0), and they are used to distribute time over the SpaceWire network. The current time value (value of latest received or transmitted time-code), and control flags, can be read from the Time-code register (TC).

70.4.1   Receiving time-codes

When a control-code is received, and either the control flags (bits 7:6) have value "00", or both control flag filtering and interrupt receive is disabled (CTRL.TF bit, and INTCFG.IR bit both set to 0), then the received control code is considered to be a Time-Code. If Time-Code reception is enabled (CTRL.TR bit set to 1) then the received time value is stored in the TC.TIMECNT field. If the received time value equals TC.TIMECNT+1 (modulo 64), then the Time-Code is considered valid.

When a valid Time-Code is received, in addition to the time value being updated, the received control flags are stored to the TC.TCTRL field. Also, when a valid Time-Code is received, the TICKOUT output signal is asserted for one system clock cycle, the STS.TO bit is set to 1, and an AMBA interrupt is generated if the CTRL.IE bit and CTRL.TQ bit are both set to 1.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

For all received control codes, Time-Codes or not, the control flags together with the time value are outputted on the TIMEOUT[7:0] signals, and the TICKOUTRAW signal is asserted for one system clock cycle.

70.4.2 Transmitting time-codes

Time-codes can be transmitted either through the AMBA APB registers or through the signals TICKIN, TICKINRAW, TIMEIN, and TICKINDONE.

In order to send a Time-code, Time-Code transmission must be enabled by setting the CTRL.TT bit to 1. To transmit a time-code through the register interface the CTRL.TI bit should be written to 1. When the bit is written the current time value (TC.TIMECNT field) is incremented, and a Time-Code consisting of the new time value together with the current control flags (TC.TCTRL field) is sent. The CTRL.TI bit will stay high until the Time-Code has been transmitted. If time-code transmission is disabled, writing the CTRL.TI bit has no effect.

To transmit a time-code using the TICKIN signal the sender must wait until the TICKINDONE output is low, then assert TICKIN. When TICKINDONE is asserted again, the TICKIN signal should be de-asserted the same cycle. Following this procedure will make the core transmit a Time-Code consisting of the current control flags and the current time value + 1 (modulo 64). This also requires that time-code transmission is enabled through the CTRL.TT bit.

To transmit a Time-Code using the TICKINRAW signal the sender must wait until TICKINDONE is low, then assert TICKINRAW and place the value of the Time-Code to be sent on the TIMEIN[7:0] signals. When TICKINDONE is asserted again, the TICKINRAW signal should be de-asserted the same cycle. Note that sending Time-Codes by using TICKINRAW does not require that Time-Code transmission is enabled from the Control register. However, in order to send Time-Codes with control flags different than "00", interrupt transmit must be disabled (INTCTRL.IT bit set to 0). If interrupt transmit is enabled then control codes "10" are interpreted as interrupt-codes, while control codes "01" and "11" are discarded.

Note that the link interface must be in run-state in order to be able to send a Time-Code.

70.5 Interrupt distribution

The core supports interrupt distribution functionality. Whether or not this functionality is implemented is indicated by the CTRL.ID bit, and the number of supported interrupt numbers is indicated by the INTCFG.NUMINT field. Either 1, 2, 4, or 32 interrupt numbers (in the range 0-31) can be supported. When less than 32 interrupt numbers are supported it is programmable through the INTCFG register which interrupt numbers in the range 0-31 that are allowed to be sent and received. When extended interrupt mode is enabled (INTCFG.EE bit set to 1), the supported interrupt number in "interrupt mode" is extended to 0-63).

The interrupts are distributed as control codes with the control flags (bits 7:6) set to "10". Bit 5 of the control code specifies if the code is an interrupt-code (bit 5 = '0') or an interrupt-acknowledge-code (bit 5 = '1'). An interrupt-code is generated by the source of the interrupt event, while the interrupt-acknowledge-code is sent by the interrupt handler for the corresponding interrupt number. When extended interrupt mode is enabled (INTCFG.EE bit set to 1), then interrupt-acknowledge-code is interpret as interrupt-codes in the range 32-63.

An Interrupt distribution ISR register holds the current state of all the interrupt numbers in the Space-Wire network. A bit in the ISR register is set to 1 when an interrupt-code with the corresponding interrupt number is received / transmitted, and the bit is set to 0 when an interrupt-acknowledge-code with the corresponding interrupt number is received / transmitted.

Each interrupt number also has its own timer that is used to clear the ISR bit if an interrupt-acknowledge-code is not received before the timer expires. There is also a timer for each interrupt-number that controls the minimum time between and interrupt-code and interrupt-acknowledge-code (and vice

GRIP

+46 31 7758650 | frontgrade.com/gaisler

versa), in order to allow propagation of the codes through the whole network before a new code with the same interrupt number is sent.

70.5.1 Interrupt distribution timers

Each interrupt number has three corresponding timers, called the ISR timer, INT/ACK-timer, and ISR change timer. Whether or not these timers are implemented in hardware, and how large they are, can be detected by probing the ISRTIMER, IATIMER, and ICTIMER registers respectively.

If the ISR timers are enabled (ISRTIMER.EN bit set to 1), the ISR timer is started and reloaded with the value from the ISRTIMER.RL field each time an interrupt-code is received such that the corresponding ISR bit is set to 1. If a matching interrupt-acknowledge-code is received, the corresponding ISR timer is stopped. If the ISR timer expires before an interrupt-acknowledge-code is received, the corresponding ISR bit is cleared. The purpose of the ISR timer is to recover from situations where an interrupt-acknowledge-code is lost. If an interrupt-acknowledge-code is lost and there were no ISR timer, then the corresponding ISR bit would stay set forever, and prevent future interrupt-codes with that interrupt number to be distributed. It is important to configure the reload value for the ISR timer correctly. The reload value shall not be less than the worst network propagation delay for the interrupt-code, plus the maximum delay in the interrupt handler, plus the worst network propagation delay for the interrupt-acknowledge-code. Note that use of the ISR timer is mandatory, so if the hardware timers are either disabled or not implemented, software must handle the timers.

The INT/ACK-timer is used to control the minimum time between an interrupt-code and interrupt-acknowledge-code with the same interrupt number, and vice versa. The purpose of the INT/ACK-timer is to make sure that each interrupt- / interrupt-acknowledge-code gets enough time to propagate through the complete network before the next interrupt- / interrupt-acknowledge-code is sent, ensuring that no interrupt- / interrupt-acknowledge-code is received out of order. If the INT/ACK-timers are enabled (IATIMER.EN bit set to 1), then each time an interrupt- / interrupt-acknowledge-code is received the corresponding INT/ACK-timer is started and reloaded with the value from the IATIMER.RL field. As long as the timer is running, an interrupt- / interrupt-acknowledge-code with that interrupt number will not be sent.

The ISR change timer is used to control the minimum time between two consecutive changes to the same ISR bit. The purpose of the timer is to protect against unexpected occurrences of interrupt- / interrupt-acknowledge-codes that could occur, for example, due to a network malfunction or a babbling idiot. If the ISR change timers are enabled (ICTIMER.EN bit set to 1), then the timer for an ISR bit is started and reloaded with the value from the ICTIMER.RL field each time a received interrupt- / interrupt-acknowledge-code makes the ISR bit change value. Until the timer has expired, the corresponding ISR bit is not allowed to change value, and any received interrupt- / interrupt-acknowledge-codes with that interrupt number are discarded.

70.5.2 Receiving interrupt- / interrupt-acknowledge-codes

When a control code with control flags set to "10" is received, and interrupt receive is enable (IR bit in Interrupt distribution control register set to 1), the control code is considered an interrupt-code if bit 5 is 0, and an interrupt-acknowledge-code if bit 5 is 1. If an interrupt-code is received and the interrupt number's corresponding ISR bit is already set to 1, or an interrupt-acknowledge-code when the ISR bit is 0, then the received interrupt- / interrupt-acknowledge-code is discarded without any further action.

When an interrupt-code is received, and the corresponding ISR bit is 0, the ISR bit is set to 1. If the interrupt number's corresponding bit in the Interrupt tick-out mask register is set to 1 then the corresponding bit in the Interrupt-code receive register is set to 1, the TICKOUT signal is asserted for one clock cycle (if the INTCTRL.IT bit is 1), and an AMBA interrupt is generated (if the IE bit in the Control register, and IQ bit in the Interrupt distribution control register are both set to 1). If the interrupt number's corresponding bit in the Interrupt-code auto acknowledge mask register is set to 1, then

GRIP

Apr 2024, Version 2024.1

+46 31 7758650 | frontgrade.com/gaisler

an interrupt-acknowledge-code will be automatically sent once the INT/ACK-timer has expired, and the ISR bit will be cleared again.

When an interrupt-acknowledge-code is received, and the corresponding ISR bit is 1, the ISR bit is set to 0. If the interrupt number's corresponding bit in the Interrupt tick-out mask register is set to 1, and the interrupt-code that made the ISR bit get set to 1 in the first place was sent by software (through register access), then the corresponding bit in the Interrupt-acknowledge-code receive register is set to 1. The TICKOUT signal is asserted for one clock cycle as well (if the INTCTRL.AT bit is 1), and an AMBA interrupt is generated (if the IE bit in the Control register, and IQ bit in the Interrupt distribution control register are both set to 1).

Note that all received control codes, interrupt- / interrupt-acknowledge-codes or not, are outputted on the TIMEOUT[7:0] signals, and the TICKOUTRAW signal is asserted for one clock cycle.

For more details regarding interrupt- / interrupt-acknowledge-code reception, please see the description of the interrupt distribution registers in section 70.13.

70.5.3 Transmitting interrupt- / interrupt-acknowledge-codes

Interrupt- / interrupt-acknowledge-codes can be transmitted either through the AMBA APB registers or through the signals TICKINRAW, TIMEIN, and TICKINDONE.

To transmit an interrupt- / interrupt-acknowledge-code through the register interface the II bit in the Interrupt distribution control register should be written to 1. When the bit is written the value of the TXINT field determine which interrupt- / interrupt-acknowledge-code that will be sent.

To transmit an interrupt- / interrupt-acknowledge-code using the TICKINRAW signal the sender must wait until TICKINDONE is low, then assert TICKINRAW and place the value of the interrupt- / interrupt-acknowledge-code to be sent on the TIMEIN[7:0] signals. When TICKINDONE is asserted again, the TICKINRAW signal should be de-asserted the same cycle.

Both methods of sending an interrupt- / interrupt-acknowledge-code requires that interrupt transmission is enabled (IT bit in Interrupt distribution control register set to 1). The actual sending of the interrupt- / interrupt-acknowledge-code is delayed until the corresponding INT/ACK-timer has expired.

For more details regarding interrupt- / interrupt-acknowledge-code transmission, please see the description of the interrupt distribution registers in section 70.13.

70.5.4 Interrupt-code generation

Interrupt-codes can be generated automatically due to a number of internal events. Which events that should force an interrupt-code to be sent, and what interrupt-number to use, is controlled from the Interrupt distribution control register, and the DMA control/status register. Interrupt transmission must also be enabled (IT bit in Interrupt distribution control register) for interrupt-codes to be generated. Internally generated interrupt-codes are sent in the same manner as interrupt-codes transmitted through the register interface and the TICKINRAW signal, as described in section 70.5.3. For more details regarding interrupt-code generation please see the description of the Interrupt distribution control register and DMA control/status register in section 70.13.

70.6 Receiver DMA channels

The receiver DMA engine handles reception of data from the SpaceWire network to different DMA channels.

70.6.1 Address comparison and channel selection

Packets are received to different channels based on the address and whether a channel is enabled or not. When the receiver N-Char FIFO contains one or more characters, N-Chars are read by the receiver DMA engine. The first character is interpreted as the logical address and is compared with

GRIP

the addresses of each channel starting from 0. The packet will be stored to the first channel with an matching address. The complete packet including address and protocol ID but excluding EOP/EEP is stored to the memory address pointed to by the descriptors (explained later in this section) of the channel.

Each SpaceWire address register has a corresponding mask register. Only bits at an index containing a zero in the corresponding mask register are compared. This way a DMA channel can accept a range of addresses. There is a Default address register which is used for address checking in all implemented DMA channels that do not have separate addressing enabled and for RMAP commands in the RMAP target. With separate addressing enabled the DMA channels' own address/mask register pair is used instead.

If an RMAP command is received it is only handled by the target if the Default address register (including mask) matches the received address. Otherwise the packet will be stored to a DMA channel if one or more of them has a matching address. If the address does not match neither the default address nor one of the DMA channels' separate register, the packet is still handled by the RMAP target if enabled since it has to return the invalid address error code. The packet is only discarded (up to and including the next EOP/EEP) if an address match cannot be found and the RMAP target is disabled.

Packets, other than RMAP commands, that do not match neither the default address register nor the DMA channels' address register will be discarded. Figure 183 shows a flowchart of packet reception.

At least 2 non EOP/EEP N-Chars needs to be received for a packet to be stored to the DMA channel unless the promiscuous mode is enabled in which case 1 N-Char is enough. If it is an RMAP packet with hardware RMAP enabled 3 N-Chars are needed since the command byte determines where the packet is processed. Packets smaller than these sizes are discarded.

70.6.2 Basic functionality of a channel

Reception is based on descriptors located in a consecutive area in memory that hold pointers to buffers where packets should be stored. When a packet arrives at the core the channel which should receive it is first determined as described in the previous section. A descriptor is then read from the channels' descriptor area and the packet is stored to the memory area pointed to by the descriptor. Lastly, status is stored to the same descriptor and increments the descriptor pointer to the next one. The following sections will describe DMA channel reception in more detail.

70.6.3 Setting up the core for reception

A few registers need to be initialized before reception to a channel can take place. First the link interface need to be put in the run state before any data can be sent. The DMA channel has a maximum length register which sets the maximum packet size in bytes that can be received to this channel. Larger packets are truncated and the excessive part is spilled. If this happens an indication will be given in the status field of the descriptor. The minimum value for the receiver maximum length field is 4 and the value can only be incremented in steps of four bytes up to the maximum value 33554428. If the maximum length is set to zero the receiver will *not* function correctly.

Either the Default address register or the channel specific address register (the accompanying mask register must also be set) needs to be set to hold the address used by the channel. A control bit in the DMA channel control register determines whether the channel should use default address and mask registers for address comparison or the channel's own registers. Using the default register the same address range is accepted as for other channels with default addressing and the RMAP target while the separate address provides the channel its own range. If all channels use the default registers they will accept the same address range and the enabled channel with the lowest number will receive the packet.

Finally, the descriptor table and Control register must be initialized. This will be described in the two following sections.

70.6.4 Setting up the descriptor table address

The core reads descriptors from an area in memory pointed to by the receiver descriptor table address register. The register consists of a base address and a descriptor selector. The base address points to the beginning of the area and must start on an address that is aligned to the size of the descriptor table. The size of the descriptor table can be determined from the formula: STS.NRXD*8. The STS.NRXD field shows the number of entries in the descriptor table, and each descriptor size is 8 bytes.

The descriptor selector points to individual descriptors and is increased by 1 when a descriptor has been used. When the selector reaches the upper limit of the area it wraps to the beginning automatically. It can also be set to wrap at a specific descriptor before the upper limit by setting the wrap bit in the descriptor. The idea is that the selector should be initialized to 0 (start of the descriptor area) but it can also be written with another 8 bytes aligned value to start somewhere in the middle of the area. It will still wrap to the beginning of the area.

If one wants to use a new descriptor table the receiver enable bit has to be cleared first. When the rxactive bit for the channel is cleared it is safe to update the descriptor table register. When this is finished and descriptors are enabled the receiver enable bit can be set again.

70.6.5 Enabling descriptors

As mentioned earlier one or more descriptors must be enabled before reception can take place. Each descriptor is 8 byte in size and the layout can be found in the tables below. The descriptors should be written to the memory area pointed to by the receiver descriptor table address register. When new descriptors are added they must always be placed after the previous one written to the area. Otherwise they will not be noticed.

GRIP
Apr 2024, Version 2024.1

1048

Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

A descriptor is enabled by setting the address pointer to point at a location where data can be stored and then setting the enable bit. The WR bit can be set to cause the selector to be set to zero when reception has finished to this descriptor. IE should be set if an interrupt is wanted when the reception has finished. The DMA control register interrupt enable bit must also be set for an interrupt to be generated.

The descriptor packet address should be word aligned. All accesses on the bus are word accesses so complete words will always be overwritten regardless of whether all 32-bit contain received data. Also if the packet does not end on a word boundary the complete word containing the last data byte will be overwritten. If the *rxunaligned* or *rmap* VHDL generics are set to 1, this restriction is removed and any number of bytes can be received to any packet address without excessive bytes being overwritten.

*Table 1223.*GRSPW2 receive descriptor word 0 (address offset 0x0)

31	30	29	28	27	26	25	24		0
TR	DC	HC	EP	IE	WR	EN		PACKETLENGTH	

31	Truncated (TR) - Packet was truncated due to maximum length violation.
30	Data CRC (DC) - 1 if a CRC error was detected for the data and 0 otherwise. If the Protocol ID of the received package is 0x02 a 1 indicates a CCSDS/CCITT CRC-16 error was detected.
29	Header CRC (HC) - 1 if a CRC error was detected for the header and 0 otherwise. If the Protocol ID of the received package is 0x02 a 1 indicates a 16-bit ISO-Checksum error was detected.
28	EEP termination (EP) - This packet ended with an Error End of Packet character.
27	Interrupt enable (IE) - If set, an interrupt will be generated when a packet has been received if the receive interrupt enable bit in the DMA channel control register is set.
26	Wrap (WR) - If set, the next descriptor used by the GRSPW2 will be the first one in the descriptor table (at the base address). Otherwise the descriptor pointer will be increased with 0x8 to use the descriptor at the next higher memory location. The descriptor table is limited to 1 kbytes in size and the pointer will be automatically wrap back to the base address when it reaches the 1 kbytes boundary.
25	Enable (EN) - Set to one to activate this descriptor. This means that the descriptor contains valid control values and the memory area pointed to by the packet address field can be used to store a packet.
24: 0	Packet length (PACKETLENGTH) - The number of bytes received to this buffer. Only valid after EN has been set to 0 by the GRSPW2.

*Table 1224.*GRSPW2 receive descriptor word 1 (address offset 0x4)

31		0
	PACKETADDRESS	

31: 0	Packet address (PACKETADDRESS) - The address pointing at the buffer which will be used to store the received packet. If the *rxunaligned* and *rmap* VHDL generics are both set to zero only bit 31 to 2 are used.

70.6.6 Setting up the DMA control register

The final step to receive packets is to set the control register in the following steps: The receiver must be enabled by setting the rxen bit in the DMA control register (see section 70.13.7). This can be done anytime and before this bit is set nothing will happen. The rxdescav bit in the DMA control register is then set to indicate that there are new active descriptors. This must always be done after the descriptors have been enabled or the core might not notice the new descriptors. More descriptors can be activated when reception has already started by enabling the descriptors and writing the rxdescav bit. When these bits are set reception will start immediately when data is arriving.

+46 31 7758650 | frontgrade.com/gaisler

70.6.7 The effect to the control bits during reception

When the receiver is disabled all packets going to the DMA-channel are discarded if the packet's address does not fall into the range of another DMA channel. If the receiver is enabled and the address falls into the accepted address range, the next state is entered where the rxdescav bit is checked. This bit indicates whether there are active descriptors or not and should be set by the external application using the DMA channel each time descriptors are enabled as mentioned above. If the rxdescav bit is '0' and the nospill bit is '0' the packets will be discarded. If nospill is '1' the core waits until rxdescav is set and the characters are kept in the N-Char fifo during this time. If the fifo becomes full further N-char transmissions are inhibited by stopping the transmission of FCTs.

When rxdescav is set the next descriptor is read and if enabled the packet is received to the buffer. If the read descriptor is not enabled, rxdescav is set to '0' and the packet is spilled depending on the value of nospill.

The receiver can be disabled at any time and will stop packets from being received to this channel. If a packet is currently received when the receiver is disabled the reception will still be finished. The rxdescav bit can also be cleared at any time. It will not affect any ongoing receptions but no more descriptors will be read until it is set again. Rxdescav is also cleared by the core when it reads a disabled descriptor.

70.6.8 Status bits

When the reception of a packet is finished the enable bit in the current descriptor is set to zero. When enable is zero, the status bits are also valid and the number of received bytes is indicated in the length field. The DMA control register contains a status bit which is set each time a packet has been received. The core can also be made to generate an interrupt for this event.

RMAP CRC logic is included in the implementation if the *rmapcrc* or *rmap* VHDL generics are set to 1. The RMAP CRC calculation is always active for all received packets and all bytes except the EOP/EEP are included. The packet is always assumed to be an RMAP packet and the length of the header is determined by checking byte 3 which should be the command field. The calculated CRC value is then checked when the header has been received (according to the calculated number of bytes) and if it is non-zero the HC bit is set indicating a header CRC error.

The CRC value is not set to zero after the header has been received, instead the calculation continues in the same way until the complete packet has been received. Then if the CRC value is non-zero the DC bit is set indicating a data CRC error. This means that the core can indicate a data CRC error even if the data field was correct when the header CRC was incorrect. However, the data should not be used when the header is corrupt and therefore the DC bit is unimportant in this case. When the header is not corrupted the CRC value will always be zero when the calculation continues with the data field and the behaviour will be as if the CRC calculation was restarted

If the received packet is not of RMAP type the header CRC error indication bit cannot be used. It is still possible to use the DC bit if the complete packet is covered by a CRC calculated using the RMAP CRC definition. This is because the core does not restart the calculation after the header has been received but instead calculates a complete CRC over the packet. Thus any packet format with one CRC at the end of the packet calculated according to RMAP standard can be checked using the DC bit.

CCSDS/CCITT CRC-16 and 16-bit ISO Checksum logic is included in the implementation when the VHDL generct ccsdscrc are set to 1. When a package is received with a protocol ID equal to 0x02 (CCSDS), the core will use the CCSDS CRC/ISO-checksum logic instead of RMAP CRC logic to calculate the CRC. The result is presented by the same status bits as for the RMAP head/data CRC error, but the interpretation of these bits is changed to ISO-checksum/CCSDS CRC error instead.

If the packet is neither of RMAP type nor of the type above with RMAP CRC at the end, then both the HC and DC bits should be ignored.

70.6.9   Error handling

If a packet reception needs to be aborted because of congestion on the network, the suggested solution is to set link disable to '1'. Unfortunately, this will also cause the packet currently being transmitted to be truncated but this is the only safe solution since packet reception is a passive operation depending on the transmitter at the other end. A channel reset bit could be provided but is not a satisfactory solution since the untransmitted characters would still be in the transmitter node. The next character (somewhere in the middle of the packet) would be interpreted as the node address which would probably cause the packet to be discarded but not with 100% certainty. Usually this action is performed when a reception has stuck because of the transmitter not providing more data. The channel reset would not resolve this congestion.

If an AHB error occurs during reception the current packet is spilled up to and including the next EEP/EOP and then the currently active channel is disabled and the receiver enters the idle state. A bit in the channels control/status register is set to indicate this condition.

70.6.10 Promiscuous mode

The core supports a promiscuous mode where all the data received is stored to the first DMA channel enabled regardless of the node address and possible early EOPs/EEPs. This means that all non-EOP/ EEP N-Chars received will be stored to the DMA channel. The rxmaxlength register is still checked and packets exceeding this size will be truncated.

RMAP commands will still be handled by the hardware RMAP target when promiscuous mode is enabled, if the RMAP enable bit in the core's Control register is set. If the RMAP enable bit is cleared, RMAP commands will also be stored to a DMA channel.

70.7   Transmitter DMA channels

The transmitter DMA engine handles transmission of data from the DMA channels to the SpaceWire network. Each receive channel has a corresponding transmit channel which means there can be up to 4 transmit channels. It is however only necessary to use a separate transmit channel for each receive channel if there are also separate entities controlling the transmissions. The use of a single channel with multiple controlling entities would cause them to corrupt each other's transmissions. A single channel is more efficient and should be used when possible.

Multiple transmit channels with pending transmissions are arbitrated in a round-robin fashion.

70.7.1   Basic functionality of a channel

A transmit DMA channel reads data from the AHB bus and stores them in the transmitter FIFO for transmission on the SpaceWire network. Transmission is based on the same type of descriptors as for the receiver and the descriptor table has the same alignment and size restrictions. When there are new descriptors enabled the core reads them and transfer the amount data indicated.

70.7.2   Setting up the core for transmission

Four steps need to be performed before transmissions can be done with the core. First the link interface must be enabled and started by writing the appropriate value to the ctrl register. Then the address to the descriptor table needs to be written to the transmitter descriptor table address register and one or more descriptors must also be enabled in the table. Finally, the txen bit in the DMA control register is written with a one which triggers the transmission. These steps will be covered in more detail in the next sections.

70.7.3   Enabling descriptors

The core reads descriptors from an area in memory pointed to by the transmit descriptor table address register. The register consists of a base address and a descriptor selector. The base address points to

GRIP
Apr 2024, Version 2024.1
1051
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

the beginning of the area and must start on an address that is aligned to the size of the descriptor table. The size of the descriptor table can be determined from the formula: STS.NTXD*16. The STS.NTXD field shows the number of entries in the descriptor table, and each descriptor size is 16 bytes.

To transmit packets one or more descriptors have to be initialized in memory which is done in the following way: The number of bytes to be transmitted and a pointer to the data has to be set. There are two different length and address fields in the transmit descriptors because there are separate pointers for header and data. If a length field is zero the corresponding part of a packet is skipped and if both are zero no packet is sent. The maximum header length is 255 bytes and the maximum data length is 16 Mbyte - 1. When the pointer and length fields have been set the enable bit should be set to enable the descriptor. This must always be done last. The other control bits must also be set before enabling the descriptor.

The transmit descriptors are 16 bytes in size so the maximum number in a single table is 64. The different fields of the descriptor together with the memory offsets are shown in the tables below.

The HC bit should be set if RMAP CRC should be calculated and inserted for the header field and correspondingly the DC bit should be set for the data field. This field is only used by the core when the CRC logic is available (*rmap* or *rmapcrc* VHDL generic set to 1). The header CRC will be calculated from the data fetched from the header pointer and the data CRC is generated from data fetched from the data pointer. The CRCs are appended after the corresponding fields. The NON-CRC bytes field is set to the number of bytes in the beginning of the header field that should not be included in the CRC calculation.

When the CCSDS/CCITT CRC-16 and 16-bit ISO-checksum logic is available (VHDL generic ccsd-scrc set to 1) the core uses the CRC-type filed to determine which CRC logic should be used to calculate the data checksum. When the CCSDS CRC/ISO-checksum logic is not available, the CRC-type field is assumed to be 00 (RMAP CRC).

The CRCs are sent even if the corresponding length is zero, but when both lengths are zero no packet is sent not even an EOP.

70.7.4 Starting transmissions

When the descriptors have been initialized, the transmit enable bit in the DMA control register has to be set to tell the core to start transmitting. New descriptors can be activated in the table on the fly (while transmission is active). Each time a set of descriptors is added the transmit enable bit in the corresponding DMA channel control/status register should be set. This has to be done because each time the core encounters a disabled descriptor this register bit is set to 0.

*Table 1225.*GRSPW2 transmit descriptor word 0 (address offset 0x0)

31	20	19	18	17	16	15	14	13	12	11	8	7	0
RESERVED		CRC-T		DC	HC	LE	IE	WR	EN	NONCRCLEN		HEADERLEN	

31: 20	RESERVED
19: 18	CRC type (CRC-T) - Defines the type of data CRC to use. 00: RMAP CRC 01: CCSDS/CCITT CRC-16 10: 16-bit ISO Checksum (J.G. Fletcher, ISO 8473-1:1998) 11: Reserved
17	Append data CRC (DC) - Append CRC calculated according to the RMAP specification (or CCSDS/CCITT CRC-16 or 16-bit ISO-checksum when available) after the data sent from the data pointer. The CRC covers all the bytes from this pointer. A null CRC will be sent if the length of the data field is zero.
16	Append header CRC (HC) - Append CRC calculated according to the RMAP specification after the data sent from the header pointer. The CRC covers all bytes from this pointer except a number of bytes in the beginning specified by the non-crc bytes field. The CRC will not be sent if the header length field is zero.

*Table 1225.*GRSPW2 transmit descriptor word 0 (address offset 0x0)

15	Link error (LE) - A Link error occurred during the transmission of this packet.
14	Interrupt enable (IE) - If set, an interrupt will be generated when the packet has been transmitted and the transmitter interrupt enable bit in the DMA control register is set.
13	Wrap (WR) - If set, the descriptor pointer will wrap and the next descriptor read will be the first one in the table (at the base address). Otherwise the pointer is increased with 0x10 to use the descriptor at the next higher memory location.
12	Enable (EN) - Enable transmitter descriptor. When all control fields (address, length, wrap and crc) are set, this bit should be set. While the bit is set the descriptor should not be touched since this might corrupt the transmission. The core clears this bit when the transmission has finished.
11: 8	Non-CRC bytes (NONCRCLEN)- Sets the number of bytes in the beginning of the header which should not be included in the CRC calculation. This is necessary when using path addressing since one or more bytes in the beginning of the packet might be discarded before the packet reaches its destination.
7: 0	Header length (HEADERLEN) - Header Length in bytes. If set to zero, the header is skipped.

*Table 1226.*GRSPW2 transmit descriptor word 1 (address offset 0x4)

31	0
HEADERADDRESS	

31: 0	Header address (HEADERADDRESS) - Address from where the packet header is fetched. Does not need to be word aligned.

31	24	23	0
RESERVED		DATALEN	

31: 24	RESERVED
23: 0	Data length (DATALEN) - Length in bytes of data part of packet. If set to zero, no data will be sent. If both data- and header-lengths are set to zero no packet will be sent.

*Table 1228.*GRSPW2 transmit descriptor word 3(address offset 0xC)

31	0
DATAADDRESS	

31: 0	Data address (DATAADDRESS) - Address from where data is read. Does not need to be word aligned.

70.7.5 The transmission process

When the transmitter enable bit in the DMA channel control/status register is set the core starts reading descriptors immediately. The number of bytes indicated are read and transmitted. When a transmission has finished, status will be written to the first field of the descriptor and a packet sent bit is set in the DMA control register. If an interrupt was requested it will also be generated. Then a new descriptor is read and if enabled a new transmission starts, otherwise the transmit enable bit is cleared and nothing will happen until it is enabled again.

70.7.6 The descriptor table address register

The internal pointer which is used to keep the current position in the descriptor table can be read and written through the APB interface. This pointer is set to zero during reset and is incremented each time a descriptor is used. It wraps automatically when the limit for the descriptor table is reached, or it can be set to wrap earlier by setting a bit in the current descriptor.

The descriptor table register can be updated with a new table anytime when no transmission is active. No transmission is active if the transmit enable bit is zero and the complete table has been sent or if

the table is aborted (explained below). If the table is aborted one has to wait until the transmit enable bit is zero before updating the table pointer.

70.7.7 Error handling

Abort Tx

The DMA control register contains a bit called Abort TX which if set causes the current transmission to be aborted, the packet is truncated and an EEP is inserted. This is only useful if the packet needs to be aborted because of congestion on the SpaceWire network. If the congestion is on the AHB bus this will not help (This should not be a problem since AHB slaves should have a maximum of 16 wait-states). The aborted packet will have its LE bit set in the descriptor. The transmit enable register bit is also cleared and no new transmissions will be done until the transmitter is enabled again.

AHB error

When an AHB error is encountered during transmission the currently active DMA channel is disabled and the transmitter goes to the idle mode. A bit in the DMA channel's control/status register is set to indicate this error condition and, if enabled, an interrupt will also be generated. Further error handling depends on what state the transmitter DMA engine was in when the AHB error occurred. If the descriptor was being read the packet transmission had not been started yet and no more actions need to be taken.

If the AHB error occurs during packet transmission the packet is truncated and an EEP is inserted. Lastly, if it occurs when status is written to the descriptor the packet has been successfully transmitted but the descriptor is not written and will continue to be enabled (this also means that no error bits are set in the descriptor for AHB errors).

The client using the channel has to correct the AHB error condition and enable the channel again. No more AHB transfers are done again from the same unit (receiver or transmitter) which was active during the AHB error until the error state is cleared and the unit is enabled again.

Link error

When a link error occurs during the transmission, the remaining part of the packet is discarded up to, and including, the next EOP/EEP. When this is done, status is immediately written back to the descriptor (with the LE bit set) and the descriptor pointer is incremented. The link will be disconnected when the link error occurs but the core will automatically try to connect again, provided that the link-start bit (LS bit in Control register) is asserted, and the link-disabled bit (LD bit in Control register) is deasserted. If the LE bit in the DMA channel's control register is not set the transmitter DMA engine will wait for the link to enter run-state, and start a new transmission immediately when possible, assuming there are packets pending. If the LE bit in the DMA channel's control register is set, the transmitter will be disabled when a link error occurs during a transmission of a packet. In that case, no more packets will be transmitted until the transmitter is enabled again. See description of the DMA channel's control register for more details.

70.8 RMAP

The Remote Memory Access Protocol (RMAP) is used to implement access to resources in the node via the SpaceWire link. Some common operations are reading and writing to memory, registers and FIFOs. The core has an optional hardware RMAP target. Whether or not the RMAP target is implemented is indicated by the CTRL.RA bit. This section describes the basics of the RMAP protocol and the target implementation.

70.8.1 Fundamentals of the protocol

RMAP is a protocol which is designed to provide remote access via a SpaceWire network to memory mapped resources on a SpaceWire node. It has been assigned protocol ID 0x01. It provides three operations: write, read and read-modify-write. These operations are posted operations, which means

GRIP
Apr 2024, Version 2024.1

1054

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

that a source does not wait for an acknowledge or reply. It also implies that any number of operations can be outstanding at any time and that no timeout mechanism is implemented in the protocol. Time-outs must instead be implemented in the user application which sends the commands. Data payloads of up to 2^{24} - 1 bytes is supported by the protocol. A destination can be requested to send replies and to verify data before executing an operation. For a complete description of the protocol, see the RMAP standard (ECSS-E-ST-50-52C).

70.8.2 Implementation

The core includes a target for RMAP commands which processes all incoming packets with protocol ID = 0x01, type field (bit 7 and 6 of the 3rd byte in the packet) equal to 01b and an address falling in the range set by the default address and mask register. When such a packet is detected it is not stored to the DMA channel, instead it is passed to the RMAP receiver.

The core implements all three commands defined in the standard with some restrictions. As explained in 70.2.3, the representation of the data bytes in memory does not change with the endianness of the system. This means that the first byte received is the msb in a word. The target will not receive RMAP packets using the extended protocol ID which are always dumped to the DMA channel.

The RMAP receiver processes commands. If they are correct and accepted the operation is performed on the AHB bus and a reply is formatted. If an acknowledge is requested the RMAP transmitter automatically send the reply. RMAP transmissions have priority over DMA channel transmissions.

There is a user accessible destination key register which is compared to destination key field in incoming packets. If there is a mismatch and a reply has been requested the error code in the reply is set to 3. Replies are sent if and only if the ack field is set to '1'.

When a failure occurs during a bus access the error code is set to 1 (General Error). There is predetermined order in which error-codes are set in the case of multiple errors in the core. It is shown in table 1229.

*Table 1229.*The order of error detection in case of multiple errors. The error detected first has number 1.

Detection Order	Error Code	Error
1	12	Invalid destination logical address
2	2	Unused RMAP packet type or command code
3	3	Invalid destination key
4	9	Verify buffer overrun
5	11	RMW data length error
6	10	Authorization failure
7*	1	General Error (AHB errors during non-verified writes)
8	5/7	Early EOP / EEP (if early)
9	4	Invalid Data CRC
10	1	General Error (AHB errors during verified writes or RMW)
11	7	EEP
12	6	Cargo Too Large
*The AHB error is not guaranteed to be detected before Early EOP/EEP or Invalid Data CRC. For very long accesses the AHB error detection might be delayed causing the other two errors to appear first.		

Read accesses are performed on the fly, that is they are not stored in a temporary buffer before transmitting. This means that the error code 1 will never be seen in a read reply since the header has already been sent when the data is read. If the AHB error occurs the packet will be truncated and ended with an EEP.

Errors up to and including Invalid Data CRC (number 9) are checked before verified commands. The other errors do not prevent verified operations from being performed.

GRIP
Apr 2024, Version 2024.1

1055

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The details of the support for the different commands are now presented. All defined commands which are received but have an option set which is not supported in this specific implementation will not be executed and a possible reply is sent with error code 10.

70.8.3 Write commands

The write commands are divided into two subcategories when examining their capabilities: verified writes and non-verified writes. Verified writes have a length restriction of 4 bytes and the address must be aligned to the size. That is 1 byte writes can be done to any address, 2 bytes must be halfword aligned, 3 bytes are not allowed and 4 bytes writes must be word aligned. Since there will always be only one AHB operation performed for each RMAP verified write command the incrementing address bit can be set to any value.

Non-verified writes have no restrictions when the incrementing bit is set to 1. If it is set to 0 the number of bytes must be a multiple of 4 and the address word aligned. There is no guarantee how many words will be written when early EOP/EEP is detected for non-verified writes.

70.8.4 Read commands

Read commands are performed on the fly when the reply is sent. Thus if an AHB error occurs the packet will be truncated and ended with an EEP. There are no restrictions for incrementing reads but non-incrementing reads have the same alignment restrictions as non-verified writes. Note that the "Authorization failure" error code will be sent in the reply if a violation was detected even if the length field was zero. Also note that no data is sent in the reply if an error was detected i.e. if the status field is non-zero.

70.8.5 RMW commands

All read-modify-write sizes are supported except 6 which would have caused 3 B being read and written on the bus. The RMW bus accesses have the same restrictions as the verified writes. As in the verified write case, the incrementing bit can be set to any value since only one AHB bus operation will be performed for each RMW command. Cargo too large is detected after the bus accesses so this error will not prevent the operation from being performed. No data is sent in a reply if an error is detected i.e. the status field is non-zero.

70.8.6 Control

The RMAP target mostly runs in the background without any external intervention, but there are a few control possibilities.

There is an enable bit in the control register of the core which can be used to completely disable the RMAP target. When it is set to '0' no RMAP packets will be handled in hardware, instead they are all stored to the DMA channel.

There is a possibility that RMAP commands will not be performed in the order they arrive. This can happen if a read arrives before one or more writes. Since the target stores replies in a buffer with more than one entry several commands can be processed even if no replies are sent. Data for read replies is read when the reply is sent and thus writes coming after the read might have been performed already if there was congestion in the transmitter. To avoid this the RMAP buffer disable bit can be set to force the target to only use one buffer which prevents this situation.

The last control option for the target is the possibility to set the destination key which is found in a separate register.

Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Command	Action
Reserved	Command / Response	Write / Read	Verify data before write	Acknow-ledge	Increment Address		
0	0	-	-	-	-	Response	Stored to DMA-channel.
0	1	0	0	0	0	Not used	Does nothing. No reply is sent.
0	1	0	0	0	1	Not used	Does nothing. No reply is sent.
0	1	0	0	1	0	Read single address	Executed normally. Address has to be word aligned and data size a multiple of four. Reply is sent. If alignment restrictions are violated error code is set to 10.
0	1	0	0	1	1	Read incre-menting address.	Executed normally. No restrictions. Reply is sent.
0	1	0	1	0	0	Not used	Does nothing. No reply is sent.
0	1	0	1	0	1	Not used	Does nothing. No reply is sent.
0	1	0	1	1	0	Not used	Does nothing. Reply is sent with error code 2.
0	1	0	1	1	1	Read-Mod-ify-Write incrementing address	Executed normally. If length is not one of the allowed rmw values nothing is done and error code is set to 11. If the length was correct, alignment restrictions are checked next. 1 byte can be rmw to any address. 2 bytes must be halfword aligned. 3 bytes are not allowed. 4 bytes must be word aligned. If these restrictions are violated nothing is done and error code is set to 10. If an AHB error occurs error code is set to 1. Reply is sent.
0	1	1	0	0	0	Write, sin-gle-address, do not verify before writ-ing, no acknowledge	Executed normally. Address has to be word aligned and data size a multiple of four. If alignment is violated nothing is done. No reply is sent.
0	1	1	0	0	1	Write, incre-menting address, do not verify before writ-ing, no acknowledge	Executed normally. No restrictions. No reply is sent.
0	1	1	0	1	0	Write, sin-gle-address, do not verify before writ-ing, send acknowledge	Executed normally. Address has to be word aligned and data size a multiple of four. If alignment is violated nothing is done and error code is set to 10. If an AHB error occurs error code is set to 1. Reply is sent.

1	1	-	-	-	-	Unused	Stored to DMA-channel.

70.9 AMBA interface

The AMBA interface consists of an APB interface, an AHB master interface and DMA FIFOs. The APB interface provides access to the user registers which are described in section 70.13. The DMA engines have 32-bit wide FIFOs to the AHB master interface which are used when reading and writing to the bus.

The transmitter DMA engine reads data from the bus in bursts which are half the FIFO size in length. A burst is always started when the FIFO is half-empty or if it can hold the last data for the packet. The burst containing the last data might have shorter length if the packet is not an even number of bursts in size.

GRIP

Apr 2024, Version 2024.1

1058

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The receiver DMA works in the same way except that it checks if the FIFO is half-full and then performs a burst write to the bus which is half the fifo size in length. The last burst might be shorter. If the *rmap* or *rxunaligned* VHDL generics are set to 1 the interface also handles byte accesses. Byte accesses are used for non word-aligned buffers and/or packet lengths that are not a multiple of four bytes. There might be 1 to 3 single byte writes when writing the beginning and end of the received packets.

70.9.1 APB slave interface

As mentioned above, the APB interface provides access to the user registers which are 32-bits in width. The accesses to this interface are required to be aligned word accesses. The result is undefined if this restriction is violated.

70.9.2 AHB master interface

The core contains a single master interface which is used by both the transmitter and receiver DMA engines. The arbitration algorithm between the channels is done so that if the current owner requests the interface again it will always acquire it. This will not lead to starvation problems since the DMA engines always deassert their requests between accesses.

The AHB accesses are always word accesses (HSIZE = 0x010) of type incremental burst with unspecified length (HBURST = 0x001) if the RMAP target is not implemented (RA bit in Control register = 0) and unaligned transfers are not supported (RX bit in the Control register = 0). If either the RMAP target is implemented, or unaligned transfers are supported, then AHB accesses can be of size byte, halfword and word (HSIZE = 0x000, 0x001, 0x010) otherwise. Byte and halfword accesses are always NONSEQ. Note that read accesses are always word accesses (HSIZE = 0x010), which can result in destructive read.

The burst length will be half the AHB FIFO size except for the last transfer for a packet which might be smaller. Shorter accesses are also done during descriptor reads and status writes.

The AHB master also supports non-incrementing accesses where the address will be constant for several consecutive accesses. HTRANS will always be NONSEQ in this case while for incrementing accesses it is set to SEQ after the first access. This feature is included to support non-incrementing reads and writes for RMAP.

If the core does not need the bus after a burst has finished there will be one wasted cycle (HTRANS = IDLE).

BUSY transfer types are never requested and the core provides full support for ERROR, RETRY and SPLIT responses.

70.10 SpaceWire Plug-and-Play

The core supports parts of the SpaceWire Plug-and-Play protocol. The supported fields are listed in table 1233, and explained in more detail in tables 1234 through 1248. Table 1233 also shows which type of SpaceWire Plug-and-Play access type (read, write, compare-and-swap) that is allowed for the field. Note that two different amount of SpaceWire Plug-and-Play support may be included. Either only device identification through the Device Information fields is supported, or device configuration through the SpaceWire Protocol fields is supported as well. The amount of support is indicated by the CTRL.PNPA field. Note also that the CTRL.PE must be set in order to enable the SpaceWire Plug-and-Play support.

The SpaceWire Plug-and-Play protocol uses standard RMAP commands and replies with the same requirements as presented in section 70.8, but with the following differences:

• Protocol Identifier field of a command shall be set to 0x03.

• A command's address fields shall contain a word address. The SpaceWire Plug-and-Play addresses are encoded as shown in table 1231.

GRIP
Apr 2024, Version 2024.1
1059
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- The increment bit in the command's instruction field shall be set to 1, otherwise a reply with Status field set to 0x0A (authorization failure) is sent.

- RMAP read-modify-write command is replaced by a compare-and-swap command. The command's data fields shall contain the new data to be written, while the mask fields shall contain the value that the current data must match in order for the new data to be written. If there is a mismatch, a reply with Status field set to 0x0A (authorization failure) is sent.

- The reply packet's Status field can contain the additional status codes described in table 1232.

Table 1231. SpaceWire Plug-and-Play address encoding

31 24	23 19	18 14	13 0
Application Index	Protocol Index	FieldSet ID	Field ID

Table 1232. SpaceWire Plug-and-Play status codes

Value	Description
0xF0	Unauthorized access - A write, or compare-and-swap command, with an address other then the Device ID field's address, arrived when the core was not configured (Device ID field = 0), or the command did not match the owner information saved in the Link Information field and Owner Address fields.
0xF1	Reserved field set - A read, write, or compare-and-swap command's address field points to a non existing field set. [1]
0xF2	Read-only field - A write, or compare-and-swap command's address points to a read-only field.
0xF3	Compare-and-swap-only-field - A write command's address points to a field that is only writable through a compare-and-swap-only.
Note 1: An access to a non existing field, within a existing field set, does not generate an error response. The data returned in a read access is zero, while a write access has no effect.

70.11 Implementation

70.11.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package
(see GRLIB User's Manual).

There are five input resets, in order to cover every clock domain: AMBA reset (rst), transmitter syn-
chronous reset (txsyncrst), receiver synchronous reset for port 0 (rxsyncrst0), receiver synchronous
reset for port 1 (rxsyncrst1) and a receiver asynchronous reset shared by both ports (rxasyncrst).

Additionally, the core outputs two internal resets: the register reset, swno.ctrlregrst (bit 6 of the Con-
trol Register. See 70.13.1), and the internal reset for synchronization between transmitter and receiv-
ers, swno.rxrst.

The core does not implement any kind of internal reset generation or synchronization, the input resets
are completely independent. The reset generation shall be done in a higher instance, taking into
account the clock domains and also the output resets of the core. A description of how the resets shall
be combined and generated can be found below. Frontgrade Gaisler recommends following these
guidelines unless indicated otherwise.

- The AMBA reset is the combination of the external reset and the output register reset negated (swno.ctrlregrst), as it is active high. Then, the reset is synchronized with the AMBA clock by using a reset generator. Its output is the AMBA reset, rst.

- The transmitter reset is the combination of the external reset and the output register reset negated (swno.ctrlregrst), as it is active high. Then, the reset is synchronized with the transmitter clock by using a reset generator. Its output is the transmitter reset, txsyncrst.

- The asynchronous reset for both receiver channels is simply the output synchronization reset, swno.rxrst, connected directly to the input rxasyncrst.

- The synchronous reset for each receiver channel is the output receiver reset, swno.rxrst, synchronized with the appropriate clock domain by using a reset generator. Its output is the synchronous reset for the specific receiver port, rxsyncrst0 or rxsyncrst1.

In order to avoid the process of generating all these resets, GRLIB includes a wrapper called grspwm which instantiates either GRSPW or GRSPW2. If the latter is chosen, there is a generic to directly implement the previous reset generators in the wrapper itself, so the top entity does not need to generate the resets anymore. Further information about the proper way of combining the reset signals or using the wrapper can be found in 70.20, including an example for both possibilities.

Note that the IP may generate local asynchronous reset nets, depending on the configuration of two generics:

- If the receiver uses SDR sampling (input_type = 2) or DDR sampling (input_type = 3 or 4) and the same clock is used for TX and RX (rxtx_sameclk = 1), then the IP will not contain internal asynchronous resets.

- In any other case, i.e. different clock for TX and RX or any other receiver type (XOR, external CCC), the IP will contain internal asynchronous resets.

70.11.2 Clock-generation

The receiver module found in figure 179 should be clocked with the RXCLKO output from the GRSPW2_PHY module. See the example instantiation in this section and the GRSPW2_PHY section of the GRLIB IP Core User's Manual for more information on how to connect this clock.

The transmitter clock is generated from the TXCLK input. A separate clock input is used to allow the transmitter to be run at much higher frequencies than the system clock. The SpaceWire node contains a clock-divider which divides the TXCLK signal to the wanted frequency. The transmitter clock should be 10 MHz during initialization and any frequency above 2 MHz in the run-state.

There is an input signal called CLKDIV10 which sets the reset values for the user accessible clock divisor registers. There is one register value which is used during initialisation and one which is used in run-state. See 70.3.6 for details on how to set the clock divisor values.

Since only integer values are allowed for the clock division and the required init-frequency is 10 MHz the frequency of the TXCLK input must be a multiple of 10 MHz. The clock divisor value is 8-bits wide so the maximum TXCLK frequency supported is 2.56 GHz (note that there is also a restriction on the relation between the system and transmit clock frequencies).

70.11.3 Timers

There are two timers in the core: one for generating the 6.4/12.8 µs periods and one for disconnect timing.

The timeout periods are generated from the TX clock whose frequency must be at least 10 MHz to guarantee disconnect timing limits. The same clock divisor is used as for the TX clock during initialisation so it must be set correctly for the link timing to work.

+46 31 7758650 | frontgrade.com/gaisler

70.11.4 Synchronization

The transmitter and receiver bit rates can be eight times higher than the system clock frequency. This includes a large margin for clock skew and jitter so it might be possible to run at even higher rate differences. Note also that the receiver clocks data at both negative and positive edges for the input modes 0 and 1 so the bitrate is twice the clock frequency. There is no direct relationship between bitrate and frequency for the sampling modes.

The clock synchronization is just one limiting factor for the clock frequency, it might for example not be possible to achieve the highest possible frequency for certain technologies.

The asynchronous reset to the receiver clock domain has to have a maximum delay of one receiver clock cycle to ensure correct operation. This is needed because the receiver uses a completely asynchronous reset. To make sure that nothing bad happens there is a synchronous reset guard which prevents any signals from being assigned before all registers have their reset signals released.

In the sampling modes this asynchronous reset can be removed if both the receiver and transmitter runs on the same clock. The core is configured to use the same receiver and transmitter clock by setting the *rxtx_sameclk* generic to 1.

70.11.5 Fault-tolerance

The core can optionally be implemented with fault-tolerance against SEU errors in the FIFO memories. The fault-tolerance is enabled through the *ft* VHDL generic. Possible options are byte parity protection (*ft = 1*) or TMR registers (*ft = 2*).

70.11.6 Synthesis

The fact there are three clock domains in the core of which all are possibly high frequency clocks makes it necessary to declare all paths between the clock domains as false paths. In Synplify this is most easily done by declaring all the clocks to be in different clockgroups in the sdc file (if Synplify does not automatically put them in different groups). This will disable any timing considerations between the clock domains and these constraints will also propagate to the place and route tool.

70.11.7 Technology mapping

The core has three generics for technology mapping: *tech*, *techfifo* and *memtech*. *Tech* selects the technology used for the clock buffers and also adds reset to some registers for technologies where they would otherwise cause problems with gate-level simulations. *Techfifo* selects whether *memtech* should be used to select the technology for the FIFO memories (the RMAP buffer is not affected by the this generic) or if they should be inferred. *Tech* and *memtech* can be set to any value from 0 to NTECH as defined in the GRLIB.TECH package.

70.11.8 RAM usage

The core maps all RAM memories on the syncram_2p component if the *ft* generic is 0 and to the syncram_2pft component for other values. The syncrams are located in the technology mapping library (TECHMAP). The organization of the different memories are described below. If techfifo and/or memtech is set to 0 the synthesis tool will infer the memories. Either RAM blocks or flip-flops will be used depending on the tool and technology. The number of flip-flops used is *syncram depth x syncram width* for all the different memories. The receiver AHB FIFO with fifosize 32 will for example use 1024 flips-flops.

8	256x8

70.11.9 Endianness

The core automatically changes its endianness behavior depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for both big-endian and little-endian systems.

70.12 AXI support

The core is designed for an AMBA system but can be adapted for AXI using the AHBM2AXI adapter.

70.13 Registers

The core is programmed through registers mapped into APB address space. The registers are listed in table, 1261 and described in detail in the subsequent tables. Addresses not listed in table 1261 are reserved. A read access to a reserved register, or reserved field with a register, will always return zero, and a write access has no effect. The register layout used is exemplified in table 1258, and the values used in the reset value row and field type row are explained in tables 1259 and 1260.

Table 1258. <APB ddress offset> - <Register acronym> - <Register name>

31 24	23 16	15 8	7 0
EF3	EF2	EF1	EF0
<Reset value for EF3>	<Reset value for EF2>	<Reset value for EF1>	<Reset value for EF0>
<Bit-field type for EF3>	<Bit-field type for EF2>	<Bit-field type for EF1>	<Bit-field type for EF0>

31: 24	Example bit-field 3 (EF3) - <Bit-field description>
23: 16	Example bit-field 2 (EF2) - <Bit-field description>
15: 8	Example bit-field 1 (EF1) - <Bit-field description>
7: 0	Example bit-field 0 (EF0) - <Bit-field description>

Table 1259. Reset value definitions

Value	Description
0	Reset value 0. Used for single-bit fields.
1	Reset value 1. Used for single-bit fields.
0xNN	Hexadecimal representation of reset value. Used for multi-bit fields.
n/r	Field not reseted
*	Special reset condition, described in textual description of the bit-field. Used for example when reset value is taken from an input signal.

Table 1260. Bit-field type definitions

Value	Description
r	Read-only. Writes have no effect.
rw	Readable and writable.
rw*	Readable and writeable. Special condition for write, described in textual description of the bit-field.
wc	Write-clear. Readable, and cleared when written with a 1. Writing 0 has no effect.

*	*	*	*		*	*	*	0	0	0	*	*		0	*	*	0	0	0	0	0	0	0	0	0	0	0	0	*	0	0
r	r	r	r		r	r	r	r	rw	rw	rw	r		rw	rw	rw	r	rw	rw	rw	rw	rw	rw	r	rw	rw	rw	rw	rw	rw	rw

31   RMAP available (RA) - Set to one if the RMAP target is available. Value determined by the *rmap* VHDL generic.

30   RX unaligned access (RX) - Set to one if unaligned writes are available for the receiver. Value determined by the *rxunaligned* VHDL generic.

29   RMAP CRC available (RC) - Set to one if RMAP CRC is enabled in the core. Value determined by the *rmapcrc* VHDL generic.

28: 27   Number of DMA channels (NCH) - The number of available DMA channels minus one (Number of channels = NCH+1). Value determined by the *dmachan* VHDL generic.

26   Number of ports (PO) - The number of available SpaceWire ports minus one. Value determined by the *ports* VHDL generic.

25   CCSDS/CCITT CRC-16 and 16-bit ISO-checksum available (CC) - Set to one if this crc logic is enabled in the core. Value determined by the ccsdscrc VHDL generic.

24   Interrupt distribution available (ID) - Set to 1 if interrupt distribution support is available, otherwise set to 0. If set to 1, then the INTCTRL.NUMINT field indicates the number of supported interrupt numbers. Value determined by the *interruptdist* VHDL generic (ID = 1 if *interruptdist* /= 0).

23   RESERVED

22   Loop-back enable (LE). The value of this bit is driven on the LOOPBACK output signal.

21   Port select (PS) - Selects the active port when the CTRL.NP bit is zero. '0' selects the port connected to data and strobe on index 0, while '1' selects index data and strobe on 1. Only available in two-port configurations, which is indicated by CTRL.PO bit. This bit is reserved in one-port-configurations.

20   No port force (NP) - Disable port force. When this bit is set, the CTRL.PS bit cannot be used to select the active port. Instead, the active port is automatically selected by checking the activity on the respective receive links. Only available in two-port configurations, which is indicated by CTRL.PO bit. Reserved bit in one-port configurations. Reset value is set from input signal RMAPEN if RMAP target is available (indicated by CTRL.RA bit), otherwise the reset value is '0'.

19: 18   SpaceWire Plug-and-Play available (PNPA) - Indicates SpaceWire Plug-and-Play support. 0 = No support, 1 = Support for the device identification, 2 = Support for device identification and configuration. See section 70.10 for details. Value determined by the *pnp* VHDL generic.

17   RMAP buffer disable (RD) - If set, only one RMAP buffer is used. This ensures that all RMAP commands will be executed consecutively. Only available if the *rmap* VHDL generic is set to 1, otherwise the bit is reserved.

16   RMAP Enable (RE) - Enable RMAP target. Only available if *rmap* VHDL generic is set to 1, otherwise the bit is reserved. Reset value take from RMAPEN input signal.

15   SpaceWire Plug-and-Play enable (PE) - Enable SpaceWire Plug-and-Play support. Only available if the CTRL.PA bit is 1, otherwise this bit is reserved. Reset value taken from the PNPEN input signal.

14   RESERVED

13   Transmitter enable lock control (TL) - Enables / disables the transmitter enable lock functionality described by the DMACTRL.TL bit. 0 = Disabled, 1 = Enabled.

12   Time-code control flag filter (TF) - When set to 1, a received time-code must have its control flag bits set to "00" to be considered valid. When set to 0, all control flag bits are allowed. Note that if the interrupt code receive enable bit (INTCFG.IR) is set to 1, then the only time-code control flag bits of "00" are allowed, regardless of the setting of this bit.

11   Time Rx Enable (TR) - Enable time-code reception.

10   Time Tx Enable (TT) - Enable time-code transmission.

9   Link error IRQ (LI) - Enables / disables AMBA interrupt generation when a link error occurs. Note that the CTRL.IE bit also must be set for this bit to have any effect.

8   Tick-out IRQ (TQ) - Enables / disables AMBA interrupt generation when a valid time-code is received. Note that the CTRL.IE bit also must be set for this bit to have any effect.

7   RESERVED

*Table 1268.*0x20, 0x40, 0x60, 0x80 - DMACTRL - DMA control/status

31		26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
INTNUM			RES		EP	TR	IE	IT	RP	TP	TL	LE	SP	SA	EN	NS	RD	RX	AT	RA	TA	PR	PS	AI	RI	TI	RE	TE
*			0		0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
rw			r		wc	wc	rw	rw	wc	wc	wc	rw	rw	rw	rw	rw	rw	r	rw	wc	wc	wc	rw	rw	rw	rw	rw

31: 26   Interrupt-number (INTNUM) - The interrupt-number used for this DMA channel when sending an interrupt-code that was generated due to any of the events maskable by the DMACTRL.IE and DMACTRL.IT bits. Reset value is taken from the IRQTXDEFAULT input signal. Field is only present if interrupt distribution is supported, which is indicated by the CTRL.ID bit. Note that this field must be set to a value within the range defined by the INCTRL.NUMINT and INTCTRL.BASEINT fields. A value outside the range will result in no interrupt-code being sent. This field is only available when distributed interrupt is implemented.

25: 24   RESERVED

23   EEP termination (EP) - Set to 1 when a received packet for the corresponding DMA channel ended with an Error End of Packet (EEP) character.

22   Truncated (TR) - Set to 1 when a received packet for the corresponding DMA channel is truncated due to a maximum length violation.

21   Interrupt-code transmit enable on EEP (IE) - When set to 1, and the interrupt-code transmit enable bit (INTCTRL.IT) is set, an interrupt-code is generated when a received packet on this DMA channel ended with an Error End of Packet (EEP) character. Field is only present if interrupt distribution is supported, which is indicated by the CTRL.ID bit. This field is only available when distributed interrupt is implemented.

20   Interrupt-code transmit enable on truncation (IT) - When set to 1, and the interrupt-code transmit enable (INTCTRL.IT) bit in the Interrupt distribution control register is set, an interrupt-code is generated when a received packet on this DMA channel is truncated due to a maximum length violation. Field is only present if interrupt distribution is supported, which is indicated by the CTRL.ID bit. This field is only available when distributed interrupt is implemented.

19   Receive packet IRQ (RP) - This bit is set to 1 when an AMBA interrupt was generated due to the fact that a packet was received for the corresponding DMA channel.

18   Transmit packet IRQ (TP) - This bit is set to 1 when an AMBA interrupt was generated due to the fact that a packet was transmitted for the corresponding DMA channel.

17   Transmitter enable lock (TL) - This bit is set to 1 if the CTRL.TL bit is set, and the transmitter for the corresponding DMA channel is disabled due to a link error (controlled by the DMACTRL.LE bit). While this bit is set, it is not possible to re-enable the transmitter (e.g. not possible to set the DMACTRL.TE bit to 1).

16   Link error disable (LE) - Disable transmitter when a link error occurs. No more packets will be transmitted until the transmitter is enabled again.

15   Strip pid (SP) - Remove the pid byte (second byte) of each packet. The address byte (first byte) will also be removed when this bit is set, independent of the value of the DMACTRL.SA bit.

14   Strip addr (SA) - Remove the addr byte (first byte) of each packet.

13   Enable addr (EN) - Enable separate node address for this channel.

12   No spill (NS) - If cleared, packets will be discarded when a packet is arriving and there are no active descriptors. If set, the core will wait for a descriptor to be activated.

11   Rx descriptors available (RD) - Set to one, to indicate to the core that there are enabled descriptors in the descriptor table. Cleared by the core when it encounters a disabled descriptor.

10   RX active (RX) - Is set to '1' if a reception to the DMA channel is currently active, otherwise it is '0'.

9   Abort TX (AT) - Set to one to abort the currently transmitting packet and disable transmissions. If no packet is currently being transmitted, the only effect is to disable transmissions. Self clearing.

+46 31 7758650 | frontgrade.com/gaisler

*Table 1268.*0x20, 0x40, 0x60, 0x80 - DMACTRL - DMA control/status

8	RX AHB error (RA) - An error response was detected on the AHB bus while this receive DMA channel was accessing the bus.
7	TX AHB error (TA) - An error response was detected on the AHB bus while this transmit DMA channel was accessing the bus.
6	Packet received (PR) - This bit is set each time a packet has been received.
5	Packet sent (PS) - This bit is set each time a packet has been sent.
4	AHB error interrupt (AI) - If set, an interrupt will be generated each time an AHB error occurs when this DMA channel is accessing the bus.
3	Receive interrupt (RI) - If set, an interrupt will be generated when a packet is received, if the interrupt enable (IE) bit in the corresponding receive descriptor is set as well. This happens both if the packet is terminated by an EEP or EOP.
2	Transmit interrupt (TI) - If set, an interrupt will be generated when a packet is transmitted, if the interrupt enable (IE) bit in the corresponding transmit descriptor is set as well. The interrupt is generated regardless of whether the transmission was successful or not.
1	Receiver enable (RE) - Set to one when packets are allowed to be received to this channel.
0	Transmitter enable (TE) - Enables the transmitter for the corresponding DMA channel. Setting this bit to 1 will cause the DMA channel to read a new descriptor and try to transmit the packet it points to. Note that it is only possible to set this bit to 1 if the TL bit is 0. This bit is automatically cleared when the DMA channel encounters a descriptor which is disabled, or if a link error occurs during the transmission of a packet, and the LE bit is set.

rw		rw	rw	rw	r	rw	rw	rw	r	rw	rw	rw	r		wc	rw	rw	

31: 26	Interrupt number (INTNUM) - The interrupt-number used when sending an interrupt-code that was generated due to any of the events maskable by the RS, ER or IA bits. Reset value is taken from the IRQTXDEFAULT input signal. Note that this field must be set to a value within the range defined by the NUMINT and BASEINT fields. A value outside the range will result in no interrupt-code being sent.
25	Interrupt-code transmit on run-state entry (RS) - If set to 1, and interrupt-code with the interrupt number specified in the INTNUM field is sent each time the link interface enters run-state.
24	Interrupt-code transmit on early EOP/EEP (EE) - If set to 1, an interrupt-code with the interrupt number specified in the INTNUM field is sent each time an event occurs such that the STS.EE bit is set to 1 (even if the bit was already set when the event occurrepriod).
23	Interrupt-code transmit on invalid address (IA) - If set to 1, an interrupt-code with the interrupt number specified in the INTNUM field is sent each time an event occurs such that the STS.IA bit is set to 1 (even if the bit was already set when the event occurred).
22: 21	RESERVED
20	Interrupt-code timeout IRQ enable (TQ) - When set to 1, an AMBA interrupt is generated when a bit in the INTTO register is set. Note that the IE bit in the Control register also must be set for this bit to have any effect. Bit is only available if support for the Interrupt distribution ISR timer is implemented.
19	Interrupt-code-acknowledge receive IRQ enable (AQ) - When set to 1, an AMBA interrupt is generated when an interrupt-acknowledge-code is received for which the corresponding bit in the Interrupt tick-out mask register is set, and the core was the source of the matching interrupt-code. Note that the IE bit in the Control register also must be set for this bit to have any effect.
18	Interrupt-code receive IRQ enable (IQ) - When set to 1, an AMBA interrupt is generated when an interrupt-code is received for which the corresponding bit in the Interrupt tick-out mask register is set to 1. Note that the IE bit in the Control register also must be set for this bit to have any effect.
17: 16	RESERVED
15	Handle all interrupt acknowledgement codes (AA) - Is set to 0, only those received interrupt acknowledgement codes that match an interrupt code sent by software are handled. If set to 1, all received interrupt acknowledgement codes are handled.
14	Interrupt acknowledgement / extended interrupt tickout enable (AT) - When set to 1, the internal tickout signal is set when an interrupt acknowledgement code or extended interrupt code is received such that a bit in the AUTOACK / INTRXEXT register is set to 1 (even if the bit was already set when the code was received).

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 1273.*0xA0 - INTCTRL - Interrupt distribution control

13	Interrupt tickout enable (IT) - When set to 1, the internal tickout signal is set when an interrupt code is received such that a bit in the INTRX register is set to 1 (even if the bit was already set when the code was received).
12: 8	RESERVED
7	Interrupt-code discarded (ID) - This bit is set to 1 when and interrupt-code that software tried to send by writing the II bit was discarded, either because there already was a pending request to send an interrupt-code with the same interrupt-number, or because the corresponding ISR bit is 1. There is a one clock cycle delay between the II bit being written and this bit being set.
6	Interrupt-code tick-in (II) - When this field is written to 1 the interrupt- / interrupt-acknowledge-code specified in the TXINT field will be sent. The actual sending of the interrupt- / interrupt-acknowledge-code might be delayed, depending on the value for the corresponding ISR bit and INT/ACK-timer. Note that the interrupt-code transmit enable bit (IT) must be set to '1', otherwise writing this bit has no effect. This bit is automatically cleared and always reads '0'. Writing a '0' has no effect.
5: 0	Transmit interrupt- / interrupt-code (TXINT) - The interrupt- / interrupt-acknowledge-code that the core will send when the Interrupt-code tick-in bit (II) is written with 1. Reset value for bit 5 is '0', while bits 4:0 are set from the input signal IRQTXDEFAULT. Note that bits 4:0 of this field must be set to a value within the range defined by the NUMINT and BASEINT fields. A value outside the range will result in no interrupt-code being sent.

70.13.13 Interrupt Receive

*Table 1274.*0xA4 - INTRX - Interrupt-code receive

31					0
		RXIRQ			
		0x00000000			
		wc			

31: 0   Received interrupt-code (RXIRQ) - Each bit corresponds to the interrupt number with the same number as the bit index. The core sets a bit to 1 when it receives an interrupt-code for which the corresponding bit in the Interrupt tick out mask register is set to 1. Note that the number of implemented bits depends on the number of supported interrupts (INTCTRL.NUMINT field).

70.13.14 Interrupt-acknowledge-code Receive

*Table 1275.*0xA8 - ACKRX / INTRXEXT - Interrupt-acknowledge-code receive / Interrupt receive extended

31					0
		RXACK / INTRXEXT			
		0x00000000			
		wc			

31: 0   Received interrupt-acknowledge-code (RXACK) / Interrupt receive extended (INTRXEXT) - Each bit corresponds to the interrupt number with the same number as the bit index. The core sets a bit to 1 when it receives a interrupt-acknowledge-code for which the corresponding bit in the Interrupt tick out mask register is set, and for which the matching interrupt-code was sent by software (valid for interrupt-acknowledge). Note that the number of implemented bits depends on the number of supported interrupts (INTCTRL.NUMINT field). When extended interrupt mode is enabled this register is an extension of the Interrupt Receive register for interrupt 32-63.

70.13.15 Interrupt Timeout

*Table 1276.*0xAC - INTTO - Interrupt timeout

31					0
		INTTO			
		0x00000000			
		wc			

31: 0   Interrupt-code timeout (INTTO) - Each bit corresponds to the interrupt number with the same number as the bit index. The core sets a bit to 1 when an interrupt-code that was sent by software doesn't receive an interrupt-acknowledge-code for the duration of a timeout period (specified in the Interrupt distribution ISR timer reload registers), and if the corresponding bit in the Interrupt-code tick out mask register is set. Note that the number of implemented bits depends on the number of supported interrupts (INTCTRL.NUMINT field).

70.13.16 Interrupt Timeout Extended

*Table 1277.*0xB0 - INTTOEXT - Interrupt timeout extended

31					0
		INTTOEXT			
		0x00000000			
		wc			

31: 0   Interrupt timeout extended (INTTOEXT) - When extended interrupt mode is enabled, each bit corresponds to the interrupt number between 32 and 63. The core sets a bit to 1 when an interrupt-code that was sent by software and the time specified in the Interrupt distribution ISR timer reload registers has past and if the corresponding bit in the Interrupt-code tick out mask register is set. Note that the number of implemented bits depends on the number of supported interrupts (INTC-TRL.NUMINT field).

70.13.17 Interrupt Tick-out Mask

*Table 1278.*0xB4 - TICKMASK - Interrupt tick-out mask

31	0
MASK	
0x00000000	
rw*	

31: 0	Interrupt tick-out mask (MASK) - Each bit corresponds to the interrupt number with the same value as the bit index. If a bit is set, the TICKOUT signal as well as the corresponding bit in the Interrupt-code receive register, Interrupt-acknowledge-code receive register, and Interrupt-code timeout register is set when respective event occurs. Note that the number of implemented bits depends on the number of supported interrupts (INTCTRL.NUMINT field).

70.13.18 Interrupt-code Auto Acknowledge Mask

*Table 1279.*0xB8 - AUTOACK / TICKMASKEXT - Interrupt-code auto acknowledge mask / Interrupt tick-out mask extended.

31	0
AAMASK	
0x00000000	
rw*	

31: 0	Auto acknowledge mask (AAMASK) - For each bit set to 1, the core will automatically send an interrupt-acknowledge-code when it receives an interrupt-code with the corresponding interrupt number. If the interrupt distribution timers are implemented (VHDL generic intiatimerbits /= 0) and enabled, then the core will reload the INT-to-ACK timer and wait until it expires before the interrupt-acknowledge-code is sent. Note that the number of implemented bits depends on the number of supported interrupts (INTCFG.NUMINT field). When extended interrupt mode is enabled this register is an extension of the Interrupt Tick-out Mask register.

70.13.19 Interrupt Distribution Configuration

*Table 1280.*0xBC - INTCFG - Interrupt distribution configuration

31 26	25 20	19 14	13 8	7 4	3	2	1	0
INTNUM3	INTNUM2	INTNUM1	INTNUM0	NUMINT	PR	IR	IT	EE
*	*	*	*	0	0	0	0	0
rw	rw	rw	rw	r	rw	rw	rw	rw

31: 26	Interrupt number 3 (INTNUM3) - Defines the interrupt number to support when the device supports fewer than 32 interrupts.
25: 20	Interrupt number 2 (INTNUM2) - Defines the interrupt number to support when the device supports fewer than 32 interrupts.
19: 14	Interrupt number 1 (INTNUM1) - Defines the interrupt number to support when the device supports fewer than 32 interrupts.
13: 8	Interrupt number 0 (INTNUM0) - Defines the interrupt number to support when the device supports fewer than 32 interrupts.
7: 4	Number of interrupts (NUMINT) - Indicates the number of supported interrupts according to the formula: *Number of interrupts = 2^{NUMINT}*.
3	Interrupt- / interrupt-acknowledge-code priority (PR) - When set to 0, interrupt-codes have priority over interrupt-acknowledge-codes when there are multiple codes waiting to be sent. When set to 1, interrupt-acknowledge-codes have priority.
2	Interrupt receive enable (IR) - Enable interrupt- / interrupt-acknowledge-code reception.
1	Interrupt transmit enable (IT) - Enable interrupt- / interrupt-acknowledge-code transmission. Must be set to 1 in order for any interrupt- / interrupt-acknowledge-codes to be sent.
0	Enable external interrupt (EE) - Enable the external interrupt mode, which enable the core to use and interpret the interrupt-acknowledge-code as interrupt 32-63.

70.13.20 Interrupt Distribution ISR

Table 1281.0xC4 - ISR - Interrupt distribution ISR

31	0
ISR	
0x00000000	
wc	

31: 0   Interrupt distribution ISR (ISR) - Each bit index holds the ISR bit value for the corresponding interrupt number. A bit value of 1 indicates that a interrupt-code with the corresponding interrupt number has been received, and that it has not yet been acknowledged (and not yet timed-out). A bit value of 0 indicates that either no interrupt-code with that interrupt number has been received, or that the interrupt has been acknowledged (or timed out). This register is write-clear, but should normally only be used for diagnostics and/or FDIR. Note that the number of implemented bits depends on the number of supported interrupts (INTCTRL.NUMINT field).

70.13.21 Interrupt Distribution ISR Extended

Table 1282.0xC8 - ISREXT - Interrupt distribution ISR extended

31	0
ISR	
0x00000000	
wc	

31: 0   Interrupt distribution ISR (ISR) - Each bit index holds the ISR bit value for the corresponding interrupt number. A bit value of 1 indicates that a interrupt-code with the corresponding interrupt number has been received, and that it has not yet been acknowledged (and not yet timed-out). A bit value of 0 indicates that either no interrupt-code with that interrupt number has been received, or that the interrupt has been acknowledged (or timed out). This register is write-clear, but should normally only be used for diagnostics and/or FDIR. Note that the number of implemented bits depends on the number of supported interrupts (INTCTRL.NUMINT field).

70.13.22 Interrupt Distribution Prescaler Reload

Table 1283.0xD0 - PRESCALER - Interrupt distribution prescaler reload

31	30	0
R	RL	
0	*	
r	rw	

31   RESERVED

30: 0   Prescaler reload (RL) - Reload value for the interrupt distribution prescaler. The prescaler runs on the system clock, and an internal tick is generated every RL+1 cycle. The number of bits implemented for this field is set by the VHDL generic *intscalerbits*, and might be lower than the 31 depicted here. Any unimplemented bits are reserved. Reset value set from the input signal INTPRELOAD.

70.13.23 Interrupt Distribution ISR Timer Reload

*Table 1284.*0xD4 - ISRTIMER - Interrupt distribution ISR timer reload

31	30	0
EN	RL	
1	*	
rw	rw	

31	Timer enable (EN) - Enables the use of ISR timer for each ISR bit. One global timer enable bit used for all ISR bits. If this bit is set to 1, the timer for each ISR bit is reloaded with the value in the RL field when the ISR bit is set. If the timer expires before an interrupt-code-acknowledge has been received, then ISR bit is cleared.
30: 0	Timer reload (RL) - Common reload value for the interrupt distribution ISR timers. The number of bits implemented for this field is set by the VHDL generic *intisrtimerbits*, and might be lower than the 31 depicted here. Any unimplemented bits are reserved. Reset value set from the input signal INTTRELOAD.

70.13.24 Interrupt Distribution INT/ACK Timer Reload

*Table 1285.*0xD8 - IATIMER - Interrupt distribution INT / ACK timer reload

31	30	0
EN	RL	
1	*	
rw	rw	

31	Timer enable (EN) - Enables the use of timers to control the time between an interrupt-code and an interrupt-acknowledge-code, and vice versa. One global timer enable bit is used for all ISR bits. If this bit is set to 1, the timer for each ISR bit is reloaded with the value in the RL field each time an interrupt-code is received. The core will then wait until the timer expires before an interrupt-code-acknowledge with the same interrupt number is sent. The same applies when an interrupt-code-acknowledge is received and a new interrupt-code with the same number should be sent.
30: 0	Timer reload (RL) - The number of bits implemented for this field is set by the VHDL generic *intia-timerbits*, and might be lower than the 31 depicted here. Any unimplemented bits are reserved. Reset value set from the input signal INTIARELOAD.

70.13.25 Interrupt Distribution Change Timer Reload

*Table 1286.*0xDC - ICTIMER - Interrupt distribution change timer reload

31	30	0
EN	RL	
1	*	
rw	rw	

31	Timer enable (EN) - Enables the use of timers to control the time that must pass between two changes in value for the same ISR bit. One global timer enable bit is used for all ISR bits. If this bit is set to 1, the timer for each ISR bit is reloaded with the value in the RL field each time the ISR bit changes value. All potential interrupt- / interrupt-acknowledge-codes received before the timer expires is discarded.
30: 0	Timer reload (RL) - The number of bits implemented for this field is set by the VHDL generic *intc-timerbits*, and might be lower than the 31 depicted here. Any unimplemented bits are reserved. Reset value set from the input signal INTCRELOAD.

70.15 Configuration options

Table 1295 shows the configuration options of the core (VHDL generics).

*Table 1295.*Configuration options

Generic	Function	Allowed values	Default
tech	Selects technology for transmitter DDR registers (if out-put_type=1) and enables a reset of additional registers for ASIC technologies.	0 - NTECH	inferred
hindex	AHB master index.	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar.	0 - 16#FFF#	0
pmask	Mask field of the APB bar.	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by GRSPW2.	0 - NAHBIRQ-1	0
rmap	Include hardware RMAP target. RMAP CRC logic will also be added. If set to 2 the core will only implement the RMAP target, provide a limited APB interface, enable time code reception and its interrupt.	0 - 2	0
rmapcrc	Enable RMAP CRC logic.	0 - 1	0
ccsdscrc	Enables CCSDS/CCITT CRC-16 and 16-bit ISO-check-sum (J.G. Fletcher, ISO 8473-1:1998) logic. For the core to calculate CRC rmap or rmapcrc also need to be set to 1.	0 - 1	0
fifosize1	Sets the number of entries in the 32-bit receiver and trans-mitter AHB fifos.	4 - 64	32
fifosize2	Sets the number of entries in the 9-bit receiver fifo (N-Char fifo).	16 - 64	64
rxunaligned	Receiver unaligned write support. If set, the receiver can write any number of bytes to any start address without writing any excessive bytes.	0 - 1	0
rmapbufs	Sets the number of buffers to hold RMAP replies.	2 - 8	4
ft	Enable fault-tolerance against SEU errors. The core can optionally be implemented with fault-tolerance against SEU errors in the FIFO memories. The fault-tolerance is enabled through the ft VHDL generic to 1, 2, 4 or 5. Possible options are byte parity protection (ft = 1), TMR regis-ters (ft = 2), SECDED BCH (ft = 4) or technology specific protection (ft = 5).	0 - 2, 4-5	0
scantest	Enables scantest support	0 - 1	0
techfifo	Enables technology specific RAM blocks selected with memtech. When disabled the memtech generic will have no effect.	0 - 1	1
ports	Sets the number of ports	1 - 2	1
dmachan	Sets the number of DMA channels	1 - 4	1
memtech	Selects technology for RAM blocks.	0 - NTECH	DEFMEMTECH
input_type	Select receiver type. 0 = Self clocking (xor), 1 = Interface for Frontgrade UT200SpWPHY01 SpaceWire transceiver, 2 = Single data rate sampling, 3 and 4 = Double data rate sampling, 5 = Self-clocking with external recovery, 6 = Self-clocking with external recovery and DDR register for data.. This generic must be set to the same value as the GRSPW2_PHY generic with the same name.	0 - 6	0

*Table 1295.*Configuration options

Generic	Function	Allowed values	Default
output_type	Select transmitter type. 0 = Single data rate, 1 = Double data rate, 2 = Interface for Frontgrade UT200SpWPHY01 SpaceWire transceiver.	0 - 2	0
rxtx_sameclk	Set to one if the same clock net is connected to both the receiver and transmitter (which means this feature is only applicable when the receiver uses SDR or DDR sampling). This will remove some unnecessary synchronization registers as well as local asynchronous reset nets.	0 - 1	0
netlist	Select pre-synthesized netlist instead of synthesizing from source. When enabled the specific netlist is selected with the tech generic.	0 - 1	0
nodeaddr	When set to 0 - 254: Generic specifies the reset value for the node address (DEFADDR.DEFADDR field). When set to 255: Reset value for the node address is taken from the RMAPNODEADDR input signal.	0 - 255	254
destkey	Sets the reset value for the core's destination key.	0 - 255	0
interruptdist	Enables interrupt distribution support and sets the number of supported interrupts.	0, 1, 2, 4, 8, 16, 32	0
intscalerbits	Sets the number of bits for the interrupt distribution prescaler. 0 = No Interrupt distribution prescaler implemented.	0 - 31	0
intisrtimerbits	Sets the number of bits for the Interrupt distribution ISR timers. 0 = No Interrupt distribution ISR timer implemented.	0 - 31	0
intiatimerbits	Sets the number of bits for the Interrupt distribution INT / ACK timers. 0 = No Interrupt distribution INT / ACK timers implemented.	0 - 31	0
intctimerbits	Sets the number of bits for the Interrupt distribution change timers. 0 = No Interrupt distribution change timers implemented.	0 - 31	0
tickinasync	Determines whether the TICKIN, TICKINRAW, and TIMEIN signals are synchrnous or asynchronous to CLK. 0 = synchronous, 1 = asynchronous	0 - 1	0
pnp	Enabled / disables support for SpaceWire Plug-and-Play	0 - 1	0
pnpvendid	Specifies the SpaceWire Plug-and-Play Device Vendor ID	0 - 16#FFFF#	0
pnpprodid	Specifies the SpaceWire Plug-and-Play Device Product ID	0 - 16#FFFF#	0
pnpmajorver	Specifies the device's SpaceWire Plug-and-Play Major Version	0 - 16#FFFF#	0
pnpminorver	Specifies the device's SpaceWire Plug-and-Play Minor Version	0 - 16#FFFF#	0
pnppatch	Specifies the device's SpaceWire Plug-and-Play Patch/Build Number	0 - 16#FFFF#	0
num_txdesc	Specifies the number of entries in the transmit descriptor table	64, 128, 256, 512	64
num_rxdesc	Specifies the number of entries in the receive descriptor table	128, 256, 512, 1024	128
rstsrctmr	Enables the Triple Module Redundancy for the asynchronous reset nets of the core	0 - 1	0

70.16 Signal descriptions

Table 1296 shows the interface signals of the core (VHDL ports).

Table 1296. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
RXASYNCRST	N/A	Input	Asynchronous reset for ports 0 and 1 of the receiver	Low
RXSYNCRST0	N/A	Input	Synchronous reset for port 0 of the receiver	Low
RXCLK0	N/A	Input	Receiver clock for port 0	-
RXSYNCRST1	N/A	Input	Synchronous reset for port 1 of the receiver	Low
RXCLK1	N/A	Input	Receiver clock for port 1. Unused in one-port configurations.	-
TXSYNCRST	N/A	Input	Synchronous reset for the transmitter	Low
TXCLK	N/A	Input	Transmitter default run-state clock	-
TXCLKN	N/A	Input	Transmitter inverted default run-state clock. Only used in DDR transmitter mode for technologies not supporting local generation of inverted clock.	-
AHBMI	*	Input	AMB master input signals	-
AHBMO	*	Output	AHB master output signals	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
SWNI	D[3:0]	Input	Data input. D[1:0] correspond to port 0, D[3:2] correspond to port 1. In a one-port configuration D[3:2] are unused. Connect to the DO[1:0] output of one GRSP-W2_PHY per implemented port.	-
	DV[3:0]	Input	Data valid input corresponding to SWNI.D[3:0]. Bits 3:2 are unused in one-port configurations. Connect to the DOV[1:0] output of one GRSP-W2_PHY per implemented port.	-
	DCONNECT[3:0]	Input	Disconnect. Bits 3:2 are unused in one-port configurations.	
	DCONNECT2[3:0]	Input	Disconnect. Bits 3:2 are unused in one-port configurations. This is a copy of DCONNECT, as part of the triplication of the combinational logic related to asynchronous reset nets.	
	DCONNECT3[3:0]	Input	Disconnect. Bits 3:2 are unused in one-port configurations. This is a copy of DCONNECT, as part of the triplication of the combinational logic related to asynchronous reset nets.	
	TICKIN	Input	Time counter tick input. Increments internal time-counter and transmits the new value.	High
	TICKINRAW	Input	Raw tick input. Send time-code or interrupt- / interrupt-acknowledge-code from TIMEIN signal. TICKINRAW must be deasserted the same clock cycle as the output signal TICKINDONE is asserted.	High
	TIMEIN[7:0]	Input	The time-code or interrupt- / interrupt-acknowledge-code sent when TICKINRAW is asserted.

Table 1296. Signal descriptions

Signal name	Field	Type	Function	Active
SWNI	CLKDIV10[7:0]	Input	Reset value for the Clock divisor register.	-
	RMAPEN	Input	Reset value for the CTRL.RE bit (RMAP enable bit in the Control register).	-
	RMAPNODEADDR[7:0]	Input	Reset value for the node address (DEFADDR.DEFADDR field) when the *nodeaddr* VHDL generic = 255. Unused if *nodeaddr* /= 255.	-
	INTPRELOAD[30:0]	Input	Reset value for the Interrupt distribution prescaler reload register	-
	INTTRELOAD[30:0]	Input	Reset value for the Interrupt distribution ISR timer reload register	-
	INTIARELOAD[30:0]	Input	Reset value the Interrupt distribution INT / ACK timer reload register	-
	INTCRELOAD[30:0]	Input	Reset value the Interrupt distribution change timer reload register	-
	IRQTXDEFAULT[5:0]	Input	Reset value for the differemt transmit interrupt numbers for the interrupt distribution	-
	PNPEN	Input	Reset value for the SpaceWire Plug-and-Play enable bit (CTRL.PE)	-
	PNPUVENDID	Input	Reset value for the SpaceWire Plug-and-Play Unit Vendor ID (PNPUVEND.VEND field)	-
	PNPUPRODID	Input	Reset value for the SpaceWire Plug-and-Play Unit Product ID (PNPUVEND.PROD field)	-
	PNPUSN	Input	Reset value for the SpaceWire Plug-and-Play Unit Serial Number (PNPUSN register)	-

Table 1296. Signal descriptions

Signal name	Field	Type	Function	Active
SWNO	D[3:0]	Output	Data output. The meaning of this signal changes depending on the value of the *output_type* generic. For *output_type*=0 and *output_type*=1, D[0] is the data output for port 0, and D[1] is the data output for port 1 while D[3:2] are unused. For *output_type*=2 (SpaceWire transceiver), D[1:0] is the data output for port 0, and D[3:2] is the data output for port 1.	-
	S[3:0]	Output	Strobe output. The meaning of the bits in this signal depends on the *output_type* generic in the same way as SWNO.D[3:0] described above.	-
	TICKOUT	Output	Tick-out signal that is asserted when a valid time-code or interrupt- / interrupt-acknowledge-code has been received.	High
	TICKOUTRAW	Output	Tick-out that is always asserted when a time-code or interrupt- / interrupt-acknowledge-code is received.	High
	TIMEOUT[7:0]	Output	Contains the received time-code or interrupt- / interrupt-acknowledge-code when TICK-OUTRAW is asserted.	
	TICKINDONE	Output	Asserted when a time-code or interupt- / interrupt-acknowledge-code sent via the TICKIN-RAW signal has been accepted for transmission. TICKINRAW must be deasserted the same clock cycle as TICKINDONE is asserted.	High
	RXDAV	Output	Asserted for one CLK cycle when a character has been received on the SpaceWire link.	High
	RXDATAOUT[8:0]	Output	When RXDAV is asserted, these signals contain the received character.	
	LINKDIS	Output	Asserted when the link is disabled	High
	LOOPBACK	Output	Reflects the value of the loopback bit in the Control register. Can be used to control on-chip loopback for test purposes.	High
	RXRST	Output	Internal reset generated by the transmitter for synchronization purpose between transmitter and both receiver channels. It shall be used to generate the asynchronous and synchronous receiver resets.	Low
	CTRLREGRST	Output	Register reset. It corresponds to the bit 6 of the Control Register (see 70.13.1). It shall be used negated (it is active high) to generate the AMBA and transmitter resets.	High
	RMAPACT	Output	RMAP command processing active.	High

70.19 Library dependencies

Table 1300 shows libraries used when instantiating the core (VHDL libraries).

Table 1300. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions
GAISLER	SPACEWIRE	Signals, component	Component and record declarations.

70.20 Instantiation

This example shows how the core can be instantiated.

Normally di, si, do and so should be connected to input and output pads configured with LVDS drivers. How this is done is technology dependent.

The core in the example is configured with non-ft memories of size 32, 32 and 4 entries for AHB FIFOs, N-Char FIFO and RMAP buffers respectively.

The memory technology is inferred which means that the synthesis tool will select the appropriate components.

The hardware RMAP target is enabled which also automatically enables rxunaligned and rmapcrc.

The core can be instantiated directly (grspw2) or using a wrapper (grspwm). In the first case, the top level instance is in charge of generating the resets appropriately, whereas the wrapper may include the reset generation and synchronization if the generic internalrstgen is set to 1 (default value).

    spw_txs_pad : outpad_ds generic map (padtech, lvds, x25v)
      port map (spw_txsp, spw_txsn, swno.s(0), gnd(0));
    ...
```

Example using the wrapper and the internal reset generators enabled. Replace the reset generators and the GRSPW2 core with the following wrapper:

```
sw0 : grspwm
generic map(
    tech           => fabtech,
    hindex         => CFG_NCPU+CFG_AHB_UART+CFG_AHB_JTAG+CFG_GRETH+i,
    pindex         => 13+i,
    paddr          => 13+i,
    pirq           => 8+i,
    sysfreq        => CPU_FREQ,
    nsync          => 1,
    rmap           => CFG_SPW_RMAP,
    rmapcrc        => CFG_SPW_RMAPCRC,
    fifosize1      => CFG_SPW_AHBFIFO,
    fifosize2      => CFG_SPW_RXFIFO,
    rxclkbuftype   => 1,
    memtech        => memtech,
    rmapbufs       => CFG_SPW_RMAPBUF,
    ft             => CFG_SPW_FT,
    ports          => CFG_SPW_PORTS,
    dmachan        => CFG_SPW_DMACHAN,
    netlist        => CFG_SPW_NETLIST,
    spwcore        => 2, -- GRSPW2 is instantiated
    input_type     => CFG_SPW_INPUT,
    output_type    => CFG_SPW_OUTPUT,
    rxtx_sameclk   => CFG_SPW_RTSAME,
    rxunaligned    => CFG_SPW_RXUNAL,
    internalrstgen => 1) -- The wrapper will instantiate internally the reset generators
port map( rst => rstn, clk => clkm, rxasyncrst => gnd,
        rxsyncrst0 => gnd, rxclk0 => spw_rxclk0,
        rxsyncrst1 => gnd, rxclk1 => spw_rxclk1,
        txsyncrst => gnd, txclk => spw_txclk, txclkn => spw_txclk,
        ahbmi => ahbmi, ahbmo => ahbmo(CFG_NCPU+CFG_AHB_UART+CFG_AHB_JTAG+CFG_GRETH+i),
        apbi => apbi, apbo => apbo(13),
        swni => spwi, swno => spwo);
```

It is important to note that the input resets are tied to GND in the second example, as these signals are internally generated in the wrapper and therefore nor generated neither used in the top level entity.

70.21 Constraints

This section contains example constraints for GRSPW2.

0. Define a clock called 'spw_clk'
1. spw_peri = SpaceWire Maximum clock frequency
2. tech_lib_setup = Setup timing for FlipFlop used in technology
3. tech_lib_hold = Hold timing for FlipFlop used in technology

```
### SpaceWire (LVDS)
set spw_rx_rise_max  [expr $spw_peri / 2 - $tech_lib_setup]
set spw_rx_rise_min  [expr $tech_lib_hold ]
set spw_rx_fall_max  [expr $spw_peri / 2 - $tech_lib_setup]
set spw_rx_fall_min  [expr $tech_lib_hold ]

set spw_tx_max [expr      $tech_lib_setup ]
set spw_tx_min [expr -1 * $tech_lib_hold  ]
```

}
```

70.22 API

A simple Application Programming Interface (API) is provided together with the GRSPW2. The API is located in $(GRLIB)/software/spw. The files are rmapapi.c, spwapi.c, rmapapi.h, spwapi.h. The spwapi.h file contains the declarations of the functions used for configuring the GRSPW2 and transferring data. The corresponding definitions are located in spwapi.c. The rmapapi is structured in the same manner and contains a function for building RMAP packets.

These functions could be used as a simple starting point for developing drivers for the GRSPW2. The different functions are described in this section.

70.22.1 GRSPW2 Basic API

The basic GRSPW2 API is based on a struct spwvars which stores all the information for a single GRSPW2 core. The information includes its address on the AMBA bus as well as SpaceWire parameters such as node address and clock divisor. A pointer to this struct is used as a input parameter to all the functions. If several cores are used, a separate struct for each core is created and used when the specific core is accessed.

GRIP
Apr 2024, Version 2024.1

*Table 1301.*The spwvars struct

Field	Description	Allowed range
regs	Pointer to the GRSPW2	-
nospill	The nospill value used for the core.	0 - 1
rmap	Indicates whether the core is configured with RMAP. Set by spw_init.	0 - 1
rxunaligned	Indicates whether the core is configured with rxunaligned support. Set by spw_init.	0 - 1
rmapcrc	Indicates whether the core is configured with RMAPCRC support. Set by spw_init.	0 - 1
clkdiv	The clock divisor value used for the core.	0 - 255
nodeaddr	The node address value used for the core.	0 - 255
destkey	The destination key value used for the core.	0 - 255
rxmaxlen	The Receiver maximum length value used for the core.	0 - 33554431
rxpnt	Pointer to the next receiver descriptor.	0 - 127
rxchkpnt	Pointer to the next receiver descriptor that will be polled.	0 - 127
txpnt	Pointer to the next transmitter descriptor.	0 - 63
txchkpnt	Pointer to the next transmitter descriptor that will be polled.	0 - 63
timetxen	The timetxen value used for this core.	0 - 1
timerxen	The timerxen value used for this core.	0 - 1
txd	Pointer to the transmitter descriptor table.	-
rxd	Pointer to the receiver descriptor table	-

The following functions are available in the basic API:

```
int spw_setparam(int nodeaddr, int clkdiv, int destkey, int nospill, int timetxen, int
timerxen, int rxmaxlen, int spwadr, struct spwvars *spw);
```

Used for setting the different parameters in the spwvars struct. Should always be run first after creating a spwvars struct. This function only initializes the struct. Does not write anything to the Space-Wire core.

*Table 1302.*Return values for spw_setparam

Value	Description
0	The function completed successfully
1	One or more of the parameters had an illegal value

GRIP

Apr 2024, Version 2024.1

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 1303.*Parameters for spw_setparam

Parameter	Description	Allowed range
nodeaddr	Sets the node address value of the struct spw passed to the function.	0-255
clkdiv	Sets the clock divisor value of the struct spw passed to the function.	0-255
destkey	Sets the destination key of the struct spw passed to the function.	0-255
nospill	Sets the nospill value of the struct spw passed to the function.	0 - 1
timetxen	Sets the timetxen value of the struct spw passed to the function.	0 - 1
timerxen	Sets the timerxen value of the struct spw passed to the function.	0 - 1
rxmaxlen	Sets the receiver maximum length field of the struct spw passed to the function.	$0 - 2^{25}$-1
spwadr	Sets the address to the GRSPW2 core which will be associated with the struct passed to the function.	$0 - 2^{32}$-1

```
int spw_init(struct spwvars *spw);
```

Initializes the GRSPW2 core located at the address set in the struct spw. Sets the following registers: node address, destination key, clock divisor, receiver maximum length, transmitter descriptor table address, receiver descriptor table address, ctrl and dmactrl. All bits are set to the values found in the spwvars struct. If a register bit is not present in the struct it will be set to zero. The descriptor tables are allocated to an aligned area using malloc. The status register is cleared and lastly the link interface is enabled. The run state frequency will be set according to the value in clkdiv.

*Table 1304.*Return values for spw_init

Value	Description
0	The function completed successfully
1	One or more of the parameters could not be set correctly or the link failed to initialize.

*Table 1305.*Parameters for spw_init

Parameter	Description	Allowed range
spw	The spwvars struct associated with the GRSPW2 core that should be initialized.	-

```
int set_txdesc(int pnt, struct spwvars *spw);
```

Sets a new address to the transmitter descriptor table address register. Should only be used when no transmission is active. Also resets the pointers for spw_tx and spw_checktx (Explained in the section for those functions).

*Table 1306.*Return values for spw_txdesc

Value	Description
0	The function completed successfully
1	The new address could not be written correctly

Parameter	Description	Allowed range
pnt	The new address to the descriptor table area	$0 - 2^{32}-1$
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be configured	-

```
int set_rxdesc(int pnt, struct spwvars *spw);
```

Sets a new address to the Receiver descriptor table address register. Should only be used when no transmission is active. Also resets the pointers for spw_rx and spw_checkrx (Explained in the section for those functions).

*Table 1308.*Return values for spw_rxdesc

Value	Description
0	The function completed successfully
1	The new address could not be written correctly

*Table 1309.*Parameters for spw_rxdesc

Parameter	Description	Allowed range
pnt	The new address to the descriptor table area	$0 - 2^{32}-1$
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be configured	-

```
void spw_disable(struct spwvars *spw);
```

Disables the GRSPW2 core (the link disable bit is set to '1').

*Table 1310.*Parameters for spw_disable

Parameter	Description	Allowed range
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be configured	-

```
void spw_enable(struct spwvars *spw);
```

Enables the GRSPW2 core (the link disable bit is set to '0').

```

Stops the GRSPW2 core (the link start bit is set to '0').

*Table 1313.*Parameters for spw_start

Parameter	Description	Allowed range
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be configured	-

```
int spw_setclockdiv(struct spwvars *spw);
```

Sets the clock divisor register with the clock divisor value stored in the spwvars struct.

*Table 1314.*Return values for spw_setclockdiv

Value	Description
0	The function completed successfully
1	The new clock divisor value is illegal.

*Table 1315.*Parameters for spw_setclockdiv

Parameter	Description	Allowed range
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be configured	-

```
int spw_set_nodeadr(struct spwvars *spw);
```

Sets the node address register with the node address value stored in the spwvars struct.

*Table 1316.*Return values for spw_set_nodeadr

Value	Description
0	The function completed successfully
1	The new node address value is illegal.

*Table 1317.*Parameters for spw_set_nodeadr

Parameter	Description	Allowed range
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be configured	-

```
int spw_set_rxmaxlength(struct spwvars *spw);
```

Sets the Receiver maximum length register with the rxmaxlen value stored in the spwvars struct.

*Table 1318.*Return values for spw_set_rxmaxlength

Value	Description
0	The function completed successfully
1	The new node address value is illegal.

*Table 1319.*Parameters for spw_set_rxmaxlength

Parameter	Description	Allowed range
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be configured	-

```
int spw_tx(int crc, int skipcrcsize, int hsize, char *hbuf, int dsize, char *dbuf, struct
spwvars *spw);
```

Transmits a packet. Separate header and data buffers can be used. If CRC logic is available the GSPW inserts RMAP CRC values after the header and data fields if crc is set to one. This function only sets a descriptor and initiates the transmission. Spw_checktx must be used to check if the packet has been transmitted. A pointer into the descriptor table is stored in the spwvars struct to keep track of the next location to use. It is incremented each time the function returns 0.

*Table 1320.*Return values for spw_tx

Value	Description
0	The function completed successfully
1	There are no free transmit descriptors currently available
2	There was illegal parameters passed to the function

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 1321.*Parameters for spw_tx

Parameter	Description	Allowed range
crc	Set to one to append RMAP CRC after the header and data fields. Only available if hardware CRC is available in the core.	0 - 1
skipcrcsize	The number of bytes in the beginning of a packet that should not be included in the CRC calculation	0 - 15
hsize	The size of the header in bytes	0 - 255
hbuf	Pointer to the header data	-
dsize	The size of the data field in bytes	$0 - 2^{24}-1$
dbuf	Pointer to the data area.	-
spw	Pointer to the spwvars struct associated with GRSPW2 core that should transmit the packet	-

```
int spw_rx(char *buf, struct spwvars *spw);
```

Enables a descriptor for reception. The packet will be stored to buf. Spw_checkrx must be used to check if a packet has been received. A pointer in the spwvars struct is used to keep track of the next location to use in the descriptor table. It is incremented each time the function returns 0.

*Table 1322.*Return values for spw_rx

Value	Description
0	The function completed successfully
1	There are no free receive descriptors currently available

*Table 1323.*Parameters for spw_rx

Parameter	Description	Allowed range
buf	Pointer to the data area.	-
spw	Pointer to the spwvars struct associated with GRSPW2 core that should receive the packet	-

```
int spw_checkrx(int *size, struct rxstatus *rxs, struct spwvars *spw);
```

Checks if a packet has been received. When a packet has been received the size in bytes will be stored in the size parameter and status is found in the rxs struct. A pointer in the spwvars struct is used to keep track of the location in the descriptor table to poll. It is incremented each time the function returns nonzero.

*Table 1324.*Return values for spw_checkrx

Value	Description
0	No packet has been received
1	A packet has been received

*Table 1325.*Parameters for spw_checkrx

Parameter	Description	Allowed range
size	When the function returns 1 this variable holds the number of bytes received	-
rxs	When the function returns 1 this variable holds status information	-
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be polled	-

```

Disables hardware RMAP. Has no effect if the RMAP command handler is not available in GRSPW2

*Table 1336.*Parameters for spw_rmapdis

Parameter	Description	Allowed range
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be set	-

```
int spw_setdestkey(struct spwvars *spw);
```

Set the destination key of the GRSPW2. Has no effect if the RMAP command handler is not available. The value from the spwvars struct is used.

*Table 1337.*Return values for spw_setdestkey

Value	Description
0	The function completed successfully
1	The destination key parameter in the spwvars struct contains an illegal value

Table 1338. Parameters for spw_setdestkey

Parameter	Description	Allowed range
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be set.	-

70.22.2 GRSPW2 RMAP API

The RMAP API contains only one function which is used for building RMAP headers.

```
int build_rmap_hdr(struct rmap_pkt *pkt, char *hdr, int *size);
```

Builds an RMAP header to the buffer pointed to by hdr. The header data is taken from the rmap_pkt struct.

Table 1339. Return values for build_rmap_hdr

Value	Description
0	The function completed successfully
1	One or more of the parameters contained illegal values

Table 1340. Parameters for build_rmap_hdr

Parameter	Description	Allowed range
pkt	Pointer to an rmap_pkt struct which contains the data from which the header should be built	
hdr	Pointer to the buffer where the header will be built	
spw	Pointer to the spwvars struct associated with GRSPW2 core that should be set	-

71   GRSPW2_GEN - GRSPW2 wrapper with Std_Logic interface

71.1   Overview

The GRSPW2_GEN wrapper provides an interface to the GRSPW2 core only using Std_Logic signals instead of GRLIB records. The GRLIB AMBA plug and play extensions have also been removed. This document describes the signal interface and how they map to the signal names in GRLIB. For a user manual on the core function please refer to the GRSPW2 section. An example instantiation of the core can be found at the end of this document.

71.2 Signal descriptions

Table 1296 shows the interface signals of the core (VHDL ports).

Table 1342. Signal descriptions

Signal name	Type	Function	Active	GRLIB signal name
RST	Input	Reset	Low	RST
CLK	Input	System (AMBA) Clock.	-	CLK
RXASYNCRST	Input	Receiver asynchronous reset for both ports 0 and 1	Low	RXASYNCRST
RXSYNCRST0	Input	Receiver synchronous reset for port 0	Low	RXSYNCRST0
RXCLK0	Input	Receiver clock for port 0.	-	RXCLK0
RXSYNCRST1	Input	Receiver synchronous reset for port 1	Low	RXSYNCRST1
RXCLK1	Input	Receiver clock for port 1. Unused if the VHDL generic ports is 2.	-	RXCLK1
TXSYNCRST	Input	Transmitter synchronous reset	Low	TXSYNCRST
TXCLK	Input	Transmitter clock	-	TXCLK
TXCLKN	Input	Transmitter inverted clock. Only used in DDR transmitter mode for technologies not supporting local generation of inverted clock.	-	TXCLKN
HGRANT	Input	See AMBA manual.	-	AHBMI.HGRANT
HREADY	Input	See AMBA manual.	-	AHBMI.HREADY
HRESP[1:0]	Input	See AMBA manual.	-	AHBMI.HRESP
HRDATA[31:0]	Input	See AMBA manual.	-	AHBMI.HRDATA
ENDIAN	Input	Sideband signal selecting the endianness of the host system	-	AHBMI.ENDIAN
HBUSREQ	Output	See AMBA manual.	-	AHBMO.HBUSREQ
HLOCK	Output	See AMBA manual.	-	AHBMO.HLOCK
HTRANS[1:0]	Output	See AMBA manual.	-	AHBMO.HTRANS
HADDR[31:0]	Output	See AMBA manual.	-	AHBMO.HADDR
HWRITE	Output	See AMBA manual.	-	AHBMO.HWRITE
HSIZE[2:0]	Output	See AMBA manual.	-	AHBMO.HSIZE
HBURST[2:0]	Output	See AMBA manual.	-	AHBMO.HBURST
HPROT[3:0]	Output	See AMBA manual.	-	AHBMO.HPROT
HWDATA[31:0]	Output	See AMBA manual.	-	AHBMO.HWDATA

Table 1342. Signal descriptions

Signal name	Type	Function	Active	GRLIB signal name
PSEL	Input	See AMBA manual.	-	APBI.PSEL
PENABLE	Input	See AMBA manual.	-	APBI.PENABLE
PADDR[31:0]	Input	See AMBA manual.	-	APBI.PADDR
PWRITE	Input	See AMBA manual.	-	APBI.PWRITE
PWDATA[31:0]	Input	See AMBA manual.	-	APBI.PWDATA
PRDATA[31:0]	Output	See AMBA manual.	-	APBO.PRDATA
D[3:0]	Input	SpaceWire Data input	-	SWNI.D
DV[3:0]	Input	SpaceWire Data valid.	High	SWNI.DV
DCONNECT[3:0]	Input	SpaceWire Disconnect.	-	SWNI.DCONNECT
DCONNECT2[3:0]	Input	SpaceWire Disconnect. Copy of DCONNECT (triplication of the asynchronous resets logic)	-	SWNI.DCONNECT2
DCONNECT3[3:0]	Input	SpaceWire Disconnect. Copy of DCONNECT (triplication of the asynchronous resets logic)	-	SWNI.DCONNECT3
DO[3:0]	Output	SpaceWire Data output.	-	SWNO.D
SO[3:0]	Output	SpaceWire Strobe output.	-	SWNO.S
TICKIN	Input	Time counter tick input. Increments internal time-counter and transmits the new value.	High	SWNI.TICKIN
TICKINRAW	Input	Raw tick input. Send time-code from timein input.	High	SWNI.TICKINRAW
TIMEIN[7:0]	Input	Raw tick input. Send time-code from timein input.	-	SWNI.TIMEIN
TICKINDONE	Output	Asserted when a time-code has been accepted for transmission when tickinraw is asserted. Tickinraw must be deasserted the same clock cycle as tickindone is asserted.	High	SWNO.TICKINDONE
TICKOUT	Output	Time counter tick output. Asserted when a valid time-code has been received	High	SWNO.TICKOUT
TICKOUTRAW	Output	Tick out which is always set when a time-code is received.	High	SWNO.TICKOUTRAW
TIMEOUT[7:0]	Output	Contains the received time-code when tickinraw is asserted.	-	SWNO.TIMEOUT
IRQ	Output	Common interrupt line for the core. Asserted one clock cycle for each interrupt.	High	N/A
CLKDIV10[7:0]	Input	Clock divisor value used during initialization and as reset value for the clock divisor register	-	SWNI.CLKDIV10
LINKDIS	Output	Asserted when the link is disabled	High	SWNO.LINKDIS
TESTRST	Output	Scan test reset	Low	-
TESTEN	Input	Scan test enable	High	-
RMAPEN	Input	Reset value for the rmapen control register bit	High	SWNI.RMAPEN
RXDAV	Output	Asserted each cycle a character has been receved on the SpaceWire link.	High	SWNO.RXDAV
RXDATAOUT[8:0]	Output	Contains the received character when rxdav is asserted	-	SWNO.RXDATAOUT

Table 1342. Signal descriptions

Signal name	Type	Function	Active	GRLIB signal name
CTRLREGRST	Output	Register reset. It corresponds to the bit 6 of the Control Register (see 70.13.1). It shall be used negated (it is active high) to generate the AMBA and transmitter resets.	High	SWNO.CTRLREGRST
RXRST	Output	Internal reset generated by the transmitter for synchronization purpose between transmitter and both receiver channels. It shall be used to generate the asynchronous and synchronous receiver resets.	Low	SWNO.RXRST

71.3   Instantiation

This example shows how the core can be instantiated. The reset generators have been instantiated according to the implementation section in GRSPW2 (refer to 70.11.1 for further information).

Normally di, si, do and so should be connected to input and output pads configured with LVDS drivers. How this is done is technology dependent. Instead the single ended inputs and outputs are connected directly to the external interface. The example uses only one port and the output is in SDR mode which means parts of the SpaceWire input and output vectors are unused.

72 GRSPW2_PHY - GRSPW2 Receiver Physical Interface

72.1 Overview

The GRSPW2_PHY provides a common interface for the receiver modules in GRSPW2, GRSP-WROUTER, and GRSPW_CODEC to the actual data recovery circuit. The data can be recovered in four different ways: Self-clocking (xor on data and strobe), Single Data Rate (SDR) sampling, Double Data Rate (DDR) sampling and from an SpaceWire transceiver. The GRSPW2_PHY presents the data with a data, and a data-valid signal, as well as outputs the clock used by the receiver modules. One GRSPW2_PHY core is needed for each SpaceWire link (data and strobe pair).
Figure 186. Data connection between the GRSPW2_PHY and the GRSPW2 / GRSPWROUTER / GRSPW_CODEC receiver.

72.2 Operation

As mentioned above the core supports four different input schemes, configurable through the VHDL generic input_type. The GRSPW2, GRSPWROUTER and GRSPW_CODEC cores also each have a generic named input_type, and it is important that it is set to the same value as for GRSPW2_PHY. The four different input schemes are explained in more detail in the following subsections.

72.2.1 Self-clocking (input_type = 0)

In self-clocking mode the receiver clock is recovered from the SpaceWire data and strobe by using an xor gate. The recovered clock is then used to clock the registers to which the data is stored. The recovered clock is coupled to the GRSPW2_PHY output signal RXCLKO, which should be connected to the receiver clock input of GRSPW2 / GRSPWROUTER / GRSPW_CODEC.

Since data will appear on both the rising and falling edge of the recovered clock there must be two registers, one for each edge. Figure 187 shows the clock recovery scheme. As can be seen in the figure, the SpaceWire data input is used for generating the receiver clock as well as input of several flip-flops. Care must be taken so that the delay from the data and strobe signals through the clock network is longer than the delay to the flip-flop's data input + setup time.

For self-clocking mode, the core's RXCLKI and RXCLKIN inputs are unused. The NRXCLKI input is unused if scan test support is not implemented (scantest generic set to 0). If scan test mode is implemented (scantest generic set to 1) then the NRXCLKI input is used as the receiver clock during scan test (TESTEN input high), otherwise it is not used. Details on how to connect the other input / output signals are found in section 72.5.
Figure 187. The clocking scheme for self clocking mode. The clock is recovered from the SpaceWire data and strobe signals using an xor gate.

72.2.2 Frontgrade transceiver (input_type = 1)

When using the Frontgrade UT200SpWPHY01 transceiver, the RxClk output from the transceiver shall be connected to the RXCLKI input of GRSPW2_PHY. RxDR and RxDF should be connected to DI and SI respectively. The GRSPW2_PHY outputs DO, DOV and DCONNECT are generated in the same way as for the self-clocking mode.

RXCLKIN is unused in this configuration. NRXCLKI is unused if scan test support is not implemented (SCANTEST generic set to 0). If scan test support is implemented (SCANTEST generic set to 1) the NRXCLKI is used in the following way: When not in scan test mode (TESTEN input is low) the NRXCLKI input should be the inverse of the RXCLKI input, and when in scan test mode (TESTEN input is high) the NRXCLKI input should be the same clock as the RXCLKI input. Details on how to connect the other input / output signals is found in section 72.5.

72.2.3 SDR sampling (input_type = 2)

In this mode the sampling clock should be connected to the RXCLKI input. RXCLKIN and NRX-CKLI are unused in this mode. Details on how to connect the other input / output signals is found in section 72.5.

The core internally detects new data on the data line. Since only one bit can be detected each clock cycle only bit 0 of the data signal to the receiver (DO output) is used. Normally the sampling frequency must be at least 1.5 times higher than the maximum bitrate for correct operation.

72.2.4 DDR sampling (input_type = 3)

The sampling clock should be connected to RXCLKI. If the selected technology does not have DDR primitives that automatically generate the inverted clock then the inverted sampling clock has to be connected to RXCLKIN. NRXCLKI is unused in this mode. Details on how to connect the other input / output signals is found in section 72.5.

The core internally detects new data on the data line. There can be two bits detected each clock cycle so both data signals to the receive (DO output) have to be used. The sampling frequency times two has to be at least 1,5 times the maximum bitrate.

72.2.5 DDR sampling with internal pad (input_type = 4)

Same as DDR sampling (input_type = 3) except that both DDR registers and input pads are instantiated within the GRSPW2_PHY. This option can be used on technologies where DDR registers and pads must be instantiated as one entity. This option (input_type = 4) should not be used unless recommended by Frontgrade Gaisler. If input_type = 4 is selected then the level and voltage of the instantiated pads are specified via the VHDL generics input_level and input_voltage, and external pads should not be instantiated for the SpaceWire input signals.

72.2.6 Self-clocking with external clock recovery (input_type = 5)

Same as self-clocking (input_type = 0) except that the clock recovery is done externally to the GRSPW2_PHY. The rxclki input is used to clock the receiver registers within the core.

The core's RXCLKIN input is unused. The NRXCLKI input is unused if scan test support is not implemented (scantest generic set to 0). If scan test mode is implemented (scantest generic set to 1) then the NRXCLKI input is used as the receiver clock during scan test (TESTEN input high), otherwise it is not used.

72.2.7 Self-clocking with external clock recovery and DDR register (input_type = 6)

Same as self-clocking with external clock recovery (input_type = 5) except that a DDR register is used internally in GRSPW2_PHY for the incoming data.

72.3 Configuration options

Table 1343 shows the configuration options of the core (VHDL generics).

Table 1343. Configuration options

Generic	Function	Allowed range	Default
scantest	Enable scantest mode	0 - 1	0
tech	Selects technology for DDR registers when input_type = 3, 4 or 6, as well as technology for clock buffer when input_type = 0, 5, 6 and rxclkbuftype /= 0.	0 - NTECH	1
input_type	Selects receiver type. 0 = Self clocking (xor), 1 = Interface for Frontgrade UT200SpWPHY01 SpaceWire transceiver, 2 = Single data rate sampling, 3 and 4 = Double data rate sampling, 5 = Self-clocking with external recovery, 6 = Self-clocking with external recovery and DDR register for data. This generic must be set to the same value as the GRSPW2 / GRSPWROUTER / GRSPW_CODEC generic with the same name.	0 - 4	0
input_level	Selects level for pads instantiated within PHY. Only used when input_type = 4.	-	0
input_voltage	Selects voltage for pads instantiated within PHY. Only used when input_type = 4.	-	0
rxclkbuftype	Selects clock buffer type for receiver clock. 0 = No clock buffer (synthesis tools may still infer a buffer). 1 = Hardwired clock, 2 = Routed clock.	0 - 2	0
rstsrctmr	Enables the Triple Module Redundancy for the asynchronous reset nets of the core	0 - 1	0

72.4 Scan support

Scan support is enabled by setting the SCANTEST generic to 1. When enabled, the asynchronous reset of any flip-flop will be connected to TESTRT when TESTEN = '1'.

72.5 Signal descriptions

Table 1344 shows the interface signals of the model (VHDL ports).

*Table 1344.*Signal descriptions

Signal name	Field	Type	Function	Active
RSTN	-	Input	Reset	Low
RXCLKI	-	Input	Receiver clock input. See sections 72.2.1 through 72.2.1 for details on how this signal is used for respective input type.	-
RXCLKIN	-	Input	The inverse of RXCLKI should be inputed here. See sections 72.2.1 through 72.2.1 for details on how this signal is used for respective input type.	-
NRXCLKI	-	Input	The inverse of RXCLKI should be inputed here. See sections 72.2.1 through 72.2.1 for details on how this signal is used for respective input type.	-
DI	-	Input	SpaceWire data input. When using a transceiver (input_type = 1), the transceiver's RxDR output should be connected to this input.	-
SI	-	Input	SpaceWire strobe input. When using a transceiver (input_type = 1), the transceiver's RxDF output should be connected to this input.	-
DO(1:0)	-	Output	Recovered data. Synchronous to RXCLKO. Should be connected to data inputs on GRSPW2 / GRSPWROUTER / GRSPW_CODEC. Each bit is valid when the bit at the corresponding index in the DOV signal is asserted. If only one bit is received on a given clock cycle then only the bit at the lower index is valid. If both bits are valid then the one at the bit at the lower index is the one received first.	-
DOV(1:0)	-	Output	Data valid. Synchronous to RXCLKO. Should be connected to data valid inputs on GRSPW2 / GRSPWROUTER / GRSPW_CODEC.	High
DCONNECT(1:0)	-	Output	Disconnect strobe signals. Synchronous to RXCLKO. Should be connected to the disconnect inputs on GRSPW2 / GRSPWROUTER / GRSPW_CODEC.	-
DCONNECT2 (1:0)	-	Output	If the generic rstsrctmr is set to 1 (TMR enabled), it is a replication of DCONNECT. It should be connected to the disconnect inputs on GRSPW2 / GRSPW_CODEC. If the generic rstsrctmr is set to 0 (TMR disabled), this signal is set to low and has no use.	-
DCONNECT3 (1:0)	-	Output	If the generic rstsrctmr is set to 1 (TMR enabled), it is a replication of DCONNECT. It should be connected to the disconnect inputs on GRSPW2 / GRSPW_CODEC. If the generic rstsrctmr is set to 0 (TMR disabled), this signal is set to low and has no use.	-
RXCLKO	-	Output	Receiver clock output. Should be connected to receiver clock inputs on GRSPW2 / GRSPWROUTER / GRSPW_CODEC.	-
TESTRST	-	Input	Scan test reset.	Low
TESTEN	-	Input	Scan test enable.	High

72.6 Library dependencies

Table 1345 shows the libraries used when instantiating the model (VHDL libraries).

*Table 1345.*Library dependencies

Library	Package	Imported unit(s)	Description
GAISLER	SPACEWIRE	component	Component declaration.

72.7 Instantiation

This example shows how the core can be instantiated in DDR mode (input_type = 3). rxclkin is used if the technology cannot generate the inverted clock in the DDR register otherwise it can be left floating. nrxclki is not needed at all for this mode and spw_rxtxclk is only connected not to violate VHDL syntax. Only one port is used so the same clock is coupled to both receiver clock inputs.

73 GRSPW_CODEC - SpaceWire encoder-decoder

73.1 Overview

The SpaceWire encoder-decoder implements an encoder-decoder compliant to the SpaceWire standard (ECSS-E-50-12C). It provides a generic host-interface consisting of control signals, status signals, time-code interface and 9-bit wide data buses connecting to a pair of FIFOs.

The core can also be configured with two SpaceWire ports with manual or automatic switching between them.

Transmitter outputs can be either Single Data Rate (SDR), Double Data Rate (DDR) or connected to an SpaceWire transceiver. The receiver can be connected either to an SpaceWire transceiver or recover the data itself using a self-clocking scheme or sampling (SDR or DDR).

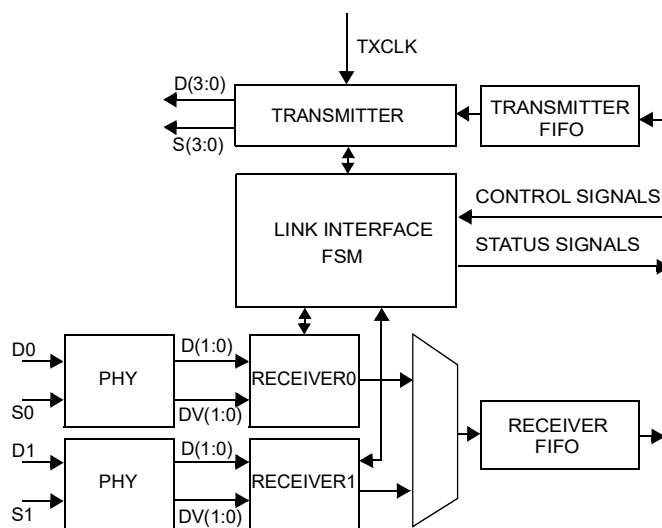
The core is practically identical to the encoder-decoder used in the GRSPW2, the only difference being the host-interface.


Figure 188. Block diagram

73.2 Operation

73.2.1 Overview

A block diagram of the internal structure of the core can be found in figure 188. It consists of the receiver, transmitter and the link interface FSM. They handle communication on the SpaceWire network. The PHY blocks provides a common interface for the receiver to the four different data recovery schemes and is external to this core. A short description is found in section 73.2.6. The complete documentation is found in the GRSPW2_PHY section of the GRIP user manual.

Time-codes are transmitted through a signal interface as specified in the SpaceWire standard.

73.2.2 Link-interface FSM

The link-interface FSM controls the link interface (a more detailed description is found in the SpaceWire standard). The low-level protocol handling (the signal and character level of the SpaceWire standard) is handled by the transmitter and receiver while the FSM handles the exchange level.

The link-interface FSM is controlled through the control signals. The link can be disabled through the link disabled signal, which depending on the current state, either prevents the link-interface from reaching the started state or forces it to the error-reset state. When the link is not disabled, the link

GRIP
Apr 2024, Version 2024.1

1124

Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

interface FSM is allowed to enter the started state when either the link start signal is asserted or when a NULL character has been received and the autostart signal is asserted.

The current state of the link-interface determines which type of characters are allowed to be transmitted which together with the requests made from the host interface determine what character will be sent.

Time-codes are sent when the FSM is in the run-state and a request is made through the time-interface (described in section 73.2.8).

When the link-interface is in the connecting- or run-state it is allowed to send FCTs. FCTs are sent automatically by the link-interface when possible. This is done based on the maximum value of 56 for the outstanding credit counter and the currently free space in the receiver FIFO. FCTs are sent as long as the outstanding counter is less than or equal to 48 and there are at least 8 more empty FIFO entries than the counter value.

N-Chars are sent in the run-state when they are available from the transmitter FIFO and there are credits available. NULLs are sent when no other character transmission is requested or the FSM is in a state where no other transmissions are allowed.

The credit counter (incoming credits) is automatically increased when FCTs are received and decreased when N-Chars are transmitted. Received N-Chars are stored to the receiver N-Char FIFO while received Time-codes are handled by the time-interface.

73.2.3 Transmitter

The state of the FSM, credit counters, requests from the time-interface and requests from the transmitter FIFO are used to decide the next character to be transmitted. The type of character and the character itself (for N-Chars and Time-codes) to be transmitted are presented to the low-level transmitter which is located in a separate clock-domain.

This is done because the SpaceWire link is usually run on a different frequency than the host system clock. The core has a separate clock input which is used to generate the transmitter clock. More information on transmitter clock generation is found in section 73.5.2. Since the transmitter often runs on high frequency clocks (> 100 MHz) as much logic as possible has been placed in the system clock domain to minimize power consumption and timing issues.

The transmitter logic in the host clock domain decides what character to send next and sets the proper control signal and presents any needed character to the low-level transmitter as shown in figure 189. The transmitter sends the requested characters and generates parity and control bits as needed. If no requests are made from the host domain, NULLs are sent as long as the transmitter is enabled. Most of the signal and character levels of the SpaceWire standard is handled in the transmitter. External LVDS drivers are needed for the data and strobe signals. The outputs can be configured as either single- or double data rate. The latter increases maximum bitrate significantly but is not available for all technologies.
Figure 189. Schematic of the link interface transmitter. Some bits in D[3:0] and S[3:0] may be unused, depending on the values of the *output_type*, and *ports* VHDL generics (see section 73.8).

+46 31 7758650 | frontgrade.com/gaisler

73.2.4 Receiver

The receiver detects connections from other nodes and receives characters as a bit stream recovered from the data and strobe signals by the GRSPW2_PHY module which presents it as a data and data-valid signal. Both the receiver and GRSPW2_PHY are located in a separate clock domain which runs on a clock driven by the PHY. More information on the clock-generation can be found in section 73.5.2.

The receiver is activated as soon as the link-interface leaves the error reset state. Then after a NULL is received it can start receiving any characters. It detects parity, escape and credit errors which causes the link interface to enter the error-reset state. Disconnections are handled in the link-interface part in the tx clock domain because no receiver clock is available when disconnected.

Received characters are flagged to the host domain and the data is presented in parallel form. The interface to the host domain is shown in figure 190. L-Chars are the handled automatically by the host domain link-interface part while all N-Chars are stored in the receiver FIFO for further handling. If two or more consecutive EOPs/EEPs are received all but the first are discarded.
Figure 190. Schematic of the link interface receiver.

73.2.5 Dual port support

The core can be configured to include an additional SpaceWire port. With dual ports the transmitter drives an additional pair of data/strobe output signals and one extra receiver is added to handle a second pair of data/strobe input signals.

One of the ports is set as active (how the active port is selected is explained below) and the transmitter drives the data/strobe signals of the active port with the actual output values as explained in section 73.2.3. The inactive port is driven with zero on both data and strobe.

Both receivers will always be active but only the active port's interface signals (see figure 190) will be propagated to the link interface FSM. Each time the active port is changed, the link will be reset so that the new link is started in a controlled manner.

When the noportforce signal is zero, the portsel signal selects the active port. When the noportforce signal is set to one, the active port is automatically selected during initialization. For the latter mode, the port on which the first bit is received will be selected as the active port. If the initialization attempt fails on that port the link is reset and the active port is again sected based on which port the first bit is received.

73.2.6 Receiver PHY

The receiver supports four different input data recovery schemes: self-clocking (xor), sampling SDR, sampling DDR and the SpaceWire transceiver. These four recovery types are handled in the PHY module and data is presented to the receiver as a data and data-valid signal. This part of the receiver must often be constrained and placing it in a separate module makes this process easier with the most common synthesis tools. The input type is selected using a VHDL generic. More information about the PHY can be found in the GRSPW2_PHY section of the GRIP user manual.

+46 31 7758650 | frontgrade.com/gaisler

73.2.7 Setting link-rate

The input signal IDIVISOR determines the link-rate during initialization (all states up to and including the connecting-state). The value of this input signal is also used to calculate the link interface FSM timeouts (6.4 µs and 12.8 µs, as defined in the SpaceWire standard). The IDIVISOR signal should always be set so that a 10 Mbit/s link-rate is achieved during initialization. In that case the timeout values will also be calculated correctly.

To achieve a 10 Mbit/s link-rate, the IDIVISOR signal should be set according to the following formulas:

With single data rate (SDR) outputs:

IDIVISOR = (<frequency in MHz of TXCLK> / 10) - 1

With double data rate (DDR) outputs, or when connected to Frontgrade SpaceWire transceiver:

IDIVISOR = (2 x <frequency in MHz of TXCLK> / 10) - 1

The link-rate in run-state is controlled with the run-state divisor, the RDIVISOR input signal. The link-rate in run-state is calculated according to the following formulas:

With SDR outputs:

<link-rate in Mbits/s> = <frequency in MHz of TXCLK> / (RDIVISOR+1)

With DDR outputs / Frontgrade SpaceWire transceiver:

<link-rate in Mbits/s> = 2 x <frequency in MHz of TXCLK> / (RDIVISOR+1)

The value of RDIVISOR only affects the link-rate in run-state, and does not affect the 6.4 us or 12.8 us timeouts values.

Note that when using DDR ouputs, or when connected to Frontgrade SpaceWire transceiver, there is a limitation in the usable clock divisor values. All even values (except 0) will result in the same bitrate as the one higher odd number.

An example of clock divisor and resulting link-rate, with a TXCLK frequency of 50 MHz, is shown in the table 1346. Also see 73.5.2 for information on clock requirements.

Table 1346. SpaceWire link-rate example with 50 MHz TXCLK

Clock divisor value	Link-rate in Mbit/s	
	SDR outputs	DDR outputs / Frontgrade SpaceWire transceiver
0	50	100
1	25	50
2	16.67	25
3	12.5	25
4	10	16.67
5	8.33	16.67
6	7.14	12.5
7	6.25	12.5
8	5.56	10
9	5	10

73.2.8 Time interface

The time interface is used for sending Time-codes over the SpaceWire network and consists of a timein signal, tickin signal, timeout signal and a tickout signal, plus the status flags tickin_done and tickin_busy.

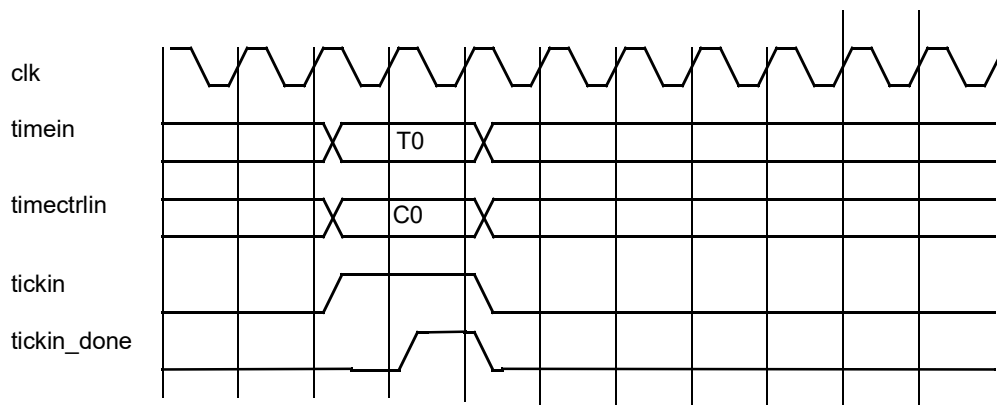
Each Time-code sent from the core is a concatenation of the time-code control bits (timein(7:6), represented as timectrlin in the diagram below) and the time-code value (timein(5:0)). It is transmitted each time tickin is kept asserted until the tickin_done output is asserted. Time-codes are only transmitted when the link-interface FSM is in run-state and when the previous character transmission is finished. This can cause a delay between when the assertion of tickin_done after tickin has been asserted. If tickin is not kept asserted until tickin_done is asserted the time-code will not be transmitted. Figure 191 shows an example of how a time-code is transmitted.


Figure 191. Transmitting a time-code using tickin, timein and timectrlin.

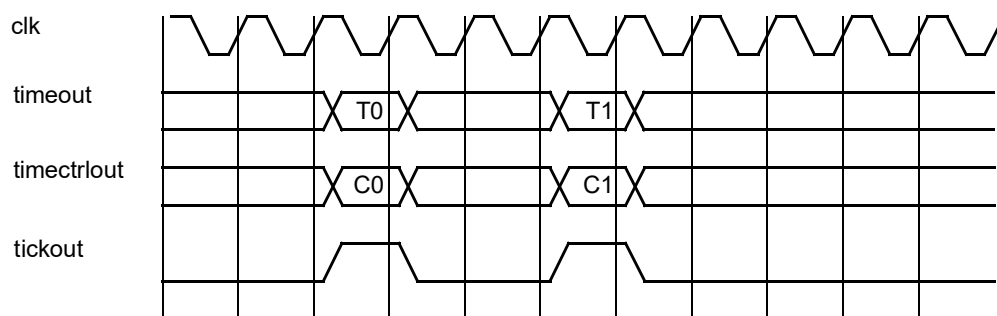
Received Time-codes are presented on the timeout signal, where the control bits are timeout(7:6) and displayed as timectrlout in the diagram below. They are valid when the tickout output is asserted. A tickout is generated each time a valid time-code is received. When the tickout is generated the tick-out signal will be asserted one clock-cycle. Figure 192 shows how time-codes are received.


Figure 192. Receiving time-codes using tickout, timeout and timectrlout.

73.3 Receiver interface

The receiver interface consists of the following signals connected to the receiver FIFO: rxicharav, rxicharcnt, rxichar, rxiread. Rxicharav is asserted when there are one or more characters available in the receiver FIFO whereas rxicharcnt shows the actual number available. Rxiread should be asserted for one cycle when rxicharav is asserted to read out a character. The character is available immediately, so it shall be read during the same clock cycle that rxiread is asserted. Figure 193 shows an example of reading characters from the receiver FIFO.

+46 31 7758650 | frontgrade.com/gaisler
Figure 193. Receiving characters through the FIFO interface.

73.3.1 Link errors

When an link error occurs during reception an EEP is automatically inserted into the Receiver FIFO if the previous character written to the FIFO was not an EOP or EEP.

73.4 Transmitter interface

The transmitter interface consists of the following signals: txiwrite, txichar, txififorst, txicharcnt, txifull, txiempty. Txifull is asserted when the transmitter FIFO is full while txicharcnt shows the actual number of characters currently in the FIFO. Txiwrite should be asserted for one cycle to write the value on txichar into the FIFO. Txififorst should be asserted for one cycle to discard all characters in the FIFO. No new characters should be written to the FIFO the same or the following cycle that txififorst is asserted. Figure 194 shows an example of writing characters to the transmitter FIFO.
Figure 194. Transmitting characters through the FIFO interface.

73.4.1 Link errors

When a link error occurs characters read from the transmitter FIFO by the transmission logic will be discarded up to and including the next EOP or EEP character.

73.5 Implementation

73.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

There are five input resets, in order to cover every clock domain: AMBA reset (rst), transmitter synchronous reset (txsyncrst), receiver synchronous reset for port 0 (rxsyncrst0), receiver synchronous reset for port 1 (rxsyncrst1) and a receiver asynchronous reset shared by both ports (rxasyncrst).

Additionally, the core outputs an internal reset for synchronization between transmitter and receivers, lio.rxrst.

The core does not implement any kind of internal reset generation or synchronization, the input resets are completely independent. The reset generation shall be done in a higher instance, taking into account the clock domains and also the output reset of the core. A description of how the resets shall be combined and generated can be found below. Frontgrade Gaisler advise to follow these guidelines unless indicated otherwise.

• The AMBA reset is the external reset synchronized with the AMBA clock by using a reset generator.

• The transmitter reset is the external reset synchronized with the transmitter clock by using a reset generator.

• The asynchronous reset for both receiver channels is simply the output synchronization reset, lio.rxrst, connected directly to the input rxasyncrst.

• The synchronous reset for each receiver channel is the output receiver reset, lio.rxrst, synchronized with the appropriate clock domain by using a reset generator. Its output is the synchronous reset for the specific receiver port, rxsyncrst0 or rxsyncrst1.

Further information about the proper way of combining the reset signals or using the wrapper can be found in 73.13. Instantiation.

73.5.2   Clock-generation

The receiver module found in figure 188 should be clocked with the RXCLKO output signal from the GRSPW2_PHY module. See the example instantiation in this section and the GRSPW2_PHY section of the GRIP manual for more information on how to connect this clock.

The transmitter clock is generated from the TXCLK input. A separate clock input is used to allow the transmitter to be run at much higher frequencies than the system clock. The SpaceWire node contains a clock-divider which divides the TXCLK signal to the wanted frequency. The transmitter clock should be 10 MHz during initialization and any frequency above 2 MHz in the run-state.

There is an input signal called CLKDIV10 which sets the frequency during initialisation and one called CLKDIV which is used in run-state. See 73.2.7 for details on how to set the clock divisor values.

Since only integer values are allowed for the clock division and the required init-frequency is 10 MHz the frequency of the TXCLK input must be a multiple of 10 MHz. The clock divisor value is 8-bits wide so the maximum txclk frequency supported is 2.56 GHz (note that there is also a restriction on the relation between the system and transmit clock frequencies).

73.5.3   Timers

There are two timers in the codec: one for generating the 6.4/12.8 µs periods and one for disconnect timing.

The timeout periods are generated from the TX clock whose frequency must be at least 10 MHz to guarantee disconnect timing limits. The same clock divisor is used as for the TX clock during initialisation so it must be set correctly for the link timing to work.

73.5.4   Synchronization

The transmitter and receiver bit rates can be eight times higher than the system clock frequency. This includes a large margin for clock skew and jitter so it might be possible to run at even higher rate differences. Note also that the receiver clocks data at both negative and positive edges for the input modes 0 and 1 so the bitrate is twice the clock frequency. There is no direct relationship between bitrate and frequency for the sampling modes.

The clock synchronization is just one limiting factor for the clock frequency, it might for example not be possible to achieve the highest possible frequency for certain technologies.

The asynchronous reset to the receiver clock domain has to have a maximum delay of one receiver clock cycle to ensure correct operation. This is needed because the receiver uses a completely asynchronous reset. To make sure that nothing bad happens there is a synchronous reset guard which prevents any signals from being assigned before all registers have their reset signals released.

In the sampling modes this asynchronous reset can be removed if both the receiver and transmitter runs on the same clock. In that case set the RXTX_SAMECLK generic to 1.

73.5.5   Fault-tolerance

The core can optionally be implemented with fault-tolerance against SEU errors in the FIFO memories. The fault-tolerance is enabled through the *ft* VHDL generic. Possible options are byte parity protection (*ft = 1*) or TMR registers (*ft = 2*). Note: the GPL version of GRLIB does not include fault-tolerance, and the core will not work unless the *ft* VHDL generic is 0.

73.5.6   Synthesis

The fact there are three clock domains in the core of which all are possibly high frequency clocks makes it necessary to declare all paths between the clock domains as false paths. In Synplify this is most easily done by declaring all the clocks to be in different clockgroups in the sdc file (if Synplify

GRIP
Apr 2024, Version 2024.1

1131

Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

does not automatically put them in different groups). This will disable any timing considerations between the clock domains and these constraints will also propagate to the place and route tool.

73.5.7 Technology mapping

The core has two generics for technology mapping: *tech and techfifo*. *Tech* selects the technology for DDR registers (if applicable) and FIFO memories. *Techfifo* selects whether *tech* should be used to select the technology for the FIFO memories or if they should be inferred. *Tech* and *memtech* can be set to any value from 0 to NTECH as defined in the GRLIB.TECH package.

73.5.8 RAM usage

The core maps all RAM memories on the syncram_2p component if the *ft* generic is 0 and to the syncram_2pft component for other values. The syncrams are located in the technology mapping library (TECHMAP). The organization of the different memories are described below. If techfifo and/or memtech is set to 0 the synthesis tool will infer the memories. Either RAM blocks or flip-flops will be used depending on the tool and technology. The number of flip-flops used is *syncram depth x syncram width* for all the different memories.

Transmitter FIFO

The transmitter FIFO consists of one syncram_2p block with a width of 9-bits. The depth is determined by the configured FIFO depth. Table 1347 shows the syncram organization for the allowed configurations.

Table 1347. syncram_2p sizes for the transmitter FIFO.

Fifosize	Syncram_2p organization

ports	Sets the number of ports	1 - 2	1
input_type	Select receiver type. 0 = Self clocking (xor), 1 = Interface for Frontgrade UT200SpWPHY01 SpaceWire transceiver, 2 = Single data rate sampling, 3 and 4 = Double data rate sampling, 5 = Self-clocking with external recovery, 6 = Self-clocking with external recovery and DDR register for data.. This generic must be set to the same value as the GRSPW2_PHY generic with the same name.	0 - 6	0
output_type	Select transmitter type. 0 = single data rate, 1 = double data rate, 2 = interface for Frontgrade UT200SpWPHY01 SpaceWire transceiver	0 - 2	0
rxtx_sameclk	Set to one if the same clock net is connected to both the receiver and transmitter (which means this feature is only applicable when the receiver uses sampling). This will remove some unnecessary synchronization registers.	0 - 1	0
fifosize	Sets the number of entries in the 9-bit wide transmitter and receiver FIFOs.	16 - 2048	64
tech	Technology for FIFO memories.	0 - NTECH	inferred
scantest	Enable scantest features.	0 - 1	0
techfifo	Enable GRLIB technology mapped FIFO memories. If not enabled a behavioral model is used and the result will be synthesis tool dependent.	0 - 1	0
ft	Enable fault-tolerance against SEU errors	0 - 2	0
rstsrctmr	Enables the Triple Module Redundancy for the asynchronous reset nets of the core	0 - 1	0

73.9 Signal descriptions

Table 1350 shows the interface signals of the core (VHDL ports).

Table 1350. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	AMBA Reset	Low
CLK	N/A	Input	AMBA Clock	-
RXASYNCRST	N/A	Input	Asynchronous reset for ports 0 and 1 of the receiver	Low
RXSYNCRST0	N/A	Input	Synchronous reset for port 0 of the receiver	Low
RXCLK0	N/A	Input	Receiver clock for port 0.	-
RXSYNCRST1	N/A	Input	Synchronous reset for port 1 of the receiver	Low
RXCLK1	N/A	Input	Receiver clock for port 1. Unused if the VHDL generic ports is 2.	-
TXSYNCRST	N/A	Input	Synchronous reset for the transmitter	Low
TXCLK	N/A	Input	Transmitter default run-state clock	-

Table 1350. Signal descriptions

Signal name	Field	Type	Function	Active
TXCLKN	N/A	Input	Transmitter inverted default run-state clock. Only used in DDR transmitter mode for technologies not supporting local generation of inverted clock.	-
TESTEN	N/A	Input	Scan test enable	High
TESTRST	N/A	Input	Scan test reset	Low
LII	D[3:0]	Input	Data input. Each bit is valid when the bit at the corresponding index in the DV signal is asserted. Bits (1:0) are used for port 0 and bits (3:2) are used for port 1 if enabled. If only one bit is received during one clock cycle then only the bit at the lower index is valid. If both bits are valid then the one at the lower index was the one received first. Bits (1:0) should be synchronous to RXCLK0 and bits (3:2) to RXCLK1. Connect to the DO[1:0] output of one GRSPW2_PHY per implemented port.	-
	DV[3:0]	Input	Data valid qualifier for the LII.D[3:0] input. Connect to the DOV[1:0] output of one GRSPW2_PHY per implemented port.	High
	DCONNECT[3:0]	Input	Disconnect reset. When asserted the corresponding disconnect counter will be reset. The counters connected to bits (1:0) apply to port 0 while (3:2) apply to port 1 if enabled.	Low
	DCONNECT2[3:0]	Input	Disconnect. Bits 3:2 are unused in one-port configurations. This is a copy of DCONNECT, as part of the triplication of the combinational logic related to asynchronous reset nets.	Low
	DCONNECT3[3:0]	Input	Disconnect. Bits 3:2 are unused in one-port configurations. This is a copy of DCONNECT, as part of the triplication of the combinational logic related to asynchronous reset nets.	Low
	LINKDISABLED	Input	Disables the SpaceWire link	High
	LINKSTART	Input	Starts the SpaceWire link	High
	AUTOSTART	Input	Enables the autostart feature for the SpaceWire link	High
	PORTSEL	Input	Selects the active port if the NOPORTFORCE signal is set to 0 and the core is configured with dual ports.	-
	NOPORTFORCE	Input	Disables forced port selection using the PORTSEL signal and lets the core automatically select the active link.	High
	RDIVISOR[7:0]	Input	Clock divisor value used for generating the transmit frequency from the txclk input in run-state. Bit 0 is the least significant. See 73.2.7 for details on how to set this input signal.	-
	IDIVISOR[7:0]	Input	Clock divisor value used for generating the transmit frequency from the txclk input during initialization (started and connecting states). Bit 0 is the least significant. See 73.2.7 for details on how to set this input signal.	-

Table 1350. Signal descriptions

Signal name	Field	Type	Function	Active
LII	RXIREAD	Input	Receiver FIFO read. Assert for one cycle (synchronous to CLK) and the next character will be available on the RXICHAR output the next clock cycle if available in the FIFO.	High
	RXIFIFORST	Input	Empty the receiver FIFO. When asserted for one cycle (synchronous to CLK) all characters currently present in the FIFO will be discarded. The reset will have taken on the second cycle after the reset. The first cycle after characters may still be present.	High
	TXIWRITE	Input	Transmitter FIFO write. Assert for one cycle (synchronous to CLK) to write the character on the TXICHAR input into the FIFO on the rising edge of the clock.	High
	TXICHAR[8:0]	Input	Transmit character input to FIFO. Characters are transmitted in the order they are written into the FIFO. Bit 0 is the SpaceWire control bit. When set to 1 only bits (2:1) are transmitted (EOP or EEP). Bits are transmitted in order beginning at the lowest index.	-
	TXIFIFORST	Input	Empty the transmitter FIFO. When asserted for one cycle (synchronous to CLK) all characters currently present in the FIFO will be discarded. New characters shall not be written to the transmitter FIFO the same cycle or the cycle after TXIFIFORST is asserted.	High
	TICKIN	Input	Time counter tick input. Should be asserted one clock cycle (synchronous to CLK) to transmit a time-code. If the FSM is not in run-state no time-code will be transmitted and the tick will not be registered. The TICKIN_DONE output can be used to verify that the time-code has been transmitted,	High
	TIMEIN[7:0]	Input	Control bits (7:6) and value (5:0) for the time-code interface. Transmitted in order starting at the lowest index when tickin is asserted.	-
LIO	DO[3:0]	Output	Data output. The meaning of the bits depends on the value of the *output_type* generic. When output_type=0 or 1, DO[0] is the data output for port 0, DO[1] is the data output for port 1, and DO[3:2] are unused. In single-port configurations DO[3:1] are unused. When output_type=2 (external UT200SpW-PHY01 SpaceWire transceiver), DO[1:0] is the output for port 0 and DO[3:2] is the output for port 1. In single-port configurations DO[3:2] are unused.	-
	SO[3:0]	Output	Strobe output. The bit mapping is the same as for the LIO.DO[3:0] output (see above).	-
	STATE[2:0]	Output	Current linkinterface FSM state. 0=error-reset, 1=error-wait, 2=ready, 3=started, 4=connecting, 5=run.	-
	ACTPORT	Output	0=port 0 is active and 1=port 1 is active. Unused if the second port is not enabled.	-
	DCONNECTERR	Output	Asserted for one clock cycle (synchronous to CLK) when a disconnect error is detected.	High

Table 1350. Signal descriptions

Signal name	Field	Type	Function	Active
LIO	CREDERR	Output	Asserted for one clock cycle (synchronous to CLK) when a credit error is detected.	High
	ESCERR	Output	Asserted for one clock cycle (synchronous to CLK) when an escape error is detected.	High
	PARERR	Output	Asserted for one clock cycle (synchronous to CLK) when a parity error is detected.	High
	RXICHARAV	Output	Asserted when one or more characters are available in the receiver FIFO. Synchronous to CLK.	High
	RXICHARCNT [11:0]	Output	Number of characters present in the receiver FIFO. Synchronous to CLK.	-
	RXICHAR[8:0]	Output	Character read from the receiver FIFO. Valid the clock cycle following the assertion of the RXIREAD input. Synchronous to CLK. Bit 0 corresponds to the SpaceWire control bit and when set to 1 only bits (2:1) are valid (EOP or EEP).	-
	TXICHARCNT [11:0]	Output	Number of characters present in the transmitter FIFO. Synchronous to CLK.	-
	TXIFULL	Output	Asserted when the transmitter FIFO is full. Synchronous to CLK.	High
	TXIEMPTY	Output	Asserted when the transmitter FIFO is empty. Synchronous to CLK.	High
	TXIFIFORST	Output	Asserted when the transmitter FIFO reset is active. If set, no new characters shall be written to the FIFO. Synchronous to CLK.	High
	TICKIN_DONE	Output	Asserted for one cycle when the time-code has been transmitted resulting from an assertion of TICKIN. When TICKIN_DONE is asserted the TICKIN should be deasserted the same cycle if it is not desired that another time-code should be deasserted.	High
	TICKIN_BUSY	Output	Set while the time-code is being transmitted.	High
	TICKOUT	Output	Time-code tickout output. Asserted for one clock cycle (synchronous to CLK) when a time-code has been received. When asserted the TIMEOUT output is valid.	High
	TIMEOUT[7:0]	Output	Time-code output. Synchronous to CLK.	-
	MERROR	Output	Asserted one clock cycle when an EDAC memory error is detected.	High
	OCREDCNT[5:0]	Output	Value of the outstanding credit counter.	-
	CREDCNT[5:0]	Output	Value of the incoming credit counter.	-
	POWERDOWN	Output	Power-down indicator.	High
	POWERDOWNRX	Output	RX power-down indicator.	High
	RXMERROR	Output	Asserted one clock cycle when an EDAC memory error is detected in the RX FIFO.	High
	TXMERROR	Output	Asserted one clock cycle when an EDAC memory error is detected in the TX FIFO.	High
	RXRST	Output	Internal reset generated by the transmitter for synchronization purpose between transmitter and both receiver channels. It shall be used to generate the asynchronous and synchronous receiver resets.	Low

73.12 Library dependencies

Table 1354 shows libraries used when instantiating the core (VHDL libraries).

Table 1354. Library dependencies

Library	Package	Imported unit(s)	Description
GAISLER	SPACEWIRE	Signals, component	Component and record declarations.

73.13 Instantiation

This example shows how the core can be instantiated.

Normally di, si, do and so should be connected to input and output pads configured with LVDS drivers. How this is done is technology dependent.

The core in the example is configured with non-ft technology mapped FIFOs of size 64. It uses DDR sampling on the input and the combined sampling/transmitter frequency (spw_rxtxclk) is 50MHz.

The minimum amount of signals that need to be driven to put the codec in a deterministic initial state is shown.

74   GRSPW_CODEC_GEN - GRSPW_CODEC wrapper with Std_Logic interface

74.1   Overview

The GRSPW_CODEC_GEN wrapper provides an interface to the GRSPW_CODEC core only using Std_Logic signals instead of GRLIB records. The GRLIB AMBA plug and play extensions have also been removed. This document describes the signal interface and how they map to the signal names in GRLIB. An example instantiation of the core can be found at the end of this document.

74.2   Signal descriptions

Table 1350 shows the interface signals of the core (VHDL ports).

Table 1355. Signal descriptions

Signal name	Type	Function	Active	GRLIB signal name
RST	Input	AMBA reset	Low	RST
CLK	Input	System (AMBA) Clock.	-	CLK
RXASYNCRST	Input	Receiver asynchronous reset for both ports 0 and 1	Low	RXASYNCRST
RXSYNCRST0	Input	Receiver synchronous reset for port 0	Low	RXSYNCRST0
RXCLK0	Input	Receiver clock for port 0.	-	RXCLK0
RXSYNCRST1	Input	Receiver synchronous reset for port 1	Low	RXSYNCRST1
RXCLK1	Input	Receiver clock for port 1. Unused if the VHDL generic ports is 2.	-	RXCLK1
TXSYNCRST	Input	Transmitter synchronous reset	Low	TXSYNCRST
TXCLK	Input	Transmitter default run-state clock	-	TXCLK
TXCLKN	Input	Transmitter inverted default run-state clock. Only used in DDR transmitter mode for technologies not supporting local generation of inverted clock.	-	TXCLKN
TESTEN	Input	Scan test enable	High	TESTEN
TESTRST	Input	Scan test reset	Low	TESTRST
D[3:0]	Input	Data input. Should be connected to the GRSPW2_PHY. Each bit is valid when the bit at the corresponding index in the DV signal is asserted. Bits (1:0) are used for port 0 and bits (3:2) are used for port 1 if enabled. If only one bit is received during one clock cycle then only the bit at the lower index is valid. If both bits are valid then the one at the lower index was the one received first. Bits (1:0) should be sycnhronous to RXCLK0 and bits (3:2) to RXCLK1.	-	LII.D
DV[3:0]	Input	Data valid qualifier for the D input.	High	LII.DV
DCONNECT[3:0]	Input	Disconnect reset. When asserted the corresponding disconnect counter will be reset. The counters connected to bits (1:0) apply to port 0 while (3:2) apply to port 1 if enabled.	Low	LII.DCONNECT
DCONNECT2 [3:0]	Input	SpaceWire Disconnect reset. Copy of DCONNECT (triplication of the asynchronous resets logic).	Low	LII.DCONNECT2
DCONNECT3 [3:0]	Input	SpaceWire Disconnect reset. Copy of DCONNECT (triplication of the asynchronous resets logic).	Low	LII.DCONNECT3
LINKDISABLED	Input	Disables the SpaceWire link	High	LII.LINKDISABLED

Table 1355. Signal descriptions

Signal name	Type	Function	Active	GRLIB signal name
LINKSTART	Input	Starts the SpaceWire link	High	LII.LINKSTART
AUTOSTART	Input	Enables the autostart feature for the SpaceWire link	High	LII.AUTOSTART
PORTSEL	Input	Selects the active port if the NOPORTFORCE signal is set to 0 and the core is configured with dual ports.	-	LII.PORTSEL
NOPORTFORCE	Input	Disables forced portselection using the PORT-SEL signal and lets the core automatically select the active link.	High	LII.NOPORTFORCE
RDIVISOR[7:0]	Input	Clock divisor value used for generating the transmit frequency from the txclk input in run-state. Bit 0 is the least significant.	-	LII.RDIVISOR
IDIVISOR[7:0]	Input	Clock divisor value used for generating the transmit frequency from the txclk input during initialization (started and connecting states). This value is also used to generate the disconnect timing and the FSM timeouts (6.4 us and 12.8 us). Bit 0 is the least significant.	-	LII.IDIVISOR
RXIREAD	Input	Receiver FIFO read. Assert for one cycle (synchronous to CLK) and the next character will be available on the RXICHAR output the next clock cycle if available in the FIFO.	High	LII.RXIREAD
RXIFIFORST	Input	Empty the receiver FIFO. When asserted for one cycle (synchronous to CLK) all characters currently present in the FIFO will be discarded. The reset will have taken on the second cycle after the reset. The first cycle after characters may still be present.	High	LII.RXIFIFORST
TXIWRITE	Input	Transmitter FIFO write. Assert for one cycle (synchronous to CLK) to write the character on the TXICHAR input into the FIFO on the rising edge of the clock.	High	LII.TXIWRITE
TXICHAR[8:0]	Input	Transmit character input to FIFO. Characters are transmitted in the order they are written into the FIFO. Bit 0 is the SpaceWire control bit. When set to 1 only bits (2:1) are transmitted (EOP or EEP). Bits are transmitted in order beginning at the lowest index.	-	LII.TXICHAR
TXIFIFORST	Input	Empty the transmitter FIFO. When asserted for one cycle (synchronous to CLK) all characters currently present in the FIFO will be discarded. New characters shall not be written to the transmitter FIFO the same cycle or the cycle after TXIFIFORST is asserted.	High	LII.TXIFIFORST
TICKIN	Input	Time counter tick input. Should be asserted one clock cycle (synchronous to CLK) to transmit a time-code. If the FSM is not in run-state no time-code will be transmitted and the tick will not be registered. The TICKIN_DONE output can be used to verify that the time-code has been transmitted,	High	LII.TICKIN
TIMEIN[7:0]	Input	Time-code input. Transmitted in order starting at the lowest index when tickin is asserted.	-	LII.TIMEIN

Table 1355. Signal descriptions

Signal name	Type	Function	Active	GRLIB signal name
DO[3:0]	Output	Data output. The meaning of the bits depends on the value of the *output_type* generic. When output_type=0 or 1, DO[0] is the data output for port 0, DO[1] is the data output for port 1, and DO[3:2] are unused. In single-port configurations DO[3:1] are unused. When output_type=2 (external UT200SpW-PHY01 SpaceWire transceiver), DO[1:0] is the output for port 0 and DO[3:2] is the output for port 1. In single-port configurations DO[3:2] are unused.	-	LIO.DO
SO[3:0]	Output	Strobe output. Bit indexes are used correspondingly to the DO output.	-	LIO.SO
STATE[2:0]	Output	Current link interface FSM state. 0=error-reset, 1=error-wait, 2=ready, 3=started, 4=connecting, 5=run.	-	LIO.STATE
ACTPORT	Output	0=port 0 is active and 1=port 1 is active. Unused if the second port is not enabled.	-	LIO.ACTPORT
DCONNECTERR	Output	Asserted for one clock cycle (synchronous to CLK) when a disconnect error is detected.	High	LIO.DCONNECTERR
CREDERR	Output	Asserted for one clock cycle (synchronous to CLK) when a credit error is detected.	High	LIO.CREDERR
ESCERR	Output	Asserted for one clock cycle (synchronous to CLK) when an escape error is detected.	High	LIO.ESCERR
PARERR	Output	Asserted for one clock cycle (synchronous to CLK) when a parity error is detected.	High	LIO.PARERR
RXICHARAV	Output	Asserted when one or more characters are available in the receiver FIFO. Synchronous to CLK.	High	LIO.RXICHARAV
RXICHARCNT [11:0]	Output	Number of characters present in the receiver FIFO. Synchronous to CLK.	-	LIO.RXICHARCNT
RXICHAR[8:0]	Output	Character read from the receiver FIFO. Valid the clock cycle following the assertion of the RXIREAD input. Synchronous to CLK. Bit 0 corresponds to the SpaceWire control bit and when set to 1 only bits (2:1) are valid (EOP or EEP).	-	LIO.RXICHAR
TXICHARCNT [11:0]	Output	Number of characters present in the transmitter FIFO. Synchronous to CLK.	-	LIO.TXICHARCNT
TXIFULL	Output	Asserted when the transmitter FIFO is full. Synchronous to CLK.	High	LIO.TXIFULL
TXIEMPTY	Output	Asserted when the transmitter FIFO is empty. Synhronous to CLK.	High	LIO.TXIEMPTY
TXIFIFORSTACT	Output	Transmitter FIFO reset active. Used in router when writing EEP after reset.	High	LIO.TXIFIFORST
TICKIN_DONE	Output	Asserted for one cycle when the time-code has been transmitted resulting from an assertion of TICKIN. When TICKIN_DONE is asserted the TICKIN should be deasserted the same cycle if it is not desired that another time-code should be deasserted.	High	LIO.TICKIN_DONE
TICKOUT	Output	Time-code tickout output. Asserted for one clock cycle (synchronous to CLK) when a time-code has been received. When asserted the TIMEOUT output is valid.	High	LIO.TICKOUT

Table 1355. Signal descriptions

Signal name	Type	Function	Active	GRLIB signal name
TIMEOUT[7:0]	Output	Time-code output. Synchronous to CLK.	-	LIO.TIMEOUT
MERROR	Output	Asserted one clock cycle when an EDAC memory error is detected.	High	LIO.MERROR
RXRST	Output	Internal reset generated by the transmitter for synchronization purpose between transmitter and both receiver channels. It shall be used to generate the asynchronous and synchronous receiver resets.	Low	LIO.RXRST

74.3   Instantiation

This example shows how the core can be instantiated. It also includes the reset generators.

Normally di, si, do and so should be connected to input and output pads configured with LVDS drivers. How this is done is technology dependent.

The core in the example is configured with non-ft technology mapped FIFOs of size 64. It uses DDR sampling on the input and the combined sampling/transmitter frequency (spw_rxtxclk) is 50MHz.

The minimum amount of signals that need to be driven to put the codec in a deterministic initial state is shown.

75 GRSPWROUTER - SpaceWire router

75.1 Overview

The SpaceWire router core implements a SpaceWire routing switch as defined in the ECSS-E-ST-50-12C standard. It supports from 2 to 31 ports in addition to the mandatory configuration port where each port (except the configuration port) can be individually configured to be SpaceWire links, FIFO interfaces or AMBA interfaces. The AMBA ports are limited to a maximum of 16 in a single router. The configuration port provides an RMAP target, and an optional AMBA AHB slave interface, both used for accessing internal configuration and status registers.

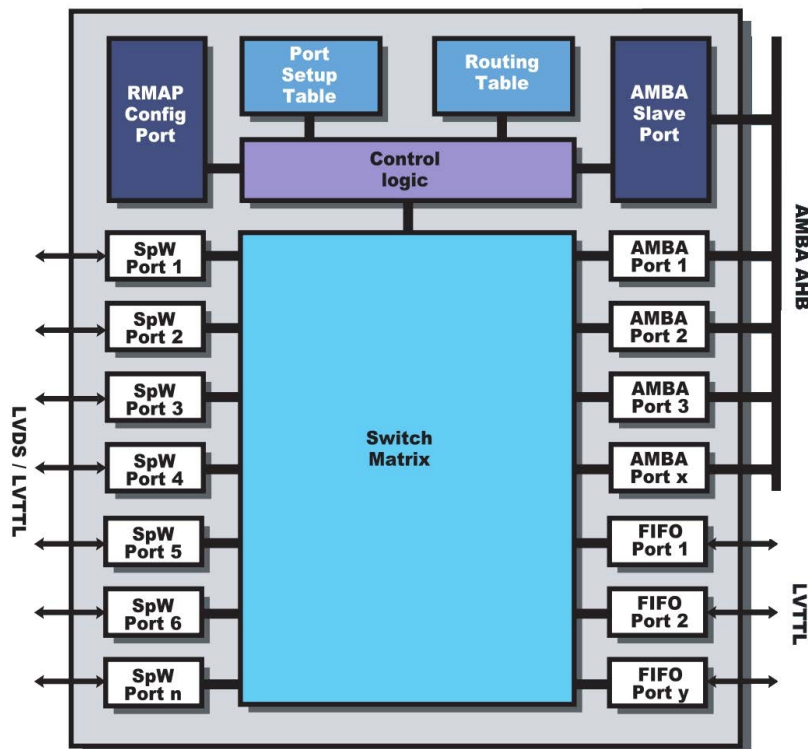
Among the features supported by the router are: group adaptive routing, packet distribution, system time-distribution, distributed interrupts, port timers to recover from deadlock situations, and SpaceWire-D [SPWD] packet truncation based time-slot violations. The router is designed to be technology independent and configurable. This enables it to be implemented in all technologies supported by the GRLIB IP library and also to remove optional features to save area.


Figure 198. Block diagram

75.2 Operation

The switch matrix can connect any input port to any output port. Access to each output port is arbitrated using a round-robin arbitration scheme based on the address of the incoming packet. A single routing-table is used for the whole router, where access to the table is arbitrated using a round-robin scheme based on the input port number.

All the ports regardless of their type have the same interface to the switch matrix and behave in the same manner. The difference in behavior is on the external side of the port. The SpaceWire ports provide standard SpaceWire link interfaces using either on- or off-chip LVDS. The FIFO interfaces store characters in two FIFOs which are accessed using 9-bit wide data paths with read/write signals. Lastly

the AMBA ports transfer characters from and to an AHB bus using DMA. The four different port types are described in further detail in sections 75.3, 75.4, 75.5 and 75.6.

75.2.1 Endianness

The core is designed for big-endian systems.

75.2.2 Port numbering

The ports are numbered in the following order: configuration port, SpW ports, AMBA ports, FIFO ports. The configuration port is always present and has number 0. If SpW ports are present in the router they are numbered starting from number 1. If AMBA ports are present they are numbered starting from the last SpW ports. If no SpW ports are present the AMBA ports start at number 1. Lastly, the FIFO ports are numbered starting after the last AMBA port, SpW port or at number 1 depending on if AMBA ports and SpW ports are present respectively.

For example if 7 SpW ports and 4 FIFO ports are included in the router they will have port numbers 1-7 and 8-11. If 16 SpW ports, 2 AMBA ports and 7 FIFO ports are included they have port numbers 1-16, 17-18 and 19-25 respectively.

75.2.3 Routing table

A single routing table is provided. The access to this routing table is arbitrated using a round-robin arbiter with each port being of equal priority. The operation is pipelined and one lookup can be done each cycle. This way the maximum latency is equal to the number of ports in the router minus one. The impact on throughput should be negligible provided that packets are not incoming at the same time. The probability for this is higher when the traffic only consist of very small packets sent continuously (the average size being about the same as the number of ports). This should be a very uncommon case. Latency is still bounded and probably negligible in comparison to other latencies in most systems. The benefit is a reduced area enabling the router to be implemented with a higher number of ports on many FPGA technologies.

Since the latency for the lookup is very small and deterministic there is not much to gain by having configurable priorities for this. Priorities are instead used for arbitrating packets contending for an output port as described in the next section.

The routing table and all the configuration registers are configured through an RMAP target or an optional AHB slave interface which use the same routing table as the logic handling packet traffic. They do not introduce any extra latency for packets, since the configuration accesses have lower priority than the packet traffic and thus are only allowed access on cycles when no lookup is needed for packets. This can slow down configuration accesses but they are probably mostly done before packet traffic starts and very seldom afterwards. The routing table is split into two parts, one which controls the port mapping for the address (RTR.RTPMAP registers), and one which controls properties for the address, such as priority and header deletion (RTR.RTACTRL registers).

75.2.3.1 Port mapping

For both physical and logical addresses it is possible to configure which port(s) the incoming packet should be routed to. This is done by programming the corresponding RTR.RTPMAP register. The RTR.RTPMAP registers also controls whether or not group adaptive routing or packet distribution should be used for the incoming packet. The RTR.RTPMAP registers are not initialized after reset / power-up. For physical addresses this has the effect that the incoming packet is routed to the port that matches the address in the packet, without any group adaptive routing or packet distribution. For logical addresses, an uninitialized RTR.RTPMAP register (or if the RTR.RTPMAP.PE field has been written with all zeros) has the effect that the incoming packet is spilled. See table 1391 in section 75.7 for more details.

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

75.2.3.2 Address control

For both physical and logical addresses it is possible to configure the priority, and to enable the spill-if-not-ready feature (explained in section 75.2.9). For logical addresses it is also possible to enable / disable the address, and enable / disable header deletion. Physical addresses are always enabled, and always have header deletion enabled, as specified by ECSS-E-ST-50-12C [SPW]. This configuration for an address is done by programming the corresponding RTR.RTACTRL register. Logical addresses are disabled after reset / power-up. An incoming packet with a disabled logical address is spilled. See table 1392 in section 75.7 for details.

75.2.4 Output port arbitration

Each output port is arbitrated individually based on the address of the incoming packet, using two priority levels, with round-robin at each level. Each physical address and logical address can be configured in the routing table (RTR.RTACTRL register) to be either high or low priority. Priority assignments can have large impact on the delays for packets, because packets can be large and the speed of the data consumer and link itself may not be known. This should therefore be considered when assigning priorities.

75.2.5 Group adaptive routing

Group adaptive routing can be used to allow incoming packets to be sent on different output ports depending on which of the output ports that are currently ready. It can be enabled for both physical and logical addresses, and is configured by programming the corresponding RTR.RTPMAP register.

When a packet arrives, and group adaptive routing is enabled for the packet's address, the router looks at the group of ports selected by the corresponding RTR.RTPMAP register and transmits the packet on the port with the lowest index that is currently ready. Ready in this context means that the port's link interface is in run-state and currently not sending any other packet. If none of the selected output ports are ready, the incoming packet will either be spilled or transmitted on the first port that becomes ready. The action taken depends on the setting of the input port's data character timer (see section 75.2.14), the spill-if-not-ready feature for the address (see section 75.2.9), and the link-start-on-request feature for the output ports (see section 75.2.12). See table 1391 in section 75.7 for details on how to enable and configure group adaptive routing.

75.2.6 Packet distribution

Packet distribution can be used to implement multicast and broadcast addresses, and can be enabled for both physical and logical addresses. Packet distribution is enabled and configured by programming the corresponding RTR.RTPMAP register.

When a packet arrives, and packet distribution is enabled for the packet's address, the router looks at the group of ports selected by the corresponding RTR.RTPMAP register. If all of the selected ports are ready, the packet is transmitted on all the ports. Ready in this context means that the port's link interface is in run-state and currently not sending any other packet. If one or more of the selected ports are not ready, the incoming packet will either be spilled or transmitted once all ports are ready. The action taken depends on the setting of the input port's data character timer (section 75.2.14), the spill-if-not-ready feature for the address (section 75.2.9), and the link-start-on-request feature for the output ports (section 75.2.12). See table 1391 in section 75.7 for details on how to enable and configure packet distribution.

75.2.7 Port disable

A port can be disabled for data traffic by setting the corresponding RTR.PCTRL.DI bit. Incoming packets on a disabled port are silently spilled, and no packets are routed to a disabled port. A disabled port will not be included in any group used for group adaptive routing or packet distribution, even if the corresponding bit in that address' RTR.RTPMAP.PE field is set. When routing packets that are

GRIP

Apr 2024, Version 2024.1

1151

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

incoming on other ports, the router will simply behave as if the disabled port did not exist. The RTR.PCTRL.DI bit only affects routing of data, thus the transmission and reception of time-codes and distributed interrupt codes are not affected.

The link interface for a SpaceWire port is not affected solely by the RTR.PCTRL.DI bit. However, note that the RTR.PCTRL.DI bit, together with the RTR.PCTRL.LD bit, is used to clock-gate a SpaceWire port (see section 75.2.24).

75.2.8 Static routing

The router supports a feature called static routing, which can be enabled individually per port. When enabled, all incoming packets on the port are routed based on the physical address specified in the port's RTR.PCTRL2.SC field, and the setting of the corresponding RTR.PCTRL2.SC bit, instead of the address in the packets. Header deletion is not used for the incoming packets when static routing is enabled, which means that the first byte of the packets are always sent to the output port as well. Static routing to port 0 is not allowed, and will generate an invalid address error if attempted.

The STATICROUTEEN signal works as a global enable / disable for the static routing feature during reset. The feature is enabled if the signal is high during reset, and disabled if the signal is low during reset. The RTR.RTRCFG.SR bit shows if the static routing feature is globally enabled or disabled.

Note that when static routing is enabled for a port, it is not possible to access the configuration port from the same port.

75.2.9 Spill-if-not-ready

The spill-if-not-ready feature can be enabled individually for each physical and logical address by configuring the corresponding RTR.RTACTRL.SR bit. When enabled, an incoming packet is spilled if the selected output port's link interface is not in run-state. If group adaptive routing is used for the incoming packet then the packet is only spilled if none of the ports in the group is in run-state. If packet distribution is used for the incoming packet then the packet is spilled unless the link interfaces for all selected output ports are in run-state. The spill-if-not-ready feature has priority over the incoming port's data character timer (section 75.2.14) and the output port's link-start-on-request feature (section 75.2.12). This means that if the spill-if-not-ready feature is enabled, the packet is spilled before the timer starts, and the link-start-on-request feature will never be activated.

75.2.10 Self addressing

Self addressing occurs when a selected output port for a packet is the same port as the input port. Whether or not this is allowed is controlled by the RTR.RTRCFG.SA bit. If self addressing is not allowed, the incoming packet is spilled and an invalid address error occurs.

When group adaptive routing is used, and self addressing is not allowed, the input port is still allowed to be in the group of ports configured for the packet. The packet is not spilled until the router actually selects the input port as output port. If the router selects one of the other ports in the group, the packet is not spilled.

When packet distribution is used, and self addressing is not allowed, the input port is not allowed to be in the group of ports configured for the packet, since the packet should be sent to all ports in the group.

75.2.11 Invalid address error

An invalid address error occurs under the conditions listed below.

- When an incoming packet's address corresponds to a non-existing port (physical addresses 20-31).

- When an incoming packet's address is a logical address that is not enabled (RTR.RTACTRL.EN = 0).

GRIP
Apr 2024, Version 2024.1
1152
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- When an incoming packet's address is a logical address for which the corresponding RTR.RTPMAP register is not initialized, or the corresponding RTR.RTPMAP.PE field set to all zeroes.

- When only one output port is selected for an incoming packet, and that port is disabled (RTR.PCTRL.DI = 1).

- When self addressing occurs, and the router is configured not to allow self addressing (RTR.RTRCFG.SA = 0).

- When a packet is routed with the static routing feature, and the physical address programmed in RTR.PCTRL2.SD is 0 (static routing to port 0 is not allowed).

For all the invalid address cases above, the incoming packet is spilled, and the RTR.PSTS.IA bit corresponding to the input port will be set to 1.

75.2.12 Link-start-on-request

The link-start-on-request feature gives the possibility to automatically start a SpaceWire port's link interface when a packet is routed to the port (i.e, port is selected as output port). Each port can have the feature individually enabled by setting the corresponding RTR.PCTRL.LR bit to 1.

If a packet arrives, and the link interface of the selected output port is not in run-state, and the port has the link-start-on-request feature enabled, the router will try to start the link interface under the following conditions:

1. The link interface is not already trying to start (RTR.PCTRL.LS = 0).

2. The link is not disabled (RTR.PCTRL.LD = 0).

3. The spill-if-not-ready feature is not enabled for the packet being routed.

The link will continue to be started until either the RTR.PCTRL.LD bit is set to 1, or until the link is disabled through the auto-disconnect feature, described in section 75.2.13.

The link-start-on-request feature is only available for the SpaceWire ports, since the configuration port, FIFO ports, and AMBA ports does not have a link interface FSM, and are therefore always considered to be in run-state.

75.2.13 Auto-disconnect

The auto-disconnect feature gives the possibility to automatically disable the link interface of a SpaceWire port if the port has been inactive for a long enough period of time. Each port can have the feature individually enabled by setting their corresponding RTR.PCTRL.AD bit to 1. The amount of time the port needs to be inactive for is decided by the settings of the global prescaler register (RTR.PRESCALER), and the port's individual timer register (RTR.PTIMER). This time period is the same as the timeout period used by the port's data character timer when recovering from deadlock situations (see section 75.2.14). If the auto-disconnect feature is enabled, then a SpaceWire port will automatically disable its link interface under the following conditions:

1. The link interface entered run-state because it was started by the link-start-on-request feature, described in section 75.2.12.

2. The packet that caused the link interface to start has finished (either sent or spilled).

3. Nothing has been transmitted or received on the port for the duration of the time period specified by the RTR.PRESCALER register, and the corresponding RTR.PTIMER register.

4. The port's corresponding RTR.PCTRL.LS bit has not been set to 1.

The auto-disconnect feature is only available for the SpaceWire ports, since the configuration port and FIFO ports, and AMBA ports does not have a link interface FSM, and are therefore always considered to be in run-state.

75.2.14 Port data character timers

Timer functionality can be optionally implemented by setting the timerbits VHDL generic to a non-zero value.

Each port has an individual data character timer, which can be used to timeout an ongoing data transfer in order to recover from a deadlock situation. There are two different timeouts defined: overrun timeout, and underrun timeout. An overrun timeout is when the input port has data available, but the output port(s) can not accept data fast enough. An underrun timeout is when the output port(s) can accept more data, but the input port can not provide data fast enough.

The timeout period for a port is set in its corresponding RTR.PTIMER register, and the timer is enabled through the corresponding RTR.PCTRL.TR bit. Timeouts due to overrun and underrun can also be individually enabled / disabled through the corresponding RTR.PCTRL2.OR and RTR.PCTRL2.UR bits.

It is always the input port's data character timer that is used for timing data transfers. When the timer is enabled, it counts down on every tick from the global prescaler (RTR.PRESCALER register). If a data character is transmitted from the input port to the output port(s), then the timer is restarted. If the timer expires, the ongoing packet is spilled, and an EEP is written to the transmit FIFO of the output port(s).

The range of the timeout period depends on the system clock frequency, and is calculated with the following formula:

<timeout period> = (<clock period> x (RTR.PRESCALER+1)) x RTR.PTIMER

Sub-sections 75.2.14.1 through 75.2.14.4 clarifies the behaviour of the timers for different scenarios that can occur when a packet arrives.

75.2.14.1 Timer disabled

If the data character timer for an input port is disabled, the incoming packet will wait indefinitely for the output port(s) to be ready, unless the spill-if-not-ready feature is enabled for the packet's address (see section 75.2.9).

75.2.14.2 Timer enabled, but output port(s) not in run state

If the spill-if-not-ready feature (see section 75.2.9) is disabled for the incoming packet's address, the input port's data character timer is started when the packet arrives, and if the output port's link interface has not entered run-state when the timer expires, the packet is spilled. When group adaptive routing is used for the incoming packet, it is enough for one of the possible output ports to enter run-state before the timer expires for the packet to be transmitted. If packet distribution is used, all the output ports must enter run-state before the timer expires, otherwise the packet is spilled.

If the link-start-on-request feature is enabled for an output port, that port will try to enter run-state when the packet arrives. However, the input port's timer is unaffected of this, and will still only wait for its configured timeout period, before spilling the packet.

A timeout due to the output port not being in run-state is classified as a overrun timeout, which means that the RTR.PCFG2.OR bit for the input port must be set in order for the packet to be spilled. If the RTR.PCFG2.OR bit is not set, the packet will wait indefinitely (unless spill-if-not-ready is enabled).

75.2.14.3 Timer enabled, output port(s) in run-state but busy with other transmission

The input port's data character timer will not start, and the incoming packet will wait indefinitely until the output port either becomes free or leaves run-state. When group adaptive routing is used for the incoming packet, it is enough for one of the possible output ports to be in run-state to prevent the timer from starting. If packet distribution is used, all the output ports must be in run-state to prevent the timer from starting.

GRIP
Apr 2024, Version 2024.1

75.2.14.4 Timer functionality when accessing the configuration port

The timer functionality is basically the same for the configuration port as for the other ports. When the command is being received, the configuration port is the output port of the data transfer, and when the reply is being sent, the configuration port is the input port of the data transfer. The differences between the configuration port and the other ports are:

- The configuration port can always accept data fast enough, which means that an overrun timeout will never occur when a command is being received.

- The configuration port can always send data fast enough, which means that an underrun timeout will never occur when a reply is being sent.

75.2.15 Packet length truncation

Packet length truncation monitors the length of an incoming packet, and increases a counter for each received data character. If the counter reaches a value larger than the input port's RTR.MAXPLEN register, and truncation is enabled for the input port (RTR.PCTRL.PL = 1), the rest of the packet is spilled, and an EEP is written to the FIFO of the output port(s). Each port has its own RTR.MAX-PLEN register and counter in order to allow different maximum lengths for different ports.

Packet length truncation can also be enabled for port 0. In that case, it is the length of the RMAP / SpaceWire Plug-and-Play reply packet that is monitored.

75.2.16 System time-distribution

The router supports system time distribution through time-codes, as defined in ECSS-E-ST-50-12C [SPW]. It contains a global time-counter register (RTR.TC) where the latest received time-code can be read. All ports support time-code transmission and reception. All incoming time-codes update the RTR.TC register. If the incoming time-code has a time value which is plus one (modulo 64) compared to the old RTR.TC value, the time-code is forwarded to all the other ports. The time-code is not sent out onto the port on which it arrived.

Time-codes can be globally enabled / disabled through the RTR.TC register, as well as individually enabled / disabled per port through respective RTR.PCTRL.TE bit. When time-codes are disabled for a port, all incoming time-codes on that port are discarded, and no time-codes will be forwarded to the port.

The router can be configured to either filter out all incoming time-codes that does not have the two control flags (bit 7:6) set to "00", or to discard the control flags and allow them to have any value. This configuration is done through the RTR.RTRCFG.TF bit. The value of the control flags for the last received time-code can also be read from the RTR.TC register. Note that if interrupt distribution is globally enabled (RTR.RTRCTRL.IE = 1), only control flags "00" are considered as time-codes, no matter the value of the RTR.RTRCFG.TF bit.

75.2.17 SpaceWire distributed interrupt support

The router supports SpaceWire distributed interrupts. It can be configured to operate in two modes, interrupt with acknowledgment mode and extended interrupt mode. In the interrupt with acknowledgment mode, 32 interrupt numbers are supported, whereas the extended interrupt mode supports 64 interrupt numbers. The operation mode is configured through the RTR.RTRCFG.EE bit.

A distributed interrupt code is a control code that has the control flags (bits 7:6) always set to "10".

- *Interrupt with acknowledgment mode:* A distributed interrupt code that has bit 5 set to 0 is called an interrupt code, and bits 4:0 specify an interrupt number between 0 and 31. When operating in the interrupt with acknowledgment mode, a distributed interrupt code with bit 5 set to 1 is called an interrupt acknowledgment code, which is used to acknowledge the interrupt with the interrupt number specified by bits 4:0.

GRIP

Apr 2024, Version 2024.1

1155

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

- *Extended interrupt mode:* When operating in the extended interrupt mode, a distributed interrupt code with bit 5 set to 1 is called an extended interrupt code, and bits 4:0 specify an interrupt number between 32 and 63. If bit 5 is set to 0, bits 4:0 specify an interrupt number between 0 and 31.

The interrupt codes and extended interrupt codes are generated by the source of the interrupt event, while the interrupt acknowledgment code is sent by the interrupt handler for the corresponding interrupt number.

The router has two 32-bit ISR register (RTR.ISR0 and RTR.ISR1) where each bit corresponds to one interrupt number. A bit in the ISR registers is set to 1 when an interrupt code or extended interrupt code with the corresponding interrupt number is received. A bit in the ISR registers is set to 0 when an interrupt acknowledgment code with the corresponding interrupt number is received. Therefore, the ISR registers reflect the status of all interrupt numbers. Each interrupt number has also its own timer which is used to clear the ISR register bit if an interrupt acknowledgment code is not received before the timer expires (for example if operating in the extended interrupt mode), as well as an optional timer which is used to control how fast a bit in the RTR.ISR register is allowed to toggle. See section 75.2.17.2 for more details on the ISR timers. Note that although it is possible to clear the bits in the ISR registers, these registers should normally only be used for diagnostics and FDIR.

75.2.17.1 Receiving and transmitting distributed interrupt codes

When a distributed interrupt code is received on a port, or the auxiliary time-code / distributed interrupt code interface, the following requirements must be fulfilled in order for the code to be distributed:

1. Interrupt distribution is globally enabled (RTR.RTRCTRL.IE = 1), and enabled for the port that received the code (corresponding RTR.PCTRL.IC = 1).

2. If the received code is an interrupt code, the RTR.PCTRL2.IR bit for the port must be set to 1. If the received code is an interrupt acknowledgment code or extended interrupt code, the RTR.PCTRL2.AR bit for the port must be set to 1.

3. If the code is an interrupt code or extended interrupt code, the interrupt number's corresponding bit in RTR.ISR0 or RTR.ISR1 must be 0. If the code is an interrupt acknowledgment code, the corresponding bit in RTR.ISR0 must be 1.

4. No previous distributed interrupt code with the same interrupt number is waiting to be distributed.

5. The ISR change timers (see section 75.2.17.2) are either globally disabled (RTR.RTRCFG.IC = 0) or the interrupt number's corresponding ISR change timer has expired.

If one of the requirements above is not fulfilled, then the received code is discarded. If all of the requirements above are fulfilled, then the received code is placed in a queue. The queue is then serviced in one of the four following ways, depending on the settings of the RTR.RTRCFG.IS and RTR.RTRCFG.IP bits:

1. All interrupt codes have priority over all interrupt acknowledgment codes / extended interrupt codes (RTR.RTRCFG.IP = 0), and the interrupt numbers are serviced through a round-robin scheme (RTR.RTRCFG.IS = 0). This is the default service scheme after reset / power-up.

2. All interrupt codes have priority over all interrupt acknowledgment codes / extended interrupt codes (RTR.RTRCFG.IP = 0), and the interrupt numbers are serviced with priority to lower interrupt numbers (RTR.RTRCFG.IS = 1).

3. All interrupt acknowledgment codes / extended interrupt codes have priority over all interrupt codes (RTR.RTRCFG.IP = 1), and the interrupt numbers are serviced through a round-robin scheme (RTR.RTRCFG.IS = 0).

4. All interrupt acknowledgment codes / extended interrupt codes have priority over all interrupt codes (RTR.RTRCFG.IP = 1), and the interrupt numbers are serviced with priority to lower interrupt numbers (RTR.RTRCFG.IS = 1).

GRIP
Apr 2024, Version 2024.1

1156

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

When a distributed interrupt code has been selected from the queue, it is forwarded to all ports (except the port it was received on) that has interrupt distribution enabled (RTR.PCTRL.IC = 1), and that has enabled transmission of interrupt codes or interrupt acknowledgment codes / extended interrupt codes (RTR.PCTRL2.IT and RTR.PCTRL2.AT respectively).

75.2.17.2 Interrupt distribution timers

Each interrupt number has two corresponding timers, called the ISR timer, and ISR change timer:

The ISR timer is started and reloaded with the value from the RTR.ISRTIMER register each time a received interrupt code / extended interrupt code sets the corresponding RTR.ISR0 / RTR.ISR1 bit to 1. If an interrupt acknowledgment code is received, the corresponding ISR timer is stopped. If the ISR timer expires before an interrupt acknowledgment code is received, the corresponding bit in the RTR.ISR0 or RTR.ISR1 register is cleared. The use of ISR timers is always enabled. In the interrupt with acknowledgment mode, the purpose of the timers is to recover from situations where an interrupt acknowledgment code is lost. In the extended interrupt mode, the purpose of the ISR timers is to limit the rate of which interrupt codes are forwarded. It is important to configure the reload value for the ISR timer correctly. In the interrupt with acknowledgment mode, the reload value must not be less than the worst propagation delay for the interrupt code, plus the maximum delay in the interrupt handler, plus the worst propagation delay for the interrupt acknowledgment code. In the extended interrupt mode, the reload value must not be less than the worst propagation delay for the interrupt code / extended interrupt code.

The ISR change timers are timers that optionally can be used to control the minimum delay between two consecutive changes to the same RTR.ISR0 / RTR.ISR1 bit. The purpose of the timers is to protect against unexpected code occurrences that could occur, for example, due to a network malfunction or a babbling idiot. If the use of ISR change timers is enabled (RTR.RTRCFG.IC = 1), then the ISR change timer for an RTR.ISR0 / RTR.ISR1 bit is started and reloaded with the value from the RTR.ISRCTIMER register each time a received distributed interrupt code makes the RTR.ISR0 / RTR.ISR1 bit change value. Until the timer has expired, the corresponding RTR.ISR0 / RTR.ISR1 bit is not allowed to change value, and any received distributed interrupt code with that interrupt number is discarded. In the extended interrupt mode, the ISR change timers are not used, and should be disabled.

75.2.17.3 Interrupt code generation

In addition to distributing interrupt codes received on the ports, the router can also generate an interrupt code / extended interrupt code when an internal error event occurs, such that the IRQ pin is set to 1. See section 75.2.21 for information about how to control which errors that set the IRQ pin. In addition to the errors described in 75.2.21 the IRQ pin can also be configured to be set when a SpaceWire port's link interface enters run-state.

Everything in sections 75.2.17.1 and 75.2.17.2 also applies when the distributed interrupt code is generated by the router. The only difference is that a distributed interrupt code generated by the router will not be discarded if it is not allowed to be distributed. Instead, the distributed interrupt code will be distributed later, as soon as it is allowed. The only time a distributed interrupt code generated by the router is not distributed is if the bits in RTR.PIP are cleared by software before the interrupt code is allowed to be sent.

The interrupt code generation is controlled through the RTR.ICODEGEN register, and in addition to the enable / disable bit (RTR.ICODEGEN.EN), the following features are available:

- The interrupt number to use for a generated distributed interrupt code is programmable through the RTR.ICODEGEN.IN field.

- The generated distributed interrupt code can be configured to be either level type, or edge type. Level type means that a new distributed interrupt code will be sent as long as the IRQ pin is set (i.e. as long as any bit in the RTR.PIP register is set). Edge type means that a new distributed

GRIP
Apr 2024, Version 2024.1
1157
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

interrupt code will only be sent when a new error event occurs (an RTR.PIP bit toggles from 0 to 1). The type is selected by the RTR.ICODEGEN.IT bit.

- A timer can be enabled through the RTR.ICODEGEN.TE bit. This timer controls the minimum time between a received interrupt acknowledgment code and the distribution of a new generated interrupt code. The timer is started and reloaded with the value from the RTR.AITIMER register when an interrupt acknowledgment code is received, if the router was the source of the corresponding interrupt code. Until the timer has expired, a new generated interrupt code will not be distributed. The reload value should not be less than the worst propagation delay for the interrupt acknowledgment code. This timer is unused when operating in the extended interrupt mode.

- Through the RTR.ICODEGEN.AH and RTR.ICODEGEN.UA bits the router can be configured to, upon receiving an interrupt acknowledgment code, or the when the ISR timer expires, automatically clear the RTR.PIP bits that were set when the distributed interrupt code was generated.

75.2.18 Auxiliary time-code / distributed interrupt code interface

There is an auxiliary time-code / distributed interrupt code interface that consists of the following signals AUXTICKIN, AUXTICKOUT, AUXTIMEOUT[7:0], AUXTIMEIN[7:0], and AUXTIMEINEN.

The AUXTICKOUT is set high for one CLK cycle when a valid time-code or distributed interrupt code is received on any of the ports, and the value of the time-code / distributed interrupt code is presented on the AUXTIMEOUT[7:0] signals. The rules that determine whether or not a received time-code / distributed interrupt code will be sent out on the auxiliary interface are the same as for all the other ports.

The AUXTICKIN allows for transmission of time-codes and distributed interrupt codes from the auxiliary interface to the other ports. The AUXTICKIN signal can be either synchronous or asynchronous to CLK. In the synchronous mode, a tick is detected each clock cycle that AUXTICKIN is high. In the asynchronous mode, a tick is detected each time a rising edge is seen on AUXTICKIN.

If AUXTIMEINEN is not asserted when a tick i detected, the router's internal time-count value (RTR.TC.TC) is used to send a new time-code out onto the ports. If AUXTIMEINEN is asserted when a tick is detected, the router checks the value of the AUXTIMEIN[7:0] signals to determine if a time-code or distributed interrupt code should be sent. Note that, in the asynchronous mode, AUXTIMEIN[7:0] must hold their value for at least two CLK cycles after the rising edge on AUXTICKIN.

The rules that determine whether a distributed interrupt code should be forwarded to the ports are the same as when a distributed interrupt code is received from any other port. However, for time-codes, the value on AUXTIMEIN[7:0] is always forwarded, and the router's internal time-count value is updated. Note that time-codes / distributed interrupt codes received through the auxiliary interface is not forwarded back out onto the interface itself.

Just as for the router ports, the auxiliary interface has enable / disable bits for time-codes (RTR.RTRCFG.AT) and distributed interrupt codes (RTR.RTRCFG.AI), which need to be set high in order for respective code to be transmitted / received.

75.2.19 SpaceWire-D support

75.2.19.1 Time-code / distributed interrupt code truncation

The router supports truncation of packets when it receives a valid time-code / distributed interrupt code (time-code or distributed interrupt code). A time-code is considered valid when the value equals the internal time count plus one (modulo 64). An distributed interrupt code is considered valid if the corresponding ISR bit is flipped due to reception of the code. The feature can be enabled individually for each port by setting the corresponding RTR.PCTRL.TS bit to 1. A filter, allowing only certain time-codes / distributed interrupt codes to spill packets, can also be configured individually for each port (see RTR.PCTRL2 register).

GRIP

Apr 2024, Version 2024.1

1158

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

If a packet transfer is ongoing when a valid time-code / distributed interrupt code is received, and the code matches the filter in RTR.PCTRL2, the rest of the packet is spilled, and an EEP is written to the FIFO of the output port(s).

Time-code / distributed interrupt code truncation can also be enabled for port 0. In that case, it is the RMAP / SpaceWire Plug-and-Play reply packet that is spilled.

75.2.20 Character and packet counters

Each port, except port 0, has counters for incoming and outgoing characters and packets. For the character counters (RTR.ICHARCNT / RTR.OCHARCNT registers), only SpaceWire data characters are counted (not EOP/EEP). Characters deleted due to header deletion are counted on the incoming port but not on the outgoing port. For the packet counters (RTR.IPKTCNT / RTR.OPKTCNT registers), each EOP/EEP that is preceded by at least one data character is counted as a packet. The counters wrap around, and signal an overflow, when they reach the maximum value. The counters are accessed through the configuration port. See section 75.7 for details.

75.2.21 Error detection and reporting

The router can detect and report the following errors:

- SpaceWire link errors: parity error, disconnect error, escape error, credit error (see ECSS-E-ST-50-12C [SPW] for definition of these errors).

- Packet spill due to: timeout (see section 75.2.14), packet length truncation (see section 75.2.15), time-code / distributed interrupt code truncation (see section 75.2.19.1), and spill-if-not-ready feature (see section 75.2.9)

- Invalid address error (see section 75.2.11)

- RMAP errors (see section 75.6.1)

- Memory errors in the memory used for the routing table, RMAP command buffers, and port transmit and receive FIFO (see section 75.2.25)

- SpaceWire Plug-and-Play errors (see section 75.7.1)

Each error type has corresponding status bits in respective RTR.PSTS register (RTR.PSTSCFG for the configuration port). Common for all the status bits is that they are set when the error is detected, and stay set until they are cleared manually.

Another way the router can report an error is to asserted the IRQ pin. Whether or not the IRQ pin is set when one of the above mentioned errors occur is controlled by the two mask registers, RTR.IMASK and RTR.IPMASK. When the error occur and both the port's corresponding bit in RTR.IPMASK as well as the error type's corresponding bit in RTR.IMASK, are set, then the port's corresponding bit in the Port interrupt pending register (RTR.PIP) is set. The IRQ pin is high as long as any bit in the RTR.PIP register is set.

The router can also be configured to generate a distributed interrupt code when the IRQ pin gets set. See section 75.2.17 for more details.

75.2.22 Setting link-rate for the SpaceWire ports

The initialization divisor register (RTR.IDIV) determines the link-rate during initialization (all states up to and including the connecting-state) for all SpaceWire ports. The register is also used to calculate the link interface FSM timeouts for all SpaceWire ports (6.4 us and 12.8 us, as defined in the SpaceWire standard). The RTR.IDIV register should always be set so that a 10 Mbit/s link-rate is achieved during initialization. In that case the timeout values will also be calculated correctly. The reset value of the RTR.IDIV.ID field is taken from the IDIVISOR[7:0] signal, see Table 1403 for details.

To achieve a 10 Mbit/s link-rate, the RTR.IDIV register should be set according to the following formula:

GRIP
Apr 2024, Version 2024.1
1159
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

RTR.IDIV = (<frequency in MHz of internal SpaceWire clock> / 10) - 1

The link-rate in run-state can be controlled individually per SpaceWire port with the run-state divisor located in each port's control register (RTR.PCTRL.RD field). The link-rate in run-state is calculated according to the following formula:

<link-rate in Mbits/s> = <frequency in MHz of internal SpaceWire clock> / (RTR.PCTRL.RD+1)

The value in RTR.PCTRL.RD only affects the link-rate in run-state, and does not affect the 6.4 us or 12.8 us timeouts values. The reset value of the RTR.PCTRL.RD field is taken from the IDIVISOR[7:0] signal, see Table 1394 for details.

75.2.23 SpaceWire transceiver enable signals

There enable signals SPWEN, one for each SpaceWire port, intended for controlling external transceivers. Each index corresponds to the port with the same number. SPWEN can be used for enabling / disabling external LVDS transceivers.

The enable signal is active as long as either the corresponding LVDS driver or corresponding LVDS receiver is powered on.

75.2.24 Power saving features

The router supports two power saving features: signals for LVDS driver / receiver power down, and signals for clock gating of the ports.

When a SpaceWire port is inactive, the LVDS driver power-down signals is asserted. A SpaceWire port is considered inactive if one of the following conditions are true:

1. Link interface is disabled, either because RTR.PCTRL.LD is set to 1, or because of the automatic-disconnect feature (see section 75.2.13).

2. Link interface is not disabled, but the transmitter has not been enabled since the last time the link interface was disabled.

3. After reset, until the LVDS driver becomes enabled. The LVDS driver is enabled in the started-state, connecting-state, and run-state.

The signal for LVDS receiver is only asserted when the link interface is disabled.

For the clock gate signal for a SpaceWire port to be asserted, both the link disable bit (RTR.PCTRL.LD) and the port disable bit (RTR.PCTRL.DI) should be set. The port stays clock gated until either of the two bits are cleared.

75.2.25 On-chip memories

The router can have several memories on-chip. They are usually selected from technology specific RAM blocks but generic models can also be used which either make the synthesis tool infer the memories or use registers instead.

There are two memory blocks in the routing table, one for the port setup registers and one for the routing table. The port setup memory bit width is equal to the number of ports including the configuration port with depth 256. The routing table is 256 locations deep and 3 bits wide.

Each port excluding the configuration port also have FIFO memories. The SpaceWire ports have one FIFO per direction (rx, tx) which are 10-bit respective 9-bit wide. The depth is controlled with the fifosize VHDL generic. The FIFO ports have the exact same FIFO configuration as the SpaceWire ports controlled by the same generic.

The AMBA ports have one 9-bit wide receiver FIFO controlled by the fifosize generic and two 32-bit wide AHB FIFOs. The depth of the latter two is controlled with the fifosize2 generic (see the AMBA port section for more information).

GRIP
Apr 2024, Version 2024.1

1160

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

All of the memories are instantiated using either the syncram_2p of syncram_2pft components from GRLIB (see the syncram_2p section in the GRIP manual for more information) depending on the value of the ft generic. If ft is set to 0 the syncram_2p is used and there is no fault-tolerance support. If ft is nonzero the syncram_2pft component is chosen and there are two variants of fault-tolerance depending on the value. Setting ft=1 selects parity and ft=2 selects TMR.

Parity is used to protect the memories and up to four bits per word can be corrected and there is a signal indicating an uncorrectable error. TMR is used to protect the memories and a voter determines the correct result. No errors are detectable for TMR and thus the error signal is not used.

If a memory error occurs in the port setup table or the routing table the memory error (ME) bit in the router configuration/status register is set and remains set until cleared by the user. If a memory error is detected in any of the ports FIFO memories the memory error (ME) bit in the respective port status register is set and remains set until cleared by the user. The ME bits are only set for uncorrectable errors.

When an uncorrectable error is detected in the port setup or routing table when a packet is being routed it will be discarded. Unocrrectable errors in the FIFO memories are not handled since they only affect the contents of the routed packet not the operation of the router itself. These type of errors should be caught by CRC checks if used in the packet.

The ME bit for the ports is only usable for detecting errors and statistics since there is no need to correct the error manually since the packet has already been routed when it is detected. The ME indication for the routing table and port setup registers can be used for starting a scrubbing operation if detected. There is also an option of having automatic scrubbing (see section 75.2.25.1)

If one or more of the memory error bits described above are set the signal ro.merror will be asserted.

75.2.25.1 Autoscrub

An autoscrubbing feature can be optionally enabled using the autoscrub VHDL generic.

With autoscrubbing enabled, the routing table and port setup registers are periodically read and rewritten. This is done to prevent a buildup of SEUs, which can cause an uncorrectable error in the memories. It runs in the background and has no timing impact on SpaceWire traffic but can delay configuration accesses by two cycles.

The scrubber starts at address 0 and simultaneously writes one location in the port setup memory and the routing table memory. It then waits for a timeout period before writing the next word. Eventually, the last location is reached and the process starts over from address 0.

The period between each word refresh is approximately 2^{26} system clock cycles (system clock used for AMBA system). The scrubber uses a free time slot, in which data traffic does not perform a table lookup to read and write the memories that causes a small nondeterminism in the period.

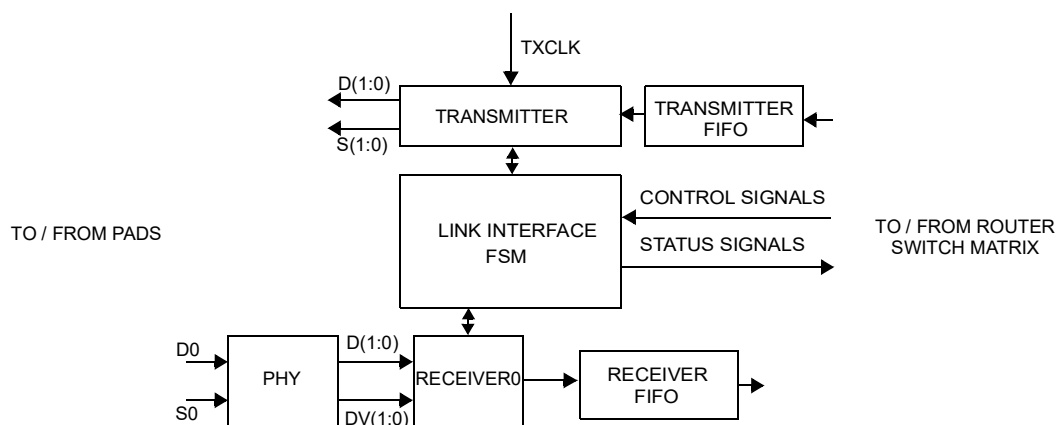
75.3   SpaceWire ports


Figure 199. Block diagram. Represents a configuration with *dualport*=0 (see sections 75.3.1 and 75.10).

Each SpaceWire port comprises a SpaceWire codec that implements an encoder-decoder compliant to ECSS-E-ST-50-12C [SPW]. This is the same SpaceWire codec core (GRSPW_CODEC) provided in GRLIB as a separate core. It is a very versatile core providing several external interface types. The receiver can be configured as self-clocking (XOR gate based), SDR-, DDR sampling or with an interface to an Frontgrade SpW transceiver (UT200SpWPHY01). The transmitter can also be configured with SDR, DDR or SpWPHY outputs. Both internal and external LVDS transceivers are supported. The interface to the router's switch matrix consists of a transmit FIFO, receive FIFO, and control and status signals, see Figure 199. The size of both transmit and receive FIFOs is configurable in terms of number of N-chars that they can store at any time; the default is 64 N-chars. All the configuration parameters and status information for the ports are accessible through the router's configuration port, either through RMAP or AMBA AHB (see section 75.7). For more detailed information about the codec itself see the SpaceWire codec section in the GRLIB IP library manual.

75.3.1   Redundant ports

Redundant ports can be optionally enabled for SpaceWire ports. This is configured using the *dualport* VHDL generic. The redundant port is part of the codec implementation and provides an extra set of SpaceWire transmit and receive signals. This means each SpaceWire router port will be connected to two external SpaceWire ports. Only one of the two external ports can have an active SpaceWire link at any given time and data transferred on that router port will be received and transmitted on the active link. The external port to use for the active link can be forced via the RTR.PCTRL register, or be determined automatically based on the current activity on primary and redundant port links.

75.3.2   Link-interface FSM

The link-interface FSM controls the link interface (a more detailed description is found in ECSS-E-ST-50-12C [SPW]). The low-level protocol handling (the signal and character level) is handled by the transmitter and receiver while the FSM handles the exchange level.

The link-interface FSM is controlled through the control signals provided in the RTR.PCTRL registers. The link can be disabled through the RTR.PCTRL.LD bit, which depending on the current state, either prevents the link-interface from reaching the started-state, or forces it to the error-reset state. When the link is not disabled, the link interface FSM is allowed to enter the started-state when either the RTR.PCTRL.LS bit is set, or the link-start-on-request feature described in section 75.2.12 is trying to start the port, or when a NULL character has been received and the RTR.PCTRL.AS bit is set.

GRIP

Apr 2024, Version 2024.1

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The current state of the link-interface determines which type of characters are allowed to be transmitted, which, together with the requests made from the host interface, determine what character will be sent.

When the link-interface is in the connecting- or run-state it is allowed to send FCTs. FCTs are sent automatically by the link-interface when possible. This is done based on the maximum value of 56 for the outstanding credit counter and the currently free space in the receive FIFO. FCTs are sent as long as the outstanding counter is less than or equal to 48, and there are at least 8 more empty FIFO entries than the counter value.

N-Chars are sent in the run-state when they are available from the transmit FIFO, and there are credits available. NULLs are sent when no other character transmission is requested, or when the FSM is in a state where no other transmission is allowed.

The credit counter (incoming credits) is automatically increased when FCTs are received, and decreased when N-Chars are transmitted. The credit counter for a SpaceWire port can be read in the corresponding RTR.CREDCNT register.

75.3.3 Transmitter

The state of the FSM, credit counters, possible request to send a time-code / distributed interrupt code, and requests from the transmit FIFO are used to decide the next character to be transmitted. The type of character and the character itself (for N-Chars and time-codes / distributed interrupt codes) to be transmitted are presented to the low-level transmitter, which run on the internal SpaceWire clock. For information on how to change the transmission rate, please see section 75.2.22.

The state of the FSM, credit counters, requests from the time-interface and requests from the transmitter FIFO are used to decide the next character to be transmitted. The type of character and the character itself (for N-Chars and Time-codes) to be transmitted are presented to the low-level transmitter which is located in a separate clock-domain.

75.3.4 Receiver

The receiver detects connections from other nodes and receives characters as a bit stream recovered from the data and strobe signals by the PHY module, which presents it as a data and data-valid signal.

The receiver is activated as soon as the link-interface leaves the error reset state. Then after a NULL is received it can start receiving any characters. It detects parity, escape and credit errors, which causes the link interface to enter the error-reset state.

Received L-Chars are the handled automatically by link-interface, while all N-Chars are stored in the receive FIFO.

75.3.5 Setting link-rate

The router's Initialization divisor register (RTR.IDIV) determines the link-rate during initialization (all states up to and including the connecting-state). The register is also used to calculate the link interface FSM timeouts (6.4 µs and 12.8 µs, as defined in the SpaceWire standard). The register's ID field should always be set so that a 10 Mbit/s link-rate is achieved during initialization. In that case the timeout values will also be calculated correctly.

To achieve a 10 Mbit/s link-rate, the ID field should be set according to the following formulas:

With single data rate (SDR) outputs:

ID = (<frequency in MHz of TXCLK> / 10) - 1

With double data rate (DDR) outputs, or when connected to Frontgrade SpaceWire transceiver:

ID = (2 x <frequency in MHz of TXCLK> / 10) - 1

GRIP

Apr 2024, Version 2024.1

1163

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The link-rate in run-state is controlled with the run-state divisor, which is set through the RD field of each port's Port control register. The link-rate in run-state is calculated according to the following formulas:

With SDR outputs:

<link-rate in Mbits/s> = <frequency in MHz of TXCLK> / (RD+1)

With DDR outputs / Frontgrade SpaceWire transceiver:

<link-rate in Mbits/s> = 2 x <frequency in MHz of TXCLK> / (RD+1)

The value of the RD field only affects the link-rate in run-state, and does not affect the 6.4 µs or 12.8 µs timeouts values.

Note that when using DDR ouputs, or when connected to Frontgrade SpaceWire transceiver, there is a limitation in the usable clock divisor values. All even values (except 0) will result in the same bitrate as the one higher odd number.

An example of clock divisor and resulting link-rate, with a TXCLK frequency of 50 MHz, is shown in the table 1356.

*Table 1356.*SpaceWire link-rate example with 50 MHz TXCLK

	Link-rate in Mbit/s	
Clock divisor value	SDR outputs	DDR outputs / Frontgrade SpaceWire transceiver
0	50	100
1	25	50
2	16.67	25
3	12.5	25
4	10	16.67
5	8.33	16.67
6	7.14	12.5
7	6.25	12.5
8	5.56	10
9	5	10

75.4   FIFO ports

A port configured as a FIFO port contains one FIFO in each direction to/from the switch matrix. The fifosize can be configured to 8, 16, 32 and 64 using a VHDL generic (note that the same generic is used for the fifosizes in the SpaceWire links and the AHB interfaces).

75.4.1 Transmitter

The transmitter FIFO interface consists of the following signals: txfull, txafull, txwrite, txchar, txcharcnt. Figure 200 illustrates the write operation. Note that txfull would only be asserted as illustrated in the figure when txcharcnt is 4 if the FIFO size is 4 (which is not the case typically).
Figure 200. Transmitter FIFO interface write cycle.

Txwrite is the write signal and each time when asserted on the rising edge of the clock the value on the txchar signal will be written into the transmitter FIFO if it is not full. If it is full the character will be dropped. Txcharcnt indicates the number of characters currently in the FIFO. Txfull is asserted when the FIFO is full and txafull is asserted when the FIFO is almost full. The almost full signal is configurable through the almostsize VHDL generic and will be asserted when the FIFO contains a number of characters more than or equal to fifosize-almostsize.

The transmitter FIFO can be reset through the port's control register using the TF bit.

75.4.2 Receiver

The receiver FIFO interface consists of the following signals: rxread, rxchar, rxcharav and rxaempty. Figure 201 illustrates the read operation. Note that rxcharav would only be deasserted as illustrated in the figure if the FIFO contained 4 characters.
Figure 201. Receiver FIFO interface read cycle.

Each time rxread is asserted on the rising edge of the clock a new character will be available on the rxchar output the next cycle if available. If the FIFO is empty the value is undefined. Rxcharav is asserted when the FIFO contains at least one character. Rxaempty is asserted when the FIFO is almost empty and is defined as when the FIFO contains a number of characters less than or equal to the almostsize VHDL generic.

The receiver FIFO can be reset using the RF bit in the port's control register.

75.4.3 Time-code transmit

The time-code transmit interface consists of the following signals: tickin, timein. Figure 202 illustrates the tickin operation.

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler
Figure 202. Time interface tickin operation.

75.4.4 Time-code receive

The time-code receive interface consists of the following signals: tickout, timeout. Figure 203 illustrates the tickout operation.
Figure 203. Time interface tickout operation.

The clock that all the interface signals are synchronized to is the same as the core clock (the clock that everything except the SpaceWire links' transmitters and receivers are running on). It can run on any frequency but to support the maximum throughput it has to be at least one eighth of the maximum link bitrate.

75.4.5 Bridge mode

The FIFO ports normally operate in standard mode which has been described so far in this section. But they can also be set in bridge mode through the bridge enable (BE) bit in the port's control register. The reset value of this signal is set through an input signal so this mode can be enabled per default after reset.

In bridge mode two FIFO ports can be connected together with automatic packet and time-code transfer without any glue logic. Table 1357 shows how the signals should be mapped. Rxaempty and txafull are unused in this mode.

75.5 AMBA ports

The AMBA ports are Frontgrade Gaisler's GRSPW2 controller with the SpaceWire codec removed.
Thus, the same drivers that are provided for the GRSPW2 can also be used for an AMBA port of the
router. Only one additional driver is needed, which handles the setup of the registers within the con-
figuration port.

75.5.1 Overview

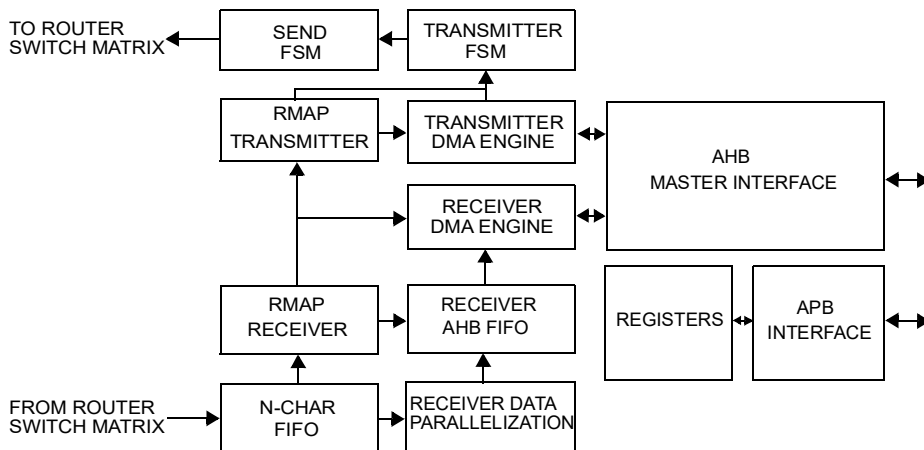
The router's AMBA ports are configured by register accesses through an APB interface. Data is trans-
ferred through one to four DMA channels using an AHB master interface. The number of DMA chan-
nels is configurable from one to four. Only byte addressed 32-bit big-endian AHB buses are
supported.


Figure 204. Block diagram of the Router DMA port

75.5.2 Operation

The main sub-blocks of the router AHB interfaces are the DMA engines, the RMAP target and the
AMBA interface. A block diagram of the internal structure can be found in figure 204.

GRIP

Apr 2024, Version 2024.1

1167

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The AMBA interface is divided into the AHB master interface and the APB interface. The DMA engines have FIFO interfaces to the router switch matrix. These FIFOs are used to transfer N-Chars between the AMBA bus and the other ports in the router.

The RMAP target is an optional part of the DMA port which can be enabled with a VHDL generic. The RMAP target handles incoming packets which are determined to be RMAP commands instead of the receiver DMA engine. The RMAP command is decoded and if it is valid, the operation is performed on the AHB bus. If a reply was requested it is automatically transmitted back to the source by the RMAP transmitter.

The AMBA ports are controlled by writing to a set of user registers through the APB interface and a set of signals. The different sub-modules are discussed in further detail in later sections.

75.5.2.1 Protocol support

The AMBA port only accepts packets with a valid destination address in the first received byte. Packets with address mismatch will be silently discarded (except in promiscuous mode which is covered in section 75.5.4.10).

The second byte is sometimes interpreted as a protocol ID a described hereafter. The RMAP protocol (ID=0x1) is the only protocol handled separately in hardware while other packets are stored to a DMA channel. If the RMAP target is present and enabled all RMAP commands will be processed, executed and replied automatically in hardware. Otherwise RMAP commands are stored to a DMA channel in the same way as other packets. RMAP replies are always stored to a DMA channel. More information on the RMAP protocol support is found in section 75.5.6 (note that this RMAP target is different from the one in the configuration port). When the RMAP target is not present or disabled, there is no need to include a protocol ID in the packets and the data can start immediately after the address.

All packets arriving with the extended protocol ID (0x00) are stored to a DMA channel. This means that the hardware RMAP target will not work if the incoming RMAP packets use the extended protocol ID. Note also that packets with the reserved extended protocol identifier (ID = 0x000000) are not ignored by the AMBA port. It is up to the client receiving the packets to ignore them.

When transmitting packets, the address and protocol-ID fields must be included in the buffers from where data is fetched. They are *not* automatically added by the AMBA port DMA engine.

Figure 205 shows the packet types accepted by the port. The port also allows reception and transmission with extended protocol identifiers but without support for RMAP CRC calculations and the RMAP target.

Addr	ProtID	D0	D1	D2	D3	..	Dn-2	Dn-1	EOP

Addr	D0	D1	D2	D3	D4	..	Dm-2	Dm-1	EOP
Figure 205. The SpaceWire packet types supported by the port.

75.5.3 Time-Code / distributed interrupt interface

75.5.3.1 Sending and receiving Time-Codes

To transmit a Time-Code through the register interface of an AMBA port, the RTR.AMBACTRL.TI bit should be written to 1. When the bit is written, the AMBA port's current time value (RTR.AMBATC.TIMECNT field) is incremented and a Time-Code consisting of the new time value together with the current control flags (RTR.AMBATC.TCTRL field) is sent. The RTR.AMBACTRL.TI bit will stay high until the Time-Code has been transmitted. Note that whether or not a Time-Code is forwarded to any other port after it has been sent by an AMBA port depends on the settings explained in 75.2.16.

GRIP

Apr 2024, Version 2024.1

1168

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

A Time-Code that is received by an AMBA port will be stored in the port's RTR.AMBATC register. There is also a possibility to generate AMBA interrupts and tick-out pulses. This is controlled through the RTR.AMBACTRL and RTR.AMBATC registers. See section 75.5.9 for details about these registers.

75.5.3.2 Sending and receiving distributed interrupts

To transmit a distributed interrupt code through the register interface of an AMBA port, the RTR.AMBAINTCTRL.II bit in should be written to 1. When the bit is written, the value of the RTR.AMBAINTCTRL.TXINT field determine which distributed interrupt code that will be sent. Note that whether or not a distributed interrupt code is forwarded to any other port after it has been sent by an AMBA port depends on the settings of the router and the state of that specific interrupt in the network. See 75.2.17 for details.

A distributed interrupt can also be configured to be generated automatically by the AMBA port upon certain events. This is controlled through the RTR.AMBAINTCTRL and RTR.AMBADMACTRL registers. See section 75.5.9 for details about these registers and features.

Distributed interrupt codes that are received by an AMBA port can be programmed to generate AMBA interrupts as well as tick out-pulses. See section 75.5.9 for details about these features.

75.5.3.3 Sending and receiving Time-Codes and distributed interrupts via signal interface

For all received control codes, Time-Codes or not, the control flags together with the time value are outputted on the TIMEOUT[7:0] signals, and the TICKOUT signal is asserted for one system clock cycle.

Control codes can be sent by asserting the TICKIN signal and place the value of the Time-Code / distributed interrupt to be sent on the TIMEIN[7:0] signals.

75.5.4 Receiver DMA channels

The receiver DMA engine handles reception of data from the SpaceWire network to different DMA channels.

75.5.4.1 Address comparison and channel selection

Packets are received to different channels based on the address and whether a channel is enabled or not. When the receiver N-Char FIFO contains one or more characters, N-Chars are read by the receiver DMA engine. The first character is interpreted as the logical address and is compared with the addresses of each channel starting from 0. The packet will be stored to the first channel with an matching address. The complete packet including address and protocol ID but excluding EOP/EEP is stored to the memory address pointed to by the descriptors (explained later in this section) of the channel.

Each SpaceWire address register has a corresponding mask register. Only bits at an index containing a zero in the corresponding mask register are compared. This way a DMA channel can accept a range of addresses. There is a default address register which is used for address checking in all implemented DMA channels that do not have separate addressing enabled and for RMAP commands in the RMAP target. With separate addressing enabled the DMA channels' own address/mask register pair is used instead.

If an RMAP command is received it is only handled by the target if the default address register (including mask) matches the received address. Otherwise the packet will be stored to a DMA channel if one or more of them has a matching address. If the address does not match neither the default address nor one of the DMA channels' separate register, the packet is still handled by the RMAP target if enabled since it has to return the invalid address error code. The packet is only discarded (up to and including the next EOP/EEP) if an address match cannot be found and the RMAP target is disabled.

GRIP
Apr 2024, Version 2024.1

1169

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Packets, other than RMAP commands, that do not match neither the default address register nor the DMA channels' address register will be discarded. Figure 206 shows a flowchart of packet reception.

At least 2 non EOP/EEP N-Chars needs to be received for a packet to be stored to the DMA channel unless the promiscuous mode is enabled in which case 1 N-Char is enough. If it is an RMAP packet with hardware RMAP enabled 3 N-Chars are needed since the command byte determines where the packet is processed. Packets smaller than these sizes are discarded.

75.5.4.2 Basic functionality of a channel

Reception is based on descriptors located in a consecutive area in memory that hold pointers to buffers where packets should be stored. When a packet arrives at the port the channel which should receive it is first determined as described in the previous section. A descriptor is then read from the channels' descriptor area and the packet is stored to the memory area pointed to by the descriptor. Lastly, status is stored to the same descriptor and increments the descriptor pointer to the next one. The following sections will describe DMA channel reception in more detail.

75.5.4.3 Setting up the port for reception

A few registers need to be initialized before reception to a channel can take place. The DMA channel has a maximum length register which sets the maximum packet size in bytes that can be received to this channel. Larger packets are truncated and the excessive part is spilled. If this happens an indication will be given in the status field of the descriptor. The minimum value for the receiver maximum length field is 4 and the value can only be incremented in steps of four bytes up to the maximum value 33554428. If the maximum length is set to zero the receiver will *not* function correctly.

Either the default address register or the channel specific address register (the accompanying mask register must also be set) needs to be set to hold the address used by the channel. A control bit in the DMA channel control register determines whether the channel should use default address and mask registers for address comparison or the channel's own registers. Using the default register the same address range is accepted as for other channels with default addressing and the RMAP target while the separate address provides the channel its own range. If all channels use the default registers they will accept the same address range and the enabled channel with the lowest number will receive the packet.

Finally, the descriptor table and control register must be initialized. This will be described in the two following sections.

75.5.4.4 Setting up the descriptor table address

The port reads descriptors from an area in memory pointed to by the receiver descriptor table address register. The register consists of a base address and a descriptor selector. The base address points to the beginning of the area and must start on a 1024 bytes aligned address. It is also limited to be 1024 bytes in size which means the maximum number of descriptors is 128 since the descriptor size is 8 bytes.

The descriptor selector points to individual descriptors and is increased by 1 when a descriptor has been used. When the selector reaches the upper limit of the area it wraps to the beginning automatically. It can also be set to wrap at a specific descriptor before the upper limit by setting the wrap bit in the descriptor. The idea is that the selector should be initialized to 0 (start of the descriptor area) but it can also be written with another 8 bytes aligned value to start somewhere in the middle of the area. It will still wrap to the beginning of the area.

If one wants to use a new descriptor table the receiver enable bit has to be cleared first. When the rxactive bit for the channel is cleared it is safe to update the descriptor table register. When this is finished and descriptors are enabled the receiver enable bit can be set again.

75.5.4.5 Enabling descriptors

As mentioned earlier one or more descriptors must be enabled before reception can take place. Each descriptor is 8 byte in size and the layout can be found in the tables below. The descriptors should be written to the memory area pointed to by the receiver descriptor table address register. When new descriptors are added they must always be placed after the previous one written to the area. Otherwise they will not be noticed.

A descriptor is enabled by setting the address pointer to point at a location where data can be stored and then setting the enable bit. The WR bit can be set to cause the selector to be set to zero when

GRIP

+46 31 7758650 | frontgrade.com/gaisler

reception has finished to this descriptor. IE should be set if an interrupt is wanted when the reception has finished. The DMA control register interrupt enable bit must also be set for an interrupt to be generated. The descriptor packet address should be word aligned. All accesses on the bus are word accesses so complete words will always be overwritten regardless of whether all 32-bit contain received data. Also if the packet does not end on a word boundary the complete word containing the last data byte will be overwritten. If the rxunaligned or rmap VHDL generic is set to 1 this restriction is removed and any number of bytes can be received to any packet address without excessive bytes being overwritten.

*Table 1358.*RXDMA receive descriptor word 0 (address offset 0x0)

31	30	29	28	27	26	25	24		0
TR	DC	HC	EP	IE	WR	EN		PACKETLENGTH	

31	Truncated (TR) - Packet was truncated due to maximum length violation.
30	Data CRC (DC) - 1 if a CRC error was detected for the data and 0 otherwise.
29	Header CRC (HC) - 1 if a CRC error was detected for the header and 0 otherwise.
28	EEP termination (EP) - This packet ended with an Error End of Packet character.
27	Interrupt enable (IE) - If set, an interrupt will be generated when a packet has been received if the receive interrupt enable bit in the DMA channel control register is set.
26	Wrap (WR) - If set, the next descriptor used by the GRSPW will be the first one in the descriptor table (at the base address). Otherwise the descriptor pointer will be increased with 0x8 to use the descriptor at the next higher memory location. The descriptor table is limited to 1 kbytes in size and the pointer will be automatically wrap back to the base address when it reaches the 1 kbytes boundary.
25	Enable (EN) - Set to one to activate this descriptor. This means that the descriptor contains valid control values and the memory area pointed to by the packet address field can be used to store a packet.
24: 0	Packet length (PACKETLENGTH) - The number of bytes received to this buffer. Only valid after EN has been set to 0 by the GRSPW.

*Table 1359.*RXDMA receive descriptor word 1 (address offset 0x4)

31		0
	PACKETADDRESS	

31: 0	Packet address (PACKETADDRESS) - The address pointing at the buffer which will be used to store the received packet. If the rxunaligned and rmap VHDL generics are both set to zero only bit 31 to 2 are used.

75.5.4.6 Setting up the DMA control register

The final step to receive packets is to set the control register in the following steps: The receiver must be enabled by setting the rxen bit in the DMA control register (see section 75.7). This can be done anytime and before this bit is set nothing will happen. The rxdescav bit in the DMA control register is then set to indicate that there are new active descriptors. This must always be done after the descriptors have been enabled or the port might not notice the new descriptors. More descriptors can be activated when reception has already started by enabling the descriptors and writing the rxdescav bit. When these bits are set reception will start immediately when data is arriving.

75.5.4.7 The effect to the control bits during reception

When the receiver is disabled all packets going to the DMA-channel are discarded if the packet's address does not fall into the range of another DMA channel. If the receiver is enabled and the address falls into the accepted address range, the next state is entered where the rxdescav bit is checked. This bit indicates whether there are active descriptors or not and should be set by the external application using the DMA channel each time descriptors are enabled as mentioned above. If the rxdescav bit is '0' and the nospill bit is '0' the packets will be discarded. If nospill is one the grspw waits until rxdes-

cav is set and the characters are kept in the N-Char fifo during this time. If the fifo becomes full further N-char transmissions are inhibited by stopping the transmission of FCTs.

When rxdescav is set the next descriptor is read and if enabled the packet is received to the buffer. If the read descriptor is not enabled, rxdescav is set to '0' and the packet is spilled depending on the value of nospill.

The receiver can be disabled at any time and will stop packets from being received to this channel. If a packet is currently received when the receiver is disabled the reception will still be finished. The rxdescav bit can also be cleared at any time. It will not affect any ongoing receptions but no more descriptors will be read until it is set again. Rxdescav is also cleared by the port when it reads a disabled descriptor.

75.5.4.8 Status bits

When the reception of a packet is finished the enable bit in the current descriptor is set to zero. When enable is zero, the status bits are also valid and the number of received bytes is indicated in the length field. The DMA control register contains a status bit which is set each time a packet has been received. The port can also be made to generate an interrupt for this event.

RMAP CRC logic is included in the implementation if the rmapcrc or rmap VHDL generic set to 1. The RMAP CRC calculation is always active for all received packets and all bytes except the EOP/EEP are included. The packet is always assumed to be a RMAP packet and the length of the header is determined by checking byte 3 which should be the command field. The calculated CRC value is then checked when the header has been received (according to the calculated number of bytes) and if it is non-zero the HC bit is set indicating a header CRC error.

The CRC value is not set to zero after the header has been received, instead the calculation continues in the same way until the complete packet has been received. Then if the CRC value is non-zero the DC bit is set indicating a data CRC error. This means that the port can indicate a data CRC error even if the data field was correct when the header CRC was incorrect. However, the data should not be used when the header is corrupt and therefore the DC bit is unimportant in this case. When the header is not corrupted the CRC value will always be zero when the calculation continues with the data field and the behaviour will be as if the CRC calculation was restarted

If the received packet is not of RMAP type the header CRC error indication bit cannot be used. It is still possible to use the DC bit if the complete packet is covered by a CRC calculated using the RMAP CRC definition. This is because the port does not restart the calculation after the header has been received but instead calculates a complete CRC over the packet. Thus any packet format with one CRC at the end of the packet calculated according to RMAP standard can be checked using the DC bit.

If the packet is neither of RMAP type nor of the type above with RMAP CRC at the end, then both the HC and DC bits should be ignored.

75.5.4.9 Error handling

If an AHB error occurs during reception the current packet is spilled up to and including the next EEP/EOP and then the currently active channel is disabled and the receiver enters the idle state. A bit in the channels control/status register is set to indicate this condition.

75.5.4.10 Promiscuous mode

The port supports a promiscuous mode where all received data (excluding EOPs/EEPs) is stored to the first enabled DMA channel regardless of the node address and possible early EOPs/EEPs. The AMBA port DMA RX maximum length register is still checked and packets exceeding this size are truncated.

GRIP
Apr 2024, Version 2024.1
1174
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

RMAP commands are still handled by the RMAP hardware target when promiscuous mode is enabled, if the RMAP enable bit in the AMBA port DMA control/status register is set. If the RMAP enable bit is cleared, RMAP commands are stored to a DMA channel instead.

75.5.5   Transmitter DMA channels

The transmitter DMA engine handles transmission of data from the DMA channels to the SpaceWire network. Each receive channel has a corresponding transmit channel which means there can be up to 4 transmit channels. It is however only necessary to use a separate transmit channel for each receive channel if there are also separate entities controlling the transmissions. The use of a single channel with multiple controlling entities would cause them to corrupt each other's transmissions. A single channel is more efficient and should be used when possible.

Multiple transmit channels with pending transmissions are arbitrated in a round-robin fashion.

75.5.5.1   Basic functionality of a channel

A transmit DMA channel reads data from the AHB bus and stores them in the transmitter FIFO for transmission on the SpaceWire network. Transmission is based on the same type of descriptors as for the receiver and the descriptor table has the same alignment and size restrictions. When there are new descriptors enabled the port reads them and transfer the amount data indicated.

75.5.5.2   Setting up the core for transmission

Four steps need to be performed before transmissions can be done with the port. First the link interface must be enabled and started by writing the appropriate value to the ctrl register. Then the address to the descriptor table needs to be written to the transmitter descriptor table address register and one or more descriptors must also be enabled in the table. Finally, the txen bit in the DMA control register is written with a one which triggers the transmission. These steps will be covered in more detail in the next sections.

75.5.5.3   Enabling descriptors

The descriptor table address register works in the same way as the receiver's corresponding register which was covered in section 75.5.4. The maximum size is 1024 bytes as for the receiver but since the descriptor size is 16 bytes the number of descriptors is 64.

To transmit packets one or more descriptors have to be initialized in memory which is done in the following way: The number of bytes to be transmitted and a pointer to the data has to be set. There are two different length and address fields in the transmit descriptors because there are separate pointers for header and data. If a length field is zero the corresponding part of a packet is skipped and if both are zero no packet is sent. The maximum header length is 255 bytes and the maximum data length is 16 Mbyte - 1. When the pointer and length fields have been set the enable bit should be set to enable the descriptor. This must always be done last. The other control bits must also be set before enabling the descriptor.

The transmit descriptors are 16 bytes in size so the maximum number in a single table is 64. The different fields of the descriptor together with the memory offsets are shown in the tables below.

The HC bit should be set if RMAP CRC should be calculated and inserted for the header field and correspondingly the DC bit should be set for the data field. This field is only used by the GRSPW when the CRC logic is available (*rmap* or *rmapcrc* VHDL generic set to 1). The header CRC will be calculated from the data fetched from the header pointer and the data CRC is generated from data fetched from the data pointer. The CRCs are appended after the corresponding fields. The NON-CRC bytes field is set to the number of bytes in the beginning of the header field that should not be included in the CRC calculation.

The CRCs are sent even if the corresponding length is zero, but when both lengths are zero no packet is sent not even an EOP.

75.5.5.4 Starting transmissions

When the descriptors have been initialized, the transmit enable bit in the DMA control register has to be set to tell the port to start transmitting. New descriptors can be activated in the table on the fly (while transmission is active). Each time a set of descriptors is added the transmit enable register bit should be set. This has to be done because each time the core encounters a disabled descriptor this register bit is set to 0.

*Table 1360.*TXDMA transmit descriptor word 0 (address offset 0x0)

31 18	17	16	15	14	13	12	11 8	7 0
RESERVED	DC	HC	RE	IE	WR	EN	NONCRCLEN	HEADERLEN

31: 18	RESERVED
17	Append data CRC (DC) - Append CRC calculated according to the RMAP specification after the data sent from the data pointer. The CRC covers all the bytes from this pointer. A null CRC will be sent if the length of the data field is zero.
16	Append header CRC (HC) - Append CRC calculated according to the RMAP specification after the data sent from the header pointer. The CRC covers all bytes from this pointer except a number of bytes in the beginning specified by the non-crc bytes field. The CRC will not be sent if the header length field is zero.
15	RESERVED
14	Interrupt enable (IE) - If set, an interrupt will be generated when the packet has been transmitted and the transmitter interrupt enable bit in the DMA control register is set.
13	Wrap (WR) - If set, the descriptor pointer will wrap and the next descriptor read will be the first one in the table (at the base address). Otherwise the pointer is increased with 0x10 to use the descriptor at the next higher memory location.
12	Enable (EN) - Enable transmitter descriptor. When all control fields (address, length, wrap and crc) are set, this bit should be set. While the bit is set the descriptor should not be touched since this might corrupt the transmission. The GRSPW clears this bit when the transmission has finished.
11: 8	Non-CRC bytes (NONCRCLEN)- Sets the number of bytes in the beginning of the header which should not be included in the CRC calculation. This is necessary when using path addressing since one or more bytes in the beginning of the packet might be discarded before the packet reaches its destination.
7: 0	Header length (HEADERLEN) - Header Length in bytes. If set to zero, the header is skipped.

*Table 1361.*TXDMA transmit descriptor word 1 (address offset 0x4)

31   0
HEADERADDRESS

31: 0	Header address (HEADERADDRESS) - Address from where the packet header is fetched. Does not need to be word aligned.

31 24	23 0
RESERVED	DATALEN

31: 24	RESERVED
23: 0	Data length (DATALEN) - Length of data part of packet. If set to zero, no data will be sent. If both data- and header-lengths are set to zero no packet will be sent.

*Table 1363.*TXDMA transmit descriptor word 3(address offset 0xC)

31	0
DATAADDRESS	

31: 0   Data address (DATAADDRESS) - Address from where data is read. Does not need to be word
             aligned.

75.5.5.5 The transmission process

When the txen bit is set the port starts reading descriptors immediately. The number of bytes indicated
are read and transmitted. When a transmission has finished, status will be written to the first field of
the descriptor and a packet sent bit is set in the DMA control register. If an interrupt was requested it
will also be generated. Then a new descriptor is read and if enabled a new transmission starts, other-
wise the transmit enable bit is cleared and nothing will happen until it is enabled again.

75.5.5.6 The descriptor table address register

The internal pointer which is used to keep the current position in the descriptor table can be read and
written through the APB interface. This pointer is set to zero during reset and is incremented each
time a descriptor is used. It wraps automatically when the 1024 bytes limit for the descriptor table is
reached or it can be set to wrap earlier by setting a bit in the current descriptor.

The descriptor table register can be updated with a new table anytime when no transmission is active.
No transmission is active if the transmit enable bit is zero and the complete table has been sent or if
the table is aborted (explained below). If the table is aborted one has to wait until the transmit enable
bit is zero before updating the table pointer.

75.5.5.7 Error handling

75.5.5.7.1Abort Tx

The DMA control register contains a bit called Abort TX which if set causes the current transmission
to be aborted, the packet is truncated and an EEP is inserted. This is only useful if the packet needs to
be aborted because of congestion on the SpaceWire network. If the congestion is on the AHB bus this
will not help (This should not be a problem since AHB slaves should have a maximum of 16 wait-
states). The aborted packet will have its LE bit set in the descriptor. The transmit enable register bit is
also cleared and no new transmissions will be done until the transmitter is enabled again.

75.5.5.7.2AHB error

When an AHB error is encountered during transmission the currently active DMA channel is disabled
and the transmitter goes to the idle mode. A bit in the DMA channel's control/status register is set to
indicate this error condition and, if enabled, an interrupt will also be generated. Further error handling
depends on what state the transmitter DMA engine was in when the AHB error occurred. If the
descriptor was being read the packet transmission had not been started yet and no more actions need
to be taken.

If the AHB error occurs during packet transmission the packet is truncated and an EEP is inserted.
Lastly, if it occurs when status is written to the descriptor the packet has been successfully transmitted
but the descriptor is not written and will continue to be enabled (this also means that no error bits are
set in the descriptor for AHB errors).

The client using the channel has to correct the AHB error condition and enable the channel again. No more AHB transfers are done again from the same unit (receiver or transmitter) which was active during the AHB error until the error state is cleared and the unit is enabled again.

75.5.6 RMAP target

The Remote Memory Access Protocol (RMAP) is used to implement access to resources on the AHB bus via the SpaceWire Link. Some common operations are reading and writing to memory, registers and FIFOs. The port has an optional hardware RMAP target which is enabled with a VHDL generic. This section describes the target implementation.

75.5.6.1 Fundamentals of the protocol

RMAP is a protocol which is designed to provide remote access via a SpaceWire network to memory mapped resources on a SpaceWire node. It has been assigned protocol ID 0x01. It provides three operations write, read and read-modify-write. These operations are posted operations which means that a source does not wait for an acknowledge or reply. It also implies that any number of operations can be outstanding at any time and that no timeout mechanism is implemented in the protocol. Timeouts must be implemented in the user application which sends the commands. Data payloads of up to 16 Mb - 1 is supported in the protocol. A destination can be requested to send replies and to verify data before executing an operation. A complete description of the protocol is found in the RMAP standard.

75.5.6.2 Implementation

The port includes a target for RMAP commands which processes all incoming packets with protocol ID = 0x01, type field (bit 7 and 6 of the 3rd byte in the packet) equal to 01b and an address falling in the range set by the default address and mask register. When such a packet is detected it is not stored to the DMA channel, instead it is passed to the RMAP receiver.

The target implements all three commands defined in the standard with some restrictions. Support is only provided for 32-bit big-endian systems. This means that the first byte received is the msb in a word. The target will not receive RMAP packets using the extended protocol ID which are always dumped to the DMA channel.

The RMAP receiver processes commands. If they are correct and accepted the operation is performed on the AHB bus and a reply is formatted. If an acknowledge is requested the RMAP transmitter automatically send the reply. RMAP transmissions have priority over DMA channel transmissions.

There is a user accessible destination key register which is compared to destination key field in incoming packets. If there is a mismatch and a reply has been requested the error code in the reply is set to 3. Replies are sent if and only if the ack field is set to '1'.

+46 31 7758650 | frontgrade.com/gaisler

When a failure occurs during a bus access the error code is set to 1 (General Error). There is predetermined order in which error-codes are set in the case of multiple errors in the core. It is shown in table 1364.

Table 1364. The order of error detection in case of multiple errors in the AMBA port. The error detected first has number 1.

Detection Order	Error Code	Error
1	12	Invalid destination logical address
2	2	Unused RMAP packet type or command code
3	3	Invalid destination key
4	9	Verify buffer overrun
5	11	RMW data length error
6	10	Authorization failure
7*	1	General Error (AHB errors during non-verified writes)
8	5/7	Early EOP / EEP (if early)
9	4	Invalid Data CRC
10	1	General Error (AHB errors during verified writes or RMW)
11	7	EEP
12	6	Too Much Data
*The AHB error is not guaranteed to be detected before Early EOP/EEP or Invalid Data CRC. For very long accesses the AHB error detection might be delayed causing the other two errors to appear first.		

Read accesses are performed on the fly, that is they are not stored in a temporary buffer before transmitting. This means that the error code 1 will never be seen in a read reply since the header has already been sent when the data is read. If the AHB error occurs the packet will be truncated and ended with an EEP.

Errors up to and including Invalid Data CRC (number 9) are checked before verified commands. The other errors do not prevent verified operations from being performed.

The details of the support for the different commands are now presented. All defined commands which are received but have an option set which is not supported in this specific implementation will not be executed and a possible reply is sent with error code 10.

75.5.6.3 Write commands

The write commands are divided into two subcategories when examining their capabilities: verified writes and non-verified writes. Verified writes have a length restriction of 4 bytes and the address must be aligned to the size. That is 1 byte writes can be done to any address, 2 bytes must be halfword aligned, 3 bytes are not allowed and 4 bytes writes must be word aligned. Since there will always be only on AHB operation performed for each RMAP verified write command the incrementing address bit can be set to any value.

Non-verified writes have no restrictions when the incrementing bit is set to 1. If it is set to 0 the number of bytes must be a multiple of 4 and the address word aligned. There is no guarantee how many words will be written when early EOP/EEP is detected for non-verified writes.

75.5.6.4 Read commands

Read commands are performed on the fly when the reply is sent. Thus if an AHB error occurs the packet will be truncated and ended with an EEP. There are no restrictions for incrementing reads but non-incrementing reads have the same alignment restrictions as non-verified writes. Note that the "Authorization failure" error code will be sent in the reply if a violation was detected even if the length field was zero. Also note that no data is sent in the reply if an error was detected i.e. if the status field is non-zero.

GRIP
Apr 2024, Version 2024.1
1179
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

75.5.6.5 RMW commands

All read-modify-write sizes are supported except 6 which would have caused 3 B being read and written on the bus. The RMW bus accesses have the same restrictions as the verified writes. As in the verified write case, the incrementing bit can be set to any value since only one AHB bus operation will be performed for each RMW command. Cargo too large is detected after the bus accesses so this error will not prevent the operation from being performed. No data is sent in a reply if an error is detected i.e. the status field is non-zero.

75.5.6.6 Control

The RMAP target mostly runs in the background without any external intervention, but there are a few control possibilities.

There is an enable bit in the control register of the core which can be used to completely disable the RMAP target. When it is set to '0' no RMAP packets will be handled in hardware, instead they are all stored to the DMA channel.

There is a possibility that RMAP commands will not be performed in the order they arrive. This can happen if a read arrives before one or more writes. Since the target stores replies in a buffer with more than one entry several commands can be processed even if no replies are sent. Data for read replies is read when the reply is sent and thus writes coming after the read might have been performed already if there was congestion in the transmitter. To avoid this the RMAP buffer disable bit can be set to force the target to only use one buffer which prevents this situation.

The last control option for the target is the possibility to set the destination key which is found in a separate register.

Table 1365. AMBA port hardware RMAP handling of different packet type and command fields.

Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Command	Action
Reserved	Command / Response	Write / Read	Verify data before write	Acknow-ledge	Increment Address		
0	0	-	-	-	-	Response	Stored to DMA-channel.

75.5.7 AMBA interface

The AMBA interface consists of an APB interface, an AHB master interface and DMA FIFOs. The APB interface provides access to the user registers which are described in section 75.7. The DMA engines have 32-bit wide FIFOs to the AHB master interface which are used when reading and writing to the bus.

The transmitter DMA engine reads data from the bus in bursts which are half the FIFO size in length. A burst is always started when the FIFO is half-empty or if it can hold the last data for the packet. The burst containing the last data might have shorter length if the packet is not an even number of bursts in size.

The receiver DMA works in the same way except that it checks if the FIFO is half-full and then per-forms a burst write to the bus which is half the FIFO size in length. The last burst might be shorter. If the rmap or rxunaligned VHDL generics are set to 1 the interface also handles byte accesses. Byte accesses are used for non word-aligned buffers and/or packet lengths that are not a multiple of four bytes. There might be 1 to 3 single byte writes when writing the beginning and end of the received packets.

75.5.7.1 APB slave interface

As mentioned above, the APB interface provides access to the user registers which are 32-bits in width. The accesses to this interface are required to be aligned word accesses. The result is undefined if this restriction is violated.

75.5.7.2 AHB master interface

The port contains a single master interface which is used by both the transmitter and receiver DMA engines. The arbitration algorithm between the channels is done so that if the current owner requests the interface again it will always acquire it. This will not lead to starvation problems since the DMA engines always deassert their requests between accesses.

The AHB accesses are always word accesses (HSIZE = 0x010) of type incremental burst with unspecified length (HBURST = 0x001) if VHDL generics rmap and rxunaligned are disabled. The AHB accesses can be of size byte, halfword and word (HSIZE = 0x000, 0x001, 0x010) otherwise. Byte and halfword accesses are always NONSEQ. Note that read accesses are always word accesses (HSIZE = 0x010), which can result in destructive read.

The burst length will be half the AHB FIFO size except for the last transfer for a packet which might be smaller. Shorter accesses are also done during descriptor reads and status writes.

The AHB master also supports non-incrementing accesses where the address will be constant for several consecutive accesses. HTRANS will always be NONSEQ in this case while for incrementing accesses it is set to SEQ after the first access. This feature is included to support non-incrementing reads and writes for RMAP.

If the core does not need the bus after a burst has finished there will be one wasted cycle (HTRANS = IDLE).

BUSY transfer types are never requested and the port provides full support for ERROR, RETRY and SPLIT responses.

75.5.8 Synthesis and hardware

75.5.8.1 Clocking

The AMBA ports run on the same clock as the router switch matrix.

75.5.8.2 Fault-tolerance

The ports can optionally be implemented with fault-tolerance against SEU errors in the FIFO memories. The fault-tolerance is enabled through the *ft* VHDL generic. Possible options are byte parity protection (*ft = 1*) or TMR (*ft = 2*).

75.5.8.3 Technology mapping

The core has three generics for technology mapping: *tech*, *techfifo* and *memtech*. *Tech* selects the technology used for the clock buffers and also adds reset to some registers for technologies where they would otherwise cause problems with gate-level simulations. *Techfifo* selects whether *memtech* should be used to select the technology for the FIFO memories (the RMAP buffer is not affected by the this generic) or if they should be inferred. *Tech* and *memtech* can be set to any value from 0 to NTECH as defined in the GRLIB.TECH package.

75.5.8.4 RAM usage

The core maps all RAM memories on the syncram_2p component if the *ft* generic is 0 and to the syncram_2pft component for other values. The syncrams are located in the technology mapping library (TECHMAP). The organization of the different memories are described below. If techfifo and/or memtech is set to 0 the synthesis tool will infer the memories. Either RAM blocks or flip-flops will be used depending on the tool and technology. The number of flip-flops used is *syncram depth x syncram width* for all the different memories. The receiver AHB FIFO with fifosize 32 will for example use 1024 flips-flops.

75.5.8.4.1 Receiver AHB FIFO

The receiver AHB FIFO consists of one syncram_2p block with a width of 32-bits. The depth is determined by the configured FIFO depth. Table 1366 shows the syncram organization for the allowed configurations.

Table 1366. syncram_2p sizes for receiver AHB FIFO.

Fifosize	Syncram_2p organization
4	4x32
8	8x32
16	16x32
32	32x32

75.5.8.4.2 Transmitter AHB FIFO

The transmitter AHB FIFO consists of one syncram_2p block with a width of 32-bits. The depth is determined by the configured FIFO depth. Table 1367 shows the syncram organization for the allowed configurations.

Table 1367. syncram_2p sizes for transmitter AHB FIFO.

Fifosize	Syncram_2p organization
4	4x32
8	8x32
16	16x32
32	32x32

75.5.8.4.3 Receiver N-Char FIFO

The receiver N-Char FIFO consists of one syncram_2p block with a width of 10-bits. The depth is determined by the configured FIFO depth. Table 1368 shows the syncram organization for the allowed configurations.

Table 1368. syncram_2p sizes for the receiver N-Char FIFO.

Fifosize	Syncram_2p organization
16	16x10
32	32x10
64	64x10

4	128x8
8	256x8

75.5.9   Registers

The port is programmed through registers mapped into APB address space. The addresses in the table below are offsets from each port's base address. The actual AMBA AHB address used to access the port is determined as follows: The AMBA ports' registers are accessed through an APB interface which resides on the APB bus. The APB bus is connected to the AHB bus using an APB controller whose AHB address determines the first base address for the AMBA ports.

See the grlib manual and APB controller manual on how to determine this base address. The starting base address on the APB bus for each AMBA port APB interface is set by the paddr and pmask VHDL generics. The starting paddr value is then incremented by one for each port. Finally a registers address is determined by adding the APB controller's AHB base address, the ports APB base address and the registers offset.

31   RMAP available (RA) - Set to 1 if the RMAP target is implemented.

30   RX unaligned access (RX) - Set to 1 if unaligned writes are available for the receiver.

29   RMAP CRC available (RC) - Set to 1 if RMAP CRC is enabled.

28: 27   Number of DMA channels (NCH) - The number of available DMA channels minus one.

26   RESERVED

25   CCSDS CRC available (CC) - Set to 1 if CCSDS CRC is enabled.

24   Distributed interrupt support (DI) - Set to 1 if distributed interrupts are supported.

23   Memory error truncation enable (ME) - If set to 1, a packet being transmitted will be truncated with an EEP if an error occur while reading from the AMBA port's TX FIFO.

22: 18   RESERVED

17   RMAP buffer disable (RD) - If set only one RMAP buffer is used. This ensures that all RMAP commands will be executed consecutively.

16   RMAP Enable (RE) - Enable RMAP target.

15: 9   RESERVED

8   Tick-out IRQ (TQ) - Generate interrupt when a valid time-code is received if the time-code also matches the time-code filter specified by the RTR.AMBATIME.TCMSK and RTR.AMBATIME.TCVAL fields.

7   Time-code tick-out enable (TO) - If set to 1, the internal tickout signal is set when a valid time-code is received. if the time-code also matches the time-code filter specified by the RTR.AMBATIME.TCMSK and RTR.AMBA-TIME.TCVAL fields.

6   Reset (RS) - Make complete reset of the SpaceWire node. Self clearing.

5   Promiscuous Mode (PM) - Enable Promiscuous mode.

4   Tick In (TI) - The host can generate a tick by writing a one to this field. This will increment the timer counter and the new value is transmitted after the current character is transferred. A tick can also be generated by asserting the tick_in signal.

3   Interrupt Enable (IE) - If set, an interrupt is generated when bit 8 is set and its corresponding event occurs.

Table 1376. 0x20,0x40,0x60,0x80 - RTR.AMBADMACTRL - AMBA port DMA control/status

20	Interrupt-code transmit enable on truncation (IT) - When set to 1, the distributed interrupt code specified in the RTR.AMBADMACTRL.INTNUM field is generated when a received packet on this DMA channel is truncated due to a maximum length violation.
19	Receive packet IRQ (RP) - This bit is set to 1 when an AMBA interrupt was generated due to the fact that a packet was received for the corresponding DMA channel.
18	Transmit packet IRQ (TP) - This bit is set to 1 when an AMBA interrupt was generated due to the fact that a packet was transmitted for the corresponding DMA channel.
17: 16	RESERVED
15	Strip pid (SP) - Remove the pid byte (second byte) of each packet. The address byte (first byte) will also be removed when this bit is set independent of the SA bit.
14	Strip addr (SA) - Remove the addr byte (first byte) of each packet.
13	Enable addr (EN) - Enable separate node address for this channel.
12	No spill (NS) - If cleared, packets will be discarded when a packet is arriving and there are no active descriptors. If set, the GRSPWROUTER will wait for a descriptor to be activated.
11	Rx descriptors available (RD) - Set to one, to indicate to the GRSPWROUTER that there are enabled descriptors in the descriptor table. Cleared by the GRSPWROUTER when it encounters a disabled descriptor:
10	RX active (RX) - Is set to '1' if a reception to the DMA channel is currently active otherwise it is '0'.
9	Abort TX (AT) - Set to one to abort the currently transmitting packet and disable transmissions. If no transmission is active the only effect is to disable transmissions. Self clearing.
8	RX AHB error (RA) - An error response was detected on the AHB bus while this receive DMA channel was accessing the bus. The AHB error interrupt (AI) field must be set to '1' for the RA field to be set.
7	TX AHB error (TA) - An error response was detected on the AHB bus while this transmit DMA channel was accessing the bus.
6	Packet received (PR) - This bit is set each time a packet has been received. Never cleared by the DMA channel.
5	Packet sent (PS) - This bit is set each time a packet has been sent. Never cleared by the DMA channel.
4	AHB error interrupt (AI) - If set, an interrupt will be generated each time an AHB error occurs when this DMA channel is accessing the bus.
3	Receive interrupt (RI) - If set, an interrupt will be generated each time a packet has been received. This happens both if the packet is terminated by an EEP or EOP.
2	Transmit interrupt (TI) - If set, an interrupt will be generated each time a packet is transmitted. The interrupt is generated regardless of whether the transmission was successful or not.
1	Receiver enable (RE) - Set to one when packets are allowed to be received to this channel.
0	Transmitter enable (TE) - Write a one to this bit each time new descriptors are activated in the table. Writing a one will cause the DMA channel to read a new descriptor and try to transmit the packet it points to. This bit is automatically cleared when the DMA channel encounters a descriptor which is disabled.

24	Interrupt transmit on early EOP/EEP (EE) - If set to 1, a distributed interrupt code with the interrupt number specified in the RTR.AMBAINTCTRL.INTNUM field is sent each time an event occurs such that the STS.EE bit is set to 1 (even if the bit was already set when the event occurred).
23	Interrupt transmit on invalid address (IA) - If set to 1, a distributed interrupt code with the interrupt number specified in the RTR.AMBAINTCTRL.INTNUM field is sent each time an event occurs such that the STS.IA bit is set to 1 (even if the bit was already set when the event occurred).
22: 21	RESERVED
20	Interrupt timeout IRQ enable (TQ) - When set to 1, an AMBA interrupt is generated when a bit in the RTR.AMBAINTTO0 or RTR.AMBAINTTO1 registers is set. Note that the RTR.AMBACTRL.IE bit also must be set for this bit to have any effect.
19	Interrupt acknowledgment / extended interrupt receive IRQ enable (AQ) - When set to 1, an AMBA interrupt is generated when an interrupt acknowledgment code or extended interrupt code is received such that a bit in the RTR.AMBAACKRX register is set to 1 (even if the bit was already set when the code was received).
18	Interrupt-code receive IRQ enable (IQ) - When set to 1, an AMBA interrupt is generated when an interrupt code is received such that a bit in the RTR.AMBAINTRX register is set to 1 (even if the bit was already set when the code was received).
17: 16	RESERVED
15	Handle all interrupt acknowledgment codes (AA) - Is set to 0, only those received interrupt acknowledgment codes that match an interrupt code sent by software are handled. If set to 1, all received interrupt acknowledgment codes are handled.
14	Interrupt acknowledgment / extended interrupt tickout enable (AT) - When set to 1, the internal tickout signal from this AMBA port is set when an interrupt acknowledgment code or extended interrupt code is received such that a bit in the RTR.AMBAACKRX register is set to 1 (even if the bit was already set when the code was received).
13	Interrupt tickout enable (IT) - When set to 1, the internal tickout signal from this AMBA port is set when an interrupt code is received such that a bit in the RTR.AMBAINTRX register is set to 1 (even if the bit was already set when the code was received).
12: 8	RESERVED
7	Interrupt discarded (ID) - This bit is set to 1 when a distributed interrupt code that software tried to send by writing the RTR.AMBAINTCTRL.II bit was discarded by the routers switch matrix. There is a maximum of ten clock cycle delay between the RTR.AMBAINTCTRL.II bit being written and this bit being set.
6	Interrupt-code tick-in (II) - When this field is written to 1 the distributed interrupt code specified by the RTR.AMBAINTCTRL.TXINT field will be sent out from the AMBA port to the routers switch matrix. This bit is automatically cleared and always reads '0'. Writing a '0' has no effect.
5: 0	Transmit distributed interrupt code (TXINT) - The distributed interrupt code that will be sent when the register RTR.AMBAINTCTRL.II is written with 1.

Table 1383. 0xA8 - RTR.AMBAACKRX - AMBA port Interrupt acknowledgment / extended interrupt receive

31: 0	Received interrupt acknowledgment code / extended interrupt code (RXACK) - When operating in extended interrupt mode (RTR.RTRCFG.EE = 1) then each bit corresponds to the interrupt number with the same number as the bit index plus 32, i.e bit 0 corresponds to interrupt number 32, bit 1 to interrupt number 33 etc. This bit gets set to 1 when an extended interrupt code is received for which the corresponding bit in the RTR.AMBAINTMSK1 register is set to 1.
	When operating in interrupt with acknowledgment mode (RTR.RTRCFG.EE = 0) then each bit corresponds to the interrupt number with the same number as the bit index. This bit gets set to 1 an interrupt acknowledgment code is received for which the corresponding bit in the RTR.AMBAINTMSK0 register is set, and either if RTR.AMBAINTCTRL.AA is set to 1 or for which the matching interrupt code was sent by software.

Table 1384. 0xAC - RTR.AMBAINTTO0 - AMBA port Interrupt timeout, interrupt 0-31

31	0
INTTO	
0x00000000	
wc	

31: 0	Interrupt code timeout (INTTO) - Each bit corresponds to the interrupt number with the same number as the bit index. This bit is set to 1 when an interrupt code that was sent by software doesn't receive an interrupt acknowledgment code for the duration of a timeout period (specified in the RTR.ISRTIMER register), and if the corresponding bit in the RTR.AMBAINTMSK0 register is set.

Table 1385. 0xB0 - RTR.AMBAINTTO1 - AMBA port Interrupt timeout, interrupt 32-63

31	0
INTTO	
0x00000000	
wc	

31: 0	Extended interrupt code timeout (INTTO) - Each bit corresponds to the interrupt number with the same number as the bit index plus 32, i.e bit 0 corresponds to interrupt number 32, bit 1 to interrupt number 33 etc.. This bit is set to 1 when an extended interrupt code that was sent by software time out, i.e after the duration of a timeout period (specified in the RTR.ISRTIMER register), and if the corresponding bit in the RTR.AMBAINTMSK1 register is set.

Table 1386. 0xB4 - RTR.AMBAINTMSK0 - AMBA port Interrupt mask, interrupt 0-31

31	0
MASK	
0x00000000	
rw	

31: 0	Interrupt mask (MASK) - Each bit corresponds to the interrupt number with the same value as the bit index. If a bit is set to 0, all received interrupt codes and interrupt acknowledgment codes with the interrupt identifier corresponding to that bit is ignored. If a bit is set to 1, then the matching distributed interrupt code is handled.

31: 0	Interrupt mask (MASK) - Each bit corresponds to the interrupt number with the same value as the bit index. plus 32, i.e bit 0 corresponds to interrupt number 32, bit 1 to interrupt number 33 etc. If a bit is set to 0, all received extended interrupt codes with the interrupt identifier corresponding to that bit is ignored. If a bit is set to 1, then the matching distributed interrupt code is handled.

75.5.10 Vendor and device identifiers

The port has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x8A. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

75.6   Configuration port

The configuration port has port number 0. It consists of an RMAP target, AMBA AHB slave interface, SpaceWire Plug-and-Play interface, and a set of configuration and status registers.

75.6.1   RMAP target

75.6.1.1   Overview

The configuration port's RMAP target implements the RMAP protocol, as defined in the RMAP standard [RMAP]. Verified writes and reads up to 128 B, and read-modify-writes of 4 B (8 B if the mask field is included in the count) are supported. Replies from the configuration port are always sent to the port they arrived on, regardless of the values of the RMAP command's Initiator Logical Address field, and Reply Address field. The address space of the configuration port is specified in section 75.7.

Additional requirements on the RMAP commands imposed by the configuration port's RMAP target are:

•   The Target Logical Address field must be 0xFE.

•   The Address fields must contain a 4 B aligned address.

•   The Extended Address field must be 0x00.

•   Key field must be 0x00.

•   For write and read commands the Data Length fields must contain a value that is a multiple of 4, ranging from 0 to 128 B.

•   For read-modify-write commands the Data Length fields must contain a value of 0 or 8.

•   For write commands the Verify Data Before Write bit in the Instruction field must be set to 1.

How the RMAP target handles commands that does not meet the above requirement is detailed in sections 75.6.1.2 and 75.6.1.4.

When an RMAP write command larger than 4 bytes is processed (i.e. more than one register written by the same command), the registers will not change value simultaneously. The command is buffered locally, since only verified write commands are allowed, and then read out from the buffer and written to the registers, with one CLK cycle delay between each register write. This needs to be considered when for example updating large parts of the routing table. Data traffic that arrives while the RMAP command is being processed may or may not be routed according to the new values depending on the address of the packet and how much of the RMAP command that has been processed. Note that the RMAP target is blocked while the RMAP write command is being processed, which means that data returned in an RMAP read command is always either the value before or after the complete RMAP write, never in between.

75.6.1.2 RMAP command support

Table 1388 lists all possible RMAP commands and shows how the configuration port's RMAP target handles them. An RMAP command will always have bits 7:6 of the command's Instruction field set to "01", and those bits are therefore left out of the table. Bits 1:0 of the command's Instruction field determines the length of the command's Reply Address Field, and does not affect the action taken, so they have been left out of the table as well. The action taken assumes that no errors were detected in the RMAP packet. For handling of RMAP packet error, see section 75.6.1.4.

Table 1388. RMAP command decoding and handling.

Bit 5	Bit 4	Bit 3	Bit 2		
Write / Read	Verify Data Before Write	Reply	Increment Addr	Function	Action taken
0	0	0	0	Invalid	No operation performed. Error code 0x02 is saved in the RTR.PSTSCFG.EC field. No reply is sent.
0	0	0	1	Invalid	No operation performed. Error code 0x02 is saved in the RTR.PSTSCFG.EC field. No reply is sent.
0	0	1	0	Read single address	Read operation performed, if the requirements in section 75.6.1.1 are met.
0	0	1	1	Read incrementing address	Read operation performed, if the requirements in section 75.6.1.1 are met.
0	1	0	0	Invalid	No operation performed. Error code 0x02 is saved in the RTR.PSTSCFG.EC field. No reply is sent.
0	1	0	1	Invalid	No operation performed. Error code 0x02 is saved in the RTR.PSTSCFG.EC field. No reply is sent.
0	1	1	0	Invalid	No operation performed. Reply is sent with error code 0x02. Error code is also saved in the RTR.PSTSCFG.EC field.
0	1	1	1	Read-modify-write incrementing address	Read-modify-write operation performed if the requirements in section 75.6.1.1 are met.
1	0	0	0	Write, single address, don't verify before writing, no reply	No operation performed. Error code 0x0A is saved in the RTR.PSTSCFG.EC field. No reply sent.
1	0	0	1	Write, incrementing address, don't verify before writing, no reply	No operation performed. Error code 0x0A is saved in the RTR.PSTSCFG.EC field. No reply sent.
1	0	1	0	Write, single address, don't verify before write, send reply	No operation performed. Reply is sent with error code 0x0A. Error code is also saved in the RTR.PSTSCFG.EC field.
1	0	1	1	Write, incrementing address, don't verify before write, send reply	No operation performed. Reply is sent with error code 0x0A. Error code is also saved in the RTR.PSTSCFG.EC field.
1	1	0	0	Write, single address, verify before writing, no reply	Write operation performed if the requirements in section 75.6.1.1 are met.

Table 1388. RMAP command decoding and handling.

Bit 5	Bit 4	Bit 3	Bit 2		
Write / Read	Verify Data Before Write	Reply	Incre-ment Addr	Function	Action taken
1	1	0	1	Write, incre-menting address, verify before writing, no reply	Write operation performed if the requirements in section 75.6.1.1 are met.
1	1	1	0	Write, single address, verify before writing, send reply	Write operation performed if the requirements in section 75.6.1.1 are met.
1	1	1	1	Write, incre-menting address, verify before writing, send reply	Write operation performed if the requirements in section 75.6.1.1 are met.

75.6.1.3 Access control

After reset / power-up the configuration port's address space can be accessed from all the ports. Configuration port accesses can be individually disabled per port by clearing the corresponding RTR.PCTRL.CE bit. Write commands, and read-modify-write commands to the configuration area can be globally disabled by writing a 0 to the RTR.CFGWE.WE bit.

There is also a CFGLOCK pin which can be used to disable configuration accesses from all ports except port 1 and 2. This signal overrides the setting of the RTR.PCTRL.CE for all ports, enabling configuration port accesses for port 1 and 2, and disabling them for all other ports. The RTR.CFGWE register still affects ports 1 and 2 in this case.

When a correct RMAP command is received but not allowed due to one or more of the access control features being enabled, a reply with Status field set to 0x0A (Authorization failure) is sent (if requested), and the RTR.PSTSCFG.EC field is updated to reflect the error. If a reply is not requested, the RTR.PSTSCFG.EC field is still set. In both cases, the operation is not performed.

75.6.1.4 RMAP Error handling

Table 1389 shows the order in which errors in an RMAP command are detected. As soon as an error is detected, the command is discarded. If a reply should be sent, to a command that included an error, the reply is sent as soon as possible after the error is detected. This means that the reply might be sent out before the complete incoming RMAP command has been received. Note that since the complete RMAP command is buffered before it is executed, a command that contains an error is never executed.

Table 1389. RMAP target error detection order

Detection Order	Error type	RMAP error code	Action taken
1	Wrong Protocol Identifier	N/A	The RTR.PSTSCFG.PT bit is set in order to indicate that the error occurred. No reply is sent.
2	EOP / EEP before com-pleted header	N/A	The RTR.PSTSCFG.EO / RTR.PSTSCFG.EE bit is set in order to indi-cate that the error occurred. No reply is sent.

*Table 1389.*RMAP target error detection order

Detection Order	Error type	RMAP error code	Action taken
3	Header CRC error	N/A	The RTR.PSTSCFG.HC bit is set in order to indicate that the error occurred. No reply is sent.
4	Unused RMAP packet type	N/A	If the packet type (bit 7:6 of the packet's Instruction field) is "10" or "11" then the bit RTR.PSTSCFG.PT is set. For the value "00" (indicating a reply), no bit in RTR.PSTSCFG is set, since the RMAP standard [RMAP] does not specify that such an event should be recorded.
5	EEP immediately after header	N/A	The RTR.PSTSCFG.EE bit is set in order to indicate that the error occurred. No reply is sent.
6	Unused RMAP command code	0x02	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
7	Invalid Target Logical Address	0x0C	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
8	Invalid Key	0x03	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
9	Verify buffer overrun	0x09	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
10	RMW data length error	0x0B	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
11	RMAP command not implemented or not authorized.	0x0A	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
12	Early EOP / early EEP (not immediately after header)	0x05 / 0x07	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
13	Invalid Data CRC	0x04	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
14	EEP	0x07	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.
15	Too much data	0x06	RMAP error code is saved in the RTR.PSTSCFG.EC field. Reply is sent if the Reply bit in the command's Instruction field was set to 1.

Most of the errors listed in table 1389 are errors that only occur in one specific way, and they are also explained in the RMAP standard [RMAP]. Authorization failure (error code 0x0A) is however an exception. All the cases that lead to an authorization failure are listed below:

- A read command's Data Length field exceed 128 B.
- A command's (read, write, or read-modify-write) Address field does not contain a 4 B aligned address.
- The access control features described in section 75.6.1.3 prevented the port from accessing the RMAP target.
- The Address field of a command (read, write, or read-modify-write) contains an address that is outside of the configuration port's memory space.
- The Address field of the command (read, write, or read-modify-write) combined with the Length field would generate an access outside of the configuration port's memory space.
- The Length field of a command (read, write, or rea-modify write) is not a multiple of 4.
- A non-verified write command was received.

75.6.2 AMBA AHB slave interface

The configuration port provides an AMBA AHB slave interface, which makes the entire address space of the configuration port accessible from the AHB bus. The address offsets are the same as when accessing through RMAP but the base address is different. The slave consists of an AHB I/O bank: the 32-bit AHB base address is calculated by setting bits 31 downto 20 to 0xFFF and bits 19 downto 8 to the VHDL generics cfghaddr and cfghmask anded. So if, for example, cfghaddr is 0xC00 and cfghmask is 0xFFF, the router AHB memory area will occupy 256 bytes starting from 0xFFFC0000.

The routing table is shared between the ports, RMAP target and AHB slave, so accesses from the AHB slave might be stalled because of accesses from the other sources. The priority order when accessing the routing table, starting from the highest, is: router ports, AHB slave, RMAP target. Note that since the AHB slave has higher priority than the RMAP target, it is possible to read and write to the configuration port's registers in the middle of an RMAP write command. This needs to be considered in order to avoid a mismatch between the expected written value and actual written value.

None of the access control mechanisms mentioned in section 75.6.1.3 have any effect on the AHB slave interface.

75.7 Registers

The configuration port's registers listed in this section can be accessed either through the RMAP target, or the AMBA AHB slave interface. The RMAP addresses specified in table 1390. The AHB addresses are determined by adding the RAMP addresses table 1390 to the AHB base address determined by the cfghaddr and cfghmask VHDL generics. Registers that exist in several identical copies, corresponding to different addresses or ports, for example the RTR.RTPMAP registers, are only described once.

Only 32-bit single-accesses to the registers through AHB are supported.

	*		0
	rw*		rw

31: 1   Port enable bits (PE) - When set to 1, each bit enables packets with the physical / logical address corresponding to this RTR.RTPMAP register to be sent on the port with the same number as the bit index. For physical addresses, the bit index corresponding to the port with the same number as the physical address itself is always 1 (not possible to write to 0). For logical addresses, at least one bit must be set to 1 in order for a packet with the corresponding address to be routed; otherwise the packet is spilled and an invalid address error generated. Reset value for physical addresses is all zeroes (except for the bit index corresponding to the port with the same number as the address). Reset value for logical addresses is zero. Only bits corresponding to existing ports, as defined by the sum of the VHDL generics *spwports*, *ambaports*, *fifoports* and *customport*, are implemented.

0   Packet distribution (PD) - When set to 1, packet distribution is used for the physical / logical address corresponding to this RTR.RTPMAP register. When set to 0, group adaptive routing is used. See section 75.2.5 and 75.2.6 for more information.

Table 1392. 0x00000404-0x0000047C, 0x00000480-0x000007FC - RTR.RTACTRL - Routing table address control, addresses 1-31 and 32-255

31	4	3	2	1	0
RESERVED		SR	EN	PR	HD
0x0000000		*	*	*	*
r		rw	rw	rw	rw

31: 4   RESERVED

3   Spill-if-not-ready (SR) - When set to 1, an incoming packet with the corresponding physical / logical address is immediately spilled if the selected output port's link interface is not in run-state. If packet distribution is used for the incoming packet, and this bit is set, the packet is spilled unless all output ports' link interfaces are in run state. For physical addresses, this bit is double mapped in the RTR.PCTRL.SR field. Reset value for physical addresses are taken from the SPILLIFNOTREADY pin. Reset value for logical addresses is N/R.

2   Enable (EN) - Enables the routing table address control entry. Address control entries for physical addresses are always enabled, and this field is constant 1. For logical addresses, this bit must be set to 1 in order for packets with the corresponding logical address to be routed. Reset value for logical addresses is 0.

1   Priority (PR) - Sets the arbitration priority of this physical / logical address. 0 = low priority, 1 = high priority. Used when more than one packet is competing for the same output port. For physical addresses, this bit is double mapped in the RTR.PCTRL.PR field. Reset value for physical addresses is 0. Reset value for logical addresses is N/R.

0   Header deletion (HD) - Enables / disabled header deletion for the corresponding logical address. For physical addresses, header deletion is always enabled, and this bit is constant 1. Reset value for logical addresses is N/R.

31: 18   RESERVED

17   Packet length truncation (PL) - When set to 1, an RMAP / SpaceWire Plug-and-Play reply is spilled, and an EEP written to the transmit FIFO of the output port, if the total length of the reply packet exceeds the maximum length specified in the RTR.MAXPLEN register for port 0. See section 75.2.15 for more information on packet length truncation.

16   Time-code / distributed interrupt code truncation (TS) - When set to 1, an RMAP / SpaceWire Plug-and-Play reply is spilled, and an EEP written to the transmit FIFO of the output port, if a valid time-code / distributed interrupt code is received and if the code matches the codes selected by the RTR.PCTRL2CFG.SV and RTR.PCTRL2CFG.SM fields. See section 75.2.19 for more information.

15: 10   RESERVED

9   Timer enable (TR) - Enable data character timer for port 0. See section 75.2.14 for details. Reset value set from TIMEEN signal.

8: 0   RESERVED

Table 1394. 0x00000804-0x0000084C - RTR.PCTRL - Port control, ports > 0

31: 24   Run-state clock divisor (RD) - Clock divisor value used for the corresponding port's link interface when in run-state. Field is only available for the SpaceWire ports. Bits 31:30 have reset value 0x0, while bits 29:24 get their reset value from the IDIVISOR[7:0] pins. For more information about setting the link-rate for SpaceWire ports during run-state see section 75.2.22.

23: 22   RESERVED

21   Static routing enable (ST) - When set to 1, incoming packets on this port are routed based on the physical address specified in the corresponding RTR.PCTRL2.SD field, and the setting of the corresponding RTR.PCTRL2.SC bit, instead of the packet's first byte. Header deletion is not used when static routing is enabled, which means that the first byte of the packet is always sent as well. This bit can only be set to 1 if the RTR.RTRCFG.SR bit is set to 1. Note that when this bit is set to 1 it is not possible to access the configuration port from this port.

20   Spill-if-not-ready (SR) - This bit is double mapping of the RTR.RTACTRL.SR bit. See table 1392.

19   Auto-disconnect (AD) - When set to 1, the auto-disconnect feature described in section 75.2.13 is enabled. Reset value taken from the AUTODCONNECT pin. This bit is only available for the SpaceWire ports.

18   Link-start-on-request (LR) - When set to 1, the link-start-on-request feature described in section 75.2.12 is enabled. Reset value taken from the LINKSTARTONREQ pin. This bit is only available for the SpaceWire ports.

17   Packet length truncation (PL) - When set to 1, packets for which this port is the input port will be spilled, and an EEP written to the transmit FIFO of the output port(s), if the packets exceed the maximum length specified in the corresponding RTR.MAXPLEN register. See section 75.2.15 for more information on packet length truncation.

16   Time-code / distributed interrupt code truncation (TS) - When set to 1, packets for which this port is the input port will be spilled, and an EEP written to the transmit FIFO of the output port(s), if a valid time-code / distributed interrupt code is received, and if the code also matches the codes selected by the RTR.PCTRL2.SV and RTR.PCTRL2.SM fields. See section 75.2.19 for more information.

+46 31 7758650 | frontgrade.com/gaisler

Table 1394. 0x00000804-0x0000084C - RTR.PCTRL - Port control, ports > 0

15	Distributed interrupt code enable (IC) - When set to 0, all incoming distributed interrupt codes on this port are discarded, and no distributed interrupt codes are sent out on the port. When set to 1, the four bits RTR.PCTRL2.IR, RTR.PCTRL2.IT, RTR.PCTRL2.AR, RTR.PCTRL2.AT are used to enable / disable distributed interrupt code transmit and receive. Note that the global distributed interrupt code enable bit, RTRT-CFG.IE, also must be set to 1 for distributed interrupt codes to be sent / received. See section 75.2.17 for a description of distributed interrupts. Reset value set from INTERRUPTFWD signal.
14	Enable external time (ET) - When a time-code is received on the port and this bit is set to 0, the router discards the received time-code value and instead increments its internal time-counter value (RTR.TC.TC), and forwards a time-code with the new value to the other ports. If this bit is set to 1 when the time-code is received, the time-code is processed according to the rules described in section 75.2.16.
13	No port force (NF) - Disables forced port selection, if the SpaceWire ports are implemented with redundant ports through the VHDL generic *dualport*, using the PS bit and lets the core automatically select the active link. This bit is only available for SpaceWire ports.
12	Port select (PS) - Select between nominal and redundant SpaceWire port if enabled through the VHDL generic *dualport*. This bit is only available for SpaceWire ports.
11	Bridge enable (BE) - Enable bridge mode for FIFO ports. See section 75.4.5 for more information. This bit is only available for FIFO ports. Reset value set from ENBRIDGE signal.
10	Disable port (DI) - When set to 1, data transfers to and from this port are disabled. See section 75.2.7 for details. NOTE: If this bit is set in combination with the RTR.PCTRL.LD bit, the link interface for this port will be clock gated, and the LVDS drivers for this port will be powered-down.
9	Packet timer enable (TR) - Enable the data character timer for incoming packets. See section 75.2.14 for details. Reset value set from TIMEREN signal.
8	Priority (PR) - This bit is double mapping of the RTR.RTACTRL.PR bit. See table 1392.
7	Transmit FIFO reset (TF) - Resets the transmit FIFO on this port. This means that the FIFO is emptied (counters and pointers set to 0), and an EEP is written to the FIFO to ensure that any incomplete packet is detected by the receiver. If a packet transmission is active (another port is using this port as output port) when this bit is set, the remainder of that packet will be spilled before the EEP is inserted. This bit is self-clearing, and should not be written with 0 while it is 1, since that could abort the ongoing transmit FIFO reset.
6	Receive FIFO spill (RS) - Spills the receive FIFO for this port, meaning that the packet currently being received is spilled. The output port(s) used for the packet will have an EEP written to the transmit FIFO to indicate that the packet was ended prematurely. If no packet is received, setting this bit has no effect. This bit is self-clearing, and should not be written with 0 while it is 1, since that could abort the ongoing receive FIFO spill.
5	Time-code enable (TE) - Enables time-codes to be received and transmitted on this port. When set to 1, received time-codes are processed according to the rules described in section 75.2.16. If this bit is set to 0, all received time-codes on this port are ignored.
4	RESERVED
3	Configuration port access enable (CE) - Enable accesses to the configuration port from this port. If set to 0, incoming packets with physical address 0 will be spilled.
2	Autostart (AS) - Enable the link interface FSM's autostart feature, as defined in ECSS-E-ST-50-12C [SPW]. This bit is only available for the SpaceWire ports.
1	Link start (LS) - Start the link interface FSM. This bit is only available for the SpaceWire ports.
0	Link disabled (LD) - Disable the link interface FSM. This bit is only available for the SpaceWire ports. NOTE: When this bit is set to 1, the LVDS driver for this SpaceWire port will be powered down. If this bit is set in combination with the RTR.PCTR.DI bit, the link interface will be clock gated.

31   Early EOP (EO) - Set to 1 when an RMAP / SpaceWire Plug-and-Play command with an early EOP was received by the configuration port. See section 75.6.1.4 for error detection order.

30   Early EEP (EE) - Set to one when an RMAP / SpaceWire Plug-and-Play command with an early EEP was received by the configuration port. See section 75.6.1.4 for error detection order.

29   Packet length truncation (PL) - Set to 1 when an RMAP / SpaceWire Plug-and-Play reply packet has been spilled due to a maximum length violation. See section 75.2.15 for details.

28   Time-code / distributed interrupt code tick truncation (TT) - Set to one when an RMAP / SpaceWire Plug-and-Play reply packet has been spilled due to a time-code / distributed interrupt code. See section 75.2.19 for details.

27   Packet type error (PT) - Set to one if an RMAP / SpaceWire Plug-and-Play packet with correct header CRC, but with the packet type bits set to the reserved values "10" or "11", was received by the configuration port. See section 75.6.1.4 for error detection order.

26   Header CRC Error (HC) - Set to one if a Header CRC error is detected in an RMAP / SpaceWire Plug-and-Play command received by the configuration port. See section 75.6.1.4 for error detection order.

25   Protocol ID Error (PI) - Set to one if a packet received by the configuration port had the wrong protocol ID. Supported protocol ID:s are 0x01 (RMAP), and 0x03 (SpaceWire Plug-and-Play). See section 75.6.1.4 for error detection order.

24   Clear error code (CE) - Write with a 1 to clear the RTR.PSTSCFG.EC field. This bit is self clearing and always reads 0. Writing 0 has no effect.

23: 20   Error code (EC) - Shows the four least significant bits of the latest non-zero RMAP status code. If zero, no error has occurred.

19   RESERVED

18   Timeout spill (TS) - Set to one when an RMAP reply was spilled due to a packet timeout. See section 75.2.14 for details.

17   Uncorrectable port buffer error (ME) - This bit is set for detected errors in port RX and TX buffers.

16: 12   RESERVED

11: 7   Input port (IP) - The number of the last port from which a packet was routed to the configuration port. This field is updated even if an operation is not performed, for example due to an incorrect RMAP packet.

6: 5   RESERVED

4   Clear SpaceWire Plug-and-Play error code (CP) - Write with a 1 to clear the RTR.PSTSCFG.PC field. This bit is self clearing and always reads 0. Writing 0 has no effect.

3: 0   SpaceWire Plug-and-Play Error code (PC) - Shows the four least significant bits of the latest non-zero SpaceWire Plug-and-Play status code. If zero, no error has occurred.

Table 1396. 0x00000884-0x000008CC - RTR.PSTS - Port status, ports > 0

Table 1396. 0x00000884-0x000008CC - RTR.PSTS - Port status, ports > 0

27	RMAP / SpaceWire Plug-and-Play spill (RS) - Set to 1 when an RMAP / SpaceWire Plug-and-Play command received on this port was spilled by the configuration port.
26	Spill-if-not-ready spill (SR) - Set to 1 when a packet received on this port was spilled due to the spill-if-not-ready feature. See section 75.2.9.
25: 23	RESERVED
22	Link-start-on-request status (LR) - Set to 1 when this port either was started, or currently is trying to start, due to the link-start-on-request feature, described in section 75.2.12. This bit is only available for the SpaceWire ports.
21	Spill status (SP) - This bit is 1 when a packet that is incoming on this port currently is being spilled. Otherwise, this bit is 0.
20	Active status (AC) - Set to 1 when a packet arrives at this port and the port has been given access to the routing table. Cleared when the packet has been transmitted or spilled.
19	Active port (AP) - Indicates the active SpaceWire ports if dual ports is implemented. This bit is only available for SpaceWire ports if *dualport* is set.
18	Timeout spill (TS) - Set to 1 when a packet for which this port was the input port was spilled due to a packet timeout. See section 75.2.14 for details.
17	Uncorrectable port buffer error (ME) - This bit is set for detected errors in port RX and TX buffers.
16	Transmit FIFO full (TF) - Set to 1 when the transmit FIFO on this port is full.
15	Receive FIFO empty (RE) - Set to 1 when the receive FIFO on this port is empty.
14: 12	Link state (LS) - Current link state. 000 = Error reset. 001 = Error wait, 010 = Ready, 011 = Started, 100 = Connecting, 101 = Run state. This field is only available for the SpaceWire ports.
11: 7	Input port (IP) - This field shows the number of the input port for either the currently ongoing packet transfer on this port (if RTR.PSTS.PB = 1), or for the last packet transfer on this port (if RTR.PSTS.PB = 0).
6	Port receive busy (PR) - Set to 1 when this port is the input port of an ongoing packet transfer.
5	Port transmit busy (PB) - Set to 1 when this port is the output port of an ongoing packet transfer.
4	Invalid address (IA) - Set to 1 when an invalid address error occurred on this port. See section 75.2.11 for details.
3	Credit error (CE) - Set to 1 when a credit error has occurred. This bit is only available for the SpaceWire ports.
2	Escape error (ER) - Set to 1 when an escape error has occurred. This bit is only available for the SpaceWire ports.
1	Disconnect error (DE) - Set to 1 when a disconnect error has occurred. This bit is only available for the SpaceWire ports.
0	Parity error (PE) - Set to 1 when a parity error has occurred on. This bit is only available for the SpaceWire ports.

Table 1397. 0x00000900-0x0000094C - RTR.PTIMER - Port timer reload

31	0
RL	
*	
rw*	

9: 0	Timer reload (RL) - Port timer reload value, counted in prescaler ticks. This value is used to reload the corresponding port timer used for packet transfer timeouts, and auto-disconnect. The minimum value of this field is 1. Trying to write 0 will result in 1 being written. Reset value set from RELOADN[31:0] signal. The width of this field is determined by the VHDL generic *porttimerbits*.

31: 24   Time-code / distributed interrupt code truncation mask (SM) - Defines which bits of a time-code / distributed interrupt code that must match the value specified in RTR.PCTRL2.SV in order for a packet, for which this port is the input port, to be spilled. If a bit in this field is set to 1, the corresponding bit in RTR.PCTRL2.SV must match the time-code / distributed interrupt code. If a bit in this field is set to 0, the corresponding bit in RTR.PCTRL2.SV does not have to match the time-code / distributed interrupt code.

23: 16   Time-code / distributed interrupt code truncation value (SV) - Defines the value to use together with the RTR.PCTRL2.SM field when checking if a time-code / distributed interrupt code should spill a packet for which this port is the input port.

15   Overrun timeout enable (OR) - Enables spilling due to overrun timeouts for packets for which this port is the input port. See section 75.2.14 for details.

14   Underrun timeout enable (UR) - Enables spilling due to unerrun timeouts for packets for which this port is the input port. See section 75.2.14 for details.

13   RESERVED

12   Interrupt acknowledgment code / extended interrupt code transmit enable (AT) - Enables the transmission of interrupt acknowledgment codes / extended interrupt codes on this port. If set to 0, no interrupt acknowledgment codes / extended interrupt codes will be forwarded to this port.

11   Interrupt acknowledgment code / extended interrupt code receive enable (AR) - Enabled the reception of interrupt acknowledgment codes / extended interrupt codes on this port. If set to 0, all received interrupt acknowledgment codes / extended interrupt codes on this port will be silently discarded.

10   Interrupt code transmit enable (IT) - Enables the transmission of interrupt codes on this port. If set to 0, no interrupt codes will be forwarded to this port.

9   Interrupt code receive enable (IR) - Enabled the reception of interrupt codes on this port. If set to 0, all received interrupt codes on this port will be silently discarded.

8: 6   RESERVED

5: 1   Static route destination (SD) - When RTR.PCTRL.ST is set to 1, incoming packets on this port will be routed based on the value of this field, and the setting of RTR.PCTRL2.SC, instead of the packet's first byte.

0   Static route configuration (SC) - When this bit is set to 1, the RTR.RTPMAP register corresponding to the physical address specified by the RTR.PCTRL2.SD field will be used when routing packets, if RTR.PCTRL.ST is set to 1.

Table 1400. 0x00000A00 - RTR.RTRCFG - Router configuration / status

31 27	26 22	21 17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
SP	AP	FP	R	SR	PE	IC	IS	IP	AI	AT	IE	RE	EE	R	SA	TF	RM	TA	PP
*	*	*	0	*	*	0	0	0	*	1	*	0	*	0	1	*	0	1	1
r	r	r	r	r	r	rw	rw	rw	rw	rw	rw	rw	rw	r	rw	rw	wc	r	r

31: 27   SpaceWire ports (SP) - Set to the number of SpaceWire ports in the router.

26: 22   AMBA ports (AP) - Set to the number of AMBA ports in the router.

21: 17   FIFO ports (FP) - Set to the number of FIFO ports in the router.

16   RESERVED

15   Static routing enable (SR) - This read-only bit specifies if the router's static routing feature is enabled (1) or disabled (0). See section 75.2.8 for details. The value is set from the STATICROUTEEN signal at reset.

14   SpaceWire Plug-and-Play enable (PE) - This read-only bit specifies if the router's SpaceWire Plug-and-Play features are enabled (1) or disabled (0). See section 75.7.1 for details. The value is set from the PNPEN pin at reset.

13   ISR change timer enable (IC) - If set to 1, the router will wait for the time period specified by the RTR.IRC-TIMER register after an ISR bit change value, before it allows an incoming distributed interrupt code to change the value of the same ISR bit. If set to 0, the ISR change timers are not used, and an ISR bit is allowed to change value again as soon as the previous distributed interrupt code has been distributed.

12   Distributed interrupt code selection routine (IS) - If set to 0, the router uses round-robin on the interrupt numbers when deciding which distributed interrupt code to distribute next. If set to 1, the router gives priority to lower interrupt numbers when deciding which distributed interrupt code to distribute. See section 75.2.17.1.

11   Distributed interrupt code priority (IP) - When set to 0, all interrupt codes have priority over all interrupt acknowledgment codes / extended interrupt codes, and will be distributed first. When set to 1, all interrupt acknowledgment codes have priority over all interrupt codes. See section 75.2.17.1.

10   Auxiliary distributed interrupt codes enable (AI) - If set to 1, distributed interrupt codes can be sent and received on the auxiliary time-code / distributed interrupt code interface. If set to 0, all distributed interrupt codes received on the auxiliary interface are silently discarded, and no distributed interrupt codes will be transmitted on the interface. Reset value set from INTERRUPTFWD signal.

9   Auxiliary time-code enable (AT) - If set to 1, time-codes can be sent and received on the auxiliary time-code / distributed interrupt code interface. If set to 0, all time-codes received on the auxiliary interface are silently discarded, and no time-codes will be transmitted on the interface.

8   Distributed interrupt codes enable (IE) - Global enable/disable for distributed interrupt codes. If set to 0, all received distributed interrupt codes will either be silently discarded (if RTRCFG.TF = 1), or handled as time-codes (if RTRCFG.TF = 0). When set to 1, whether or not distributed interrupt codes are received or transmitted on a port depends on the setting of the register bits RTR.PCTRL.IC, RTR.PCTRL2.IR, RTR.PCTRL2.IT, RTR.PCTRL2.AR, and RTR.PCTRL2.AT. Reset value taken from INTERRUPTCODEEN signal.

7   Reset (RE) - Resets the complete router when written with a 1. When this bit is written through RMAP, an RMAP reply will not be sent, even if the reply bit in the RMAP commands Instruction field is set to 1. This bit is self-clearing.

6   Enable extended distributed interrupts (EE) - If set to 0, all distributed interrupt codes with bit 5 set to 1 are handled as interrupt acknowledgment codes. If set to 1, all distributed interrupt codes with bit 5 set to 1 are handled as extended interrupt code. Reset value taken from INTERRUPTMODE signal. See section 75.2.17.

5   RESERVED

4   Self addressing enable (SA) - If set to 1, ports are allowed to send packets to themselves. If set to 0, packets with the same input port as output port are spilled, and an invalid address error is asserted for that port.

3   Time-code control flag mode (TF) - When set to 0, all received time-codes / distributed interrupt codes are handled as time-codes, no matter the value of the control flags (bits 7:6 of the code). When set to 1, the time-code control flags must have value "00" to be considered valid time-codes. Note that the RTRCFG.IE bit has priority over this bit, which means that if RTRCFG.IE is 1, then setting this bit to 0 has no impact. Reset value taken from TIMECODEFILT.

2   Routing table error (RM) - This bit is set for detected errors in Routing table (PORT_SETUP and ROUTE_TABLE) memory.

Table 1400. 0x00000A00 - RTR.RTRCFG - Router configuration / status

1	Timers available (TA) - Constant value 1. Indicates that the router has support for timers, as described in section 75.2.14.
0	SpaceWire Plug and Play available (PP) - Constant value 1. Indicates that the router support SpaceWire Plug and Play, as described in section 75.7.1.

Table 1401. 0x00000A04 - RTR.TC - Time-code

31			10	9	8	7	6	5		0
RESERVED				RE	EN	CF		TC		
0x000000				0	*	0x0		0x00		
r				rw*	rw	r		r		

31: 10	RESERVED
9	Reset time-code (RE) - When this field is written to 1, the RTR.TC.CF and RTR.TC.TC fields are reset. This bit is self-clearing, and always reads 0. Writing 0 has no effect.
8	Enable time-codes (EN) - When set to 1, received time-codes are handled by the router according to the rules described in 75.2.16. When set to 0, all received time-codes are silently discarded. Reset value set through TIMECODEREGEN signal.
7: 6	Time-control flags (CF) - The current value of the router's time-code control flags (bits 7:6 of the latest valid time-code received).
5: 0	Time-counter (TC) - Current value of the router's time counter.

Table 1402. 0x00000A08 - RTR.VER - Version / instance ID

31	24	23	16	15	8	7	0
MA		MI		PA		ID	
0x01		0x02		0x00		*	
r		r		r		rw	

31: 24	Major version (MA) - Holds the major version number of the router. Set to 0x01 for this version.
23: 16	Minor version (MI) - Holds the minor version number of the router. Set to 0x02 for this version.
15: 8	Patch (PA) - Holds the patch number of the router. Set to 0x00 for this version.
7: 0	Instance ID (ID) - Holds the instance ID number of the router. Reset value is set through INSTANVEID[7:0] signal.

Table 1403. 0x00000A0C - RTR.IDIV - Initialization divisor

Table 1404. 0x00000A10 - RTR.CFGWE - Configuration port write enable

31	1	0
RESERVED		WE
0x00000000		1
r		rw

31: 1   RESERVED

0   Configuration port write enable (WE) - When set to 1, write accesses to the configuration port area are allowed. When set to 0, write accesses are only allowed to this register. RMAP write and RMAP read-modify-write commands will be replied to with the Status field set to 0x0A (authorization failure), if a reply was requested. The value of this bit has no effect for SpaceWire Plug-and-Play commands.

Table 1405. 0x00000A14 - RTR.PRESCALER - Timer prescaler reload

31	0
RL	
*	
rw*	

31: 0   Timer prescaler reload (RL) - Global prescaler reload value used for generating a common tick for the data character timers, auto-disconnect timers, and distributed interrupt code timers. The prescaler runs on the system clock, and a tick is generated every RTR.PRESCALER.RL+1 CLK cycle. The minimum value of this field is 49. Trying to write a value less than that will result in 49 being written. Reset value is set through RELOAD[31:0] signal. The width of this field is determined by the VHDL generic *timerbits*.

Table 1406. 0x00000A18 - RTR.IMASK - Interrupt mask

r			rw	rw	rw	rw	rw	rw	rw	rw	rw	rw	rw

31: 11   RESERVED

10   SpaceWire Plug-and-Play error (PE) - Generate an interrupt when a SpaceWire Plug and Play error has been detected in the configuration port. The different errors are described in 75.7.1.

9   Spill-if-not-ready (SR) - Generate an interrupt when a packet has been spilled because of the spill-if-not-ready feature described in section 75.2.9.

8   Run-state entry (RS) - Generate an interrupt when a SpaceWire link enters run-state.

7   Time-code / distributed interruptcode tick truncation (TT) - Generate an interrupt when a packet has been spilled because of the time-code / distributed interrupt code truncation feature described in section 75.2.19.1.

6   Packet length truncation (PL) - Generate an interrupt when a packet has been spilled due to the packet length truncation feature described in section 75.2.15.

5   Timeout spill (TS) - Generate an interrupt when a packet has been spilled due to the timeout mechanism.

4   Auxiliary configuration port error (AC) - Generate an interrupt when either a header CRC error, protocol ID error, packet type error, early EOP, or early EEP has been detected in the configuration port.

3   RMAP error (RE) - Generate an interrupt when an error has been detected in the configuration port for an RMAP command such that the PSTS.EC field is set to a non-zero value.

2   Invalid address (IA)- Generate an interrupt when an invalid address error has occurred on a port. See RTR.PSTS:IA bit and section 75.2.11 for a definition of invalid address.

1   Link error (LE) - Generate an interrupt when a link error has been detected on a SpaceWire port.

0   Memory error (ME) - Generate an interrupt when a port buffer error is detected.

Table 1407. 0x00000A1C - RTR.IPMASK - Interrupt port mask

31	0
IE	
0x00000000	
rw	

31: 0   Port interrupt enable (IE) - Set a bit to 1 to enable interrupts to be generated for an error detected in the port with the same number as the bit index. An interrupt is signaled through the IRQ pin, and optionally through a distributed interrupt code. Only bits corresponding to existing ports, as defined by the sum of the VHDL generics *spwports*, *ambaports*, *fifoports* and *customport*, are implemented.

Table 1408. 0x00000A20 - RTR.PIP - Port interrupt pending

31	0
IP	
0x00000000	
wc	

31: 0   Interrupt pending (IP) - When a bit is set to 1, the port with the same number as the bit index was the source of an interrupt. A bit in this field will only be set to 1 for a generated interrupt if the port's corresponding bit in RTR.IPMASK is set, as well as the error types corresponding bit in RTR.IMASK, are set. Only bits corresponding to existing ports, as defined by the sum of the VHDL generics *spwports*, *ambaports*, *fifoports* and *customport*, are implemented.

Table 1409. 0x00000A24 - RTR.ICODEGEN - Interrupt code generation

31 22	21	20	19	18	17	16	15 6	5 0
RESERVED	HI	UA	AH	IT	TE	EN	RESERVED	IN
0x000	0	0	0	0	1	0	0x000	0x00
r	rw	rw	rw	rw	rw	rw	r	rw
						0		

31: 22   RESERVED

21   AMBA interrupt enable (HI) - Enable AHB interrupt generation.

20   Interrupt code generation un-acknowledge mode (UA) - If this bit is set to 1, an ISR timeout for a distributed interrupt that was generated by the router will clear the bits in the RTR.PIP register that were set when the interrupt was generated. If this bit is set to 0, no extra handling is done on an ISR timeout event, and the bits in RTR.PIP will stay set. See section 75.2.17.

19   Interrupt acknowledgment code handling (AH) - When set to 1, and the router has generated an interrupt code, a received interrupt acknowledgment code with the interrupt number matching the RTR.ICODEGEN.IN field will clear the bits in the RTR.PIP register that were set when the interrupt code was generated. If set to 0, no extra handling of a received interrupt acknowledgment code is done and the bits in RTR.PIP will stay set. This bit is unused when the distributed interrupts are operating in the extended interrupt mode. See section 75.2.17.

18   Interrupt type (IT) - 0 = Level. 1 = Edge. When set to 0, a new interrupt code is distributed as long as RTR.PIP register is non zero. When set to 1, a new interrupt code is distributed only when a bit in RTR.PIP toggles from 0 to 1. See section 75.2.17.

Table 1409. 0x00000A24 - RTR.ICODEGEN - Interrupt code generation

17	Interrupt acknowledgment code to interrupt code timer enable (TE) - If set to 1, the router will wait for the time period specified by the RTR.AITIMER register after the reception of an interrupt acknowledgment code (for which the router generated the corresponding interrupt code) until a new interrupt code is allowed to be generated. If set to 0, the timer is not used, and a new interrupt code is allowed to be generated as soon as the interrupt acknowledgment code has been distributed. This bit is unused when the distributed interrupts are operating in the extended interrupt mode.
16	Interrupt code generation enable (EN) - When 1, distributed interrupt code generation is enabled, and an interrupt code / extended interrupt code can be generated when an internal error event occurs. See section 75.2.17.
15: 6	RESERVED
5: 0	Interrupt number (IN) - Sets the interrupt number of the distributed interrupt code that will be generated when the interrupt code generation feature is enabled (RTR.ICODEGEN.EN = 1). Note that when the distributed interrupts are operating in interrupt with acknowledgments mode, this field must not be set to a value larger than 31, since that would specify an interrupt with acknowledgment code. See section 75.2.17.

Table 1410. 0x00000A28 - RTR.ISR0 - Interrupt code distribution ISR register, interrupt 0-31

31	0
IB	
0x00000000	
wc	

31: 0	Distributed interrupt code ISR bits (IB) - The current value of the distributed interrupt code ISR register for interrupt numbers 0 to 31. Each bit index corresponds to the ISR bit value for the corresponding interrupt number. A bit value of 1 indicates that an interrupt code with the corresponding interrupt number has been received, but not yet acknowledged. A bit value of 0 indicates either that no interrupt code with the corresponding interrupt number has been received, or that the previous interrupt code was either acknowledged or timed out. This register should be normally only be used for diagnostics and / or FDIR.

Table 1411. 0x00000A2C - RTR.ISR1 - Interrupt code distribution ISR register, interrupt 32-63

31	0
IB	
0x00000000	
wc	

31: 0	Distributed interrupt code ISR bits (IB) - The current value of the distributed interrupt code ISR register for interrupt numbers 32 to 63. Each bit index + 32 corresponds to the ISR bit value for the corresponding interrupt number. A bit value of 1 indicates that an extended interrupt code with the corresponding interrupt number has been received. A bit value of 0 indicates either that no extended interrupt code with the corresponding interrupt number has been received, or that the previous interrupt cod has timed out. Note that if the distributed interrupts are operating in interrupt with acknowledgments mode, this register is unused. This register should be normally only be used for diagnostics and / or FDIR.

Table 1412. 0x00000A30 - RTR.ISRTIMER - Interrupt code distribution ISR timer reload

31	0
RL	
*	
rw	

31: 0	Interrupt code distribution ISR timer reload (RL) - Interrupt code distribution ISR timer reload value, counted in prescaler ticks. Each ISR bit has its own timer, which is started and reloaded with the value of this field when an interrupt code / extended interrupt code with the corresponding interrupt number is received (or generated by the router). Reset value is set through IRQTIMEOUTRELOAD[31:0] pins. See section 75.2.17 for details on interrupt code distribution. The width of this field is determined by the VHDL generic *irqtimerbits*.

75.7.1 SpaceWire Plug-and-Play interface

The configuration port supports parts of the SpaceWire Plug-and-Play protocol described in [SPW-PNP]. The supported fields are listed in table 1439, and explained in more detail in tables 1440 through 1454.

The SpaceWire Plug-and-Play protocol uses standard RMAP commands and replies with the same requirements as presented in section 75.6.1, but with the following differences:

•   Protocol Identifier field of a command shall be set to 0x03.

•   A command's address fields shall contain a word address. The SpaceWire Plug-and-Play addresses are encoded as shown in table 1437.

•   The increment bit in the command's instruction field shall be set to 1, otherwise a reply with Status field set to 0x0A (authorization failure) is sent.

•   RMAP Read-modify-write command is replaced by a compare-and-swap operation. The command's data fields shall contain the new data to be written, while the mask fields shall contain the value that the current data must match in order for the new data to be written. If there is a mismatch, a reply with Status field set to 0x0A (authorization failure) is sent.

•   The reply packet's Status field can contain the additional status codes described in table 1438.

Table 1437. SpaceWire Plug-and-Play address encoding

31 24	23 19	18 14	13 0
Application Index	Protocol Index	FieldSet ID	Field ID

Table 1438. SpaceWire Plug-and-Play status codes

Value	Description
0xF0	Unauthorized access - A write, or compare-and-swap command arrived either when the router was not configured (Device ID field = 0), or the command did not match the owner information saved in the Link Information field and Owner Address fields.
0xF1	Reserved field set - A read, write, or compare-and-swap command's address field points to a non existing field set.
0xF2	Read-only field - A write, or compare-and-swap command's address points to a read-only field.
0xF3	Compare-and-swap-only-field - A write command's address points to a compare-and-swap-only field.

Note that it is not possible to access the SpaceWire Plug-and-Play fields through the AHB slave interface, except for the fields that are double mapped into the configuration port's address space (see section 75.7).

An access (read, write, or compare-and-swap) made either to a field outside the Device Information service, or to a field in an undefined field set within the Device Information service, will generate a reply with the Status field set to 0xF1. An access (read, write, or compare-and-swap) to an undefined or unsupported field in one of the defined field sets, within the Device Information service, is not treated as an error, and the Status field of the reply will be 0x00. Possible write-data for such an access is discarded, and possible read-data returned is always 0.

Please reference the [SPWPNP] for additional details to what is presented in this section.

75.8   Vendor and device identifiers

The core has AMBA vendor ID 0x01 and device ID 0x8B (applies to the AHB slave interface). SpaceWire Plug and Play is not a standard yet so identifiers for this protocol have not been assigned.

75.9 Implementation

75.9.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

75.10 Configuration options

Table 1455 shows the configuration options of the core (VHDL generics).

*Table 1455.*Configuration options

Generic	Function	Allowed range	Default
input_type	Select receiver type. 0 = Self clocking (xor), 1 = Interface for Frontgrade SpaceWire transceiver, 2 = Single data rate sampling, 3 and 4 = Double data rate sampling, 5 = Self-clocking with external recovery, 6 = Self-clocking with external recovery and DDR register for data. This generic must be set to the same value as the GRSPW2_PHY generic with the same name.	0 - 6	0
output_type	Select transmitter type. 0 = single data rate, 1 = double data rate, 2 = interface for Frontgrade SpaceWire transceiver	0 - 2	0
rxtx_sameclk	Set to one if the same clock net is connected to both the receiver and transmitter (which means this feature is only applicable when the receiver uses sampling). This will remove some unnecessary synchronization registers.	0 - 1	0
fifosize	Sets the number of entries in the 9-bit receiver fifo (N-Char fifo).	16 - 2048	64
tech	Technology for on-chip memories.	-	-
scantest	Enable scan test support	0 - 1	0
techfifo	Enable tech support for on-chip memories.	0 - 1	0
ft	Enable fault-tolerance against SEU errors	0 - 2	0
spwen	Set to 1 to enable SpaceWire ports	0 - 1	1
ambaen	Set to 1 to enable AMBA ports	0 - 1	0
fifoen	Set to 1 to enable FIFO ports	0 - 1	0
spwports	Sets the number of SpaceWire link ports.	0 - 31	2
ambaports	Sets the number of AMBA ports.	0 - 16	0
fifoports	Sets the number of FIFO ports.	0 - 31	0
arbitration	Select the arbitration type. Currently unused.	0 - 1	0
rmap	Include hardware RMAP target in the AMBA ports. RMAP CRC logic will also be added in this case and the rmapcrc generic will have no additional effect. Bit index 0 of the binary representation of the integer corresponds to amba port 1, index 1 to amba port 2 etc.	0 - 16#FFFF#	0
rmapcrc	Enable RMAP CRC logic for the AMBA ports. Bit index 0 of the binary representation of the integer corresponds to amba port 1, index 1 to amba port 2 etc.	0 - 16#FFFF#	0
fifosize2	Sets the number of entries in the 32-bit AHB fifos for the AMBA ports.	4 - 32	32
almostsize	Sets the number of characters from the full or empty conditions that is used as the limit for the almost full and almost empty indications for the FIFO ports.	1 - 32	8

*Table 1455.*Configuration options

Generic	Function	Allowed range	Default
rxunaligned	Receiver unaligned write support. If set, the receiver can write any number of bytes to any start address without writing any excessive bytes. Bit index 0 of the binary representation of the integer corresponds to amba port 1, index 1 to amba port 2 etc.	0 - 16#FFFF#	0
rmapbufs	Sets the number of buffers to hold RMAP replies.	2 - 8	4
dmachan	Sets the number of DMA channels	1 - 4	1
hindex	AHB master index.	0 - NAHBMST-1	0
pindex	APB interface index value for first AMBA port. Incremented by one for each subsequent port.	0 - NAPBLSV-1	0
paddr	Determines the starting APB address for theAMBA ports together with pmask. For the first port bits 19 downto 12 in the address will be paddr anded with pmask. See the grlib manual for more details. Subsequent ports will have a starting address which is an increment of the previous value. The increment is determined by pmask. 16#FFF# = increment 1, 16#FFE# = increment 2, 16#FFC# = increment 4 etc.	0 - 16#FFF#	0
pmask	Mask for the APB address for the AMBA ports. Anded with paddr to determine the starting address and the range of the area for each port.	0 - 16#FFF#	16#FFF#
pirq	Interrupt number for first AMBA port. Will be incremented by one for each subsequent port.	0 - NAHBIRQ-1	0
cfghindex	AHB slave index.	0 to NAHBSLV-1	0
cfghaddr	ADDR field of the AHB BAR0 defining the AHB slave address space.	0 to 16#FFF#	0
cfghmask	MASK field of the AHB BAR0 defining the AHB slave address space.	0 to 16#FFF#	16#FFF#
ahbslven	Enable AHB slave interface.	0 to 1	0
timerbits	Enables timers when set to a nonzero value. The value determines the number prescaler bits.	0 to 31	0
pnp	Enable Plug and play on the configuration port.	0 to 1	0
autoscrub	Enable automatic scrubbing of routing table and port setup memories.	0 to 1	0
sim	Enable simulation mode. It has no effect when synthesizing but for simulation it shortens the autoscrub period to 1024 clock cycles to make simulation times shorter.	0 to 1	0
dualport	Enable dual port mode (primary and redundant) for SpaceWire ports.	0 to 1	1
charcntbits	Enables characters counters if nonzero and sets the number of counter bits.	0-31	0
pktcntbits	Enables packet counters if nonzero and sets the number of counter bits.	0-31	0
prescalermin	Sets the minimum value of the prescaler reload register. This only affects writes to the register, not the reset value.	-	250
spacewired	Support for SpaceWire-D (packet truncation)	0 - 1	0
interruptdist	Enables for distributed interrupt support: 0: Disbled 1: Interrupt with acknowledgment mode 2: Extended Interrupt mode	0 - 2	0
apbctrl	Enabled the ADHOC AHB-slave interface to be connected to APBCTRL (APB bridge)	0 - 1	0

*Table 1455.*Configuration options

Generic	Function	Allowed range	Default
rmapmaxsize	Set maximum number of bytes supported in a RMAP/PNP read/write	4 - 512	4
gpolbits	Set number of bits for the general purpose level signals	0 - 128	0
gpopbits	Set number of bits for the general purpose pulse signals	0 - 128	0
gpibits	Set number of bits for the general purpose input signals	0 - 128	0
customport	Enabled custom port.	0 - 1	0
inputtest	Enables test-logic (only supported for SDR output type)	0 - 1	0
spwpnpvendid	Specifies the SpaceWire Plug-and-Play Device Vendor ID	0 - 16#FFFF#	0
spwpnpprodid	Specifies the SpaceWire Plug-and-Play Device Product ID	0 - 16#FFFF#	0
porttimerbits	Sets the number of bits for the port's data character timers.	1 - 32	10
irqtimerbits	Sets the number of bits for the Interrupt distribution time-out timers.	1 - 32	10
auxtimeen	Enables the Auxiliary time/interrupt interface.	0 - 1	1
num_txdesc	Specifies the number of entries in the transmit descriptor table	64, 128, 256, 512	64
num_rxdesc	Specifies the number of entries in the receive descriptor table	128, 256, 512, 1024	128
auxasync	0: Auxiliary time/interrupt interface is synchronous to core clock. 1: Auxiliary time/interrupt interface is asynchronous to core clock.	0 - 1	0
hirq	Interrupt line used by the AHB-slave interface.	0 - NAHBIRQ-1	0
codecclkgate	Enable the internal clockgate for the router clocks by setting this generic to 1. Note that this generic is only applicable to the wrapper grspwrouterm, as the clockgate is instantiated in there. If using the router without wrapper (grspwrouter), this generic is not available and the clockgate is disabled	0 - 1	0
internalrstgen	If this generic is set to 1, the reset generators for every clock domain are instantiated internally in the wrapper of the SpW router (grspwrouterm). Otherwise, the user is expected to implement the reset generation from the top level entity. This generic is only available when using the wrapper.	0 - 1	1
rstsrctmr	Enables the Triple Module Redundancy for the asynchronous reset nets of the core	0 - 1	0

75.11 Signal descriptions

Table 1456. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	Core clock	-
RST_CODEC [SPWPORTS-1:0]	N/A	Input	Resets to be used by the internal SpW codecs. There is one per SpW port. This signal is not used by the core if the internal reset generators are enabled in the wrapper (generic internalrstgen to 1). In that case, it is recommended to set every element of the array to '0'.	Low
CLK_CODEC [SPWPORTS-1:0]	N/A	Input	Main clock to be used by the internal SpW codecs. There is one per SpW port. This signal is not used by the core if the internal reset generators are enabled in the wrapper (generic internalrstgen to 1). In that case, it is recommended to set every element of the array to '0'.	-
RXASYNCRST [SPWPORTS-1:0]	N/A	Input	Asynchronous resets for the SpW RX clocks to be used by the internal SpW codecs. There is one per SpW port. This signal is not used by the core if the internal reset generators are enabled in the wrapper (generic internalrstgen to 1). In that case, it is recommended to set every element of the array to '0'.	Low
RXSYNCRST0 [SPWPORTS-1:0]	N/A	Input	Synchronous resets for the SpW RX clocks to be used by the internal SpW codecs. Used by the primary SpW port (in a dualport configuration). This signal is not used by the core if the internal reset generators are enabled in the wrapper (generic internalrstgen to 1). In that case, it is recommended to set every element of the array to '0'. This generic is only available on the grspwrouter entity.	Low
RXCLK0 [SPWPORTS-1:0]	N/A	Input	Receiver clock vector. Used by the primary SpW port (in a dualport configuration). This generic is only available on the grspwrouter entity.	-
RXSYNCRST1 [SPWPORTS-1:0]	N/A	Input	Synchronous resets for the SpW RX clocks to be used by the internal SpW codecs. Used by the redundant SpW port (in a dualport configuration). This signal is not used by the core if the internal reset generators are enabled in the wrapper (generic internalrstgen to 1). In that case, it is recommended to set every element of the array to '0'. This generic is only available on the grspwrouter entity.	Low
RXCLK1 [SPWPORTS-1:0]	N/A	Input	Receiver clock vector. Used by the redundant SpW port (in a dualport configuration). This generic is only available on the grspwrouter entity.	-
RXSYNCRST [SPWPORTS *(1+dualport)-1:0]	N/A	Input	Synchronous resets for the SpW RX clocks to be used by the internal SpW codecs. There are one or two per SpW port, depending on the value of the generic dualport. This signal is not used by the core if the internal reset generators are enabled in the wrapper (generic internalrstgen to 1). In that case, it is recommended to set every element of the array to '0'. This generic is only available when using the wrapper (grspwrouterm).	Low

Table 1456. Signal descriptions

Signal name	Field	Type	Function	Active
RXCLK [SPWPORTS *(1+dualport)-1:0]	N/A	Input	Receiver clock vector. One or two clocks for each SpaceWire link, depending on the value of the generic dualport. This generic is only available when using the wrapper (grspwrouterm).	-
TXSYNCRST [SPWPORTS-1:0]	N/A	Input	Synchronous resets for the SpW TX clocks to be used by the internal SpW codecs. There is one per SpW port. This signal is not used by the core if the internal reset generators are enabled in the wrapper (generic internalrstgen to 1). In that case, it is recommended to set every element of the array to '0'.	Low
TXCLK [SPWPORTS-1:0]	N/A	Input	SpaceWire link transmitter clock. If not using the wrapper or the internal reset generator feature, a clock per link is required. However, if the generic internalrstgen is set to 1, only the first element (LSB) of the array is required, and the same clock will be used for every link. Clock division is done locally.	-
TXCLKN [SPWPORTS-1:0]	N/A	Input	Transmitter inverted default run-state clock. Only used in DDR transmitter mode for technologies not supporting local generation of inverted clock. As for TXCLK, only the first element of the array is required if the internal reset generation is enabled.	-
TESTEN	N/A	Input	Scan test enable.	High
TESTRST	N/A	Input	Scan test reset.	Low
TESTOEN	N/A	Input	Scan test output enable	-
SCANEN	N/A	Input	Scan test enable	-
DI[61:0]	N/A	Input	SpaceWire link data input vector. It should be connected to the number of GRSPW2_PHY entities corresponding to the number of SpaceWire links in the router. 1:0 go to link 0, 3:2 to link 1 etc.	-
DVI[61:0]	N/A	Input	SpaceWire link data valid input vector. It should be connected to the number of GRSPW2_PHY entities corresponding to the number of SpaceWire links in the router. 1:0 go to link 0, 3:2 to link 1 etc.	
DCONNECT [61:0]	N/A	Input	Disconnect vector. It should be connected to the number of GRSPW2_PHY entities corresponding to the number of SpaceWire links in the router. 1:0 go to link 0, 3:2 to link 1 etc.	
DCONNECT2 [61:0]			Copy of the signal DCONNECT as part of the Triple Modular Redundancy protection.	
DCONNECT3 [61:0]			Copy of the signal DCONNECT as part of the Triple Modular Redundancy protection.	
DO[61:0]	N/A	Output	Data output vector. In Frontgrade PHY mode two bits per link are used. 1:0 correspond to link 0, 3:2 to link 1 and so on. In the other two modes only the lower of the two bits in each pair are used.

Table 1456. Signal descriptions

Signal name	Field	Type	Function	Active
SO[61:0]	N/A	Output	Strobe output vector. In Frontgrade PHY mode two bits per link are used. 1:0 correspond to link 0, 3:2 to link 1 and so on. In the other two modes only the lower of the two bits in each pair are used.	
AHBMI	*	Input	AHB master in signals.	-
AHBMO	*	Output	Vector of AHB master out signals. One set of signals for each AMBA port.	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
AHBSI	*	Input	AHB slave in signals.	-
AHBSO	*	Output	AHB slave out signals.	-
RI	RMAPEN[30:0]	Input	RMAP enable signal for each AMBA port. AMBA port 0 is connected to RMAPEN[0] and port 1 to [1] etc.	-
	IDIVISOR[7:0]	Input	Initialization divisor value for the SpaceWire links.	-
	TXWRITE[30:0]	Input	Transmitter FIFO write signals for the FIFO interfaces.	-
	TXCHAR[30:0][8:0]	Input	Transmitter character signals for the FIFO interfaces.	-
	RXREAD[30:0]	Input	Receiver FIFO read signals for the FIFO interfaces.	-
	TICKIN[30:0]	Input	Tick input signals for the FIFO and AHB interfaces	High
	TIMEIN[30:0][7:0]	Input	Time input signals for the FIFO and AHB interfaces.	-
	RELOAD[31:0]	Input	Prescaler default reload value (set during reset).	-
	RELOADN[31:0]	Input	Individual timer default reload value (set during reset).	-
	TIMEREN	Input	Sets the reset value for the timer enable bit in the port control registers..	-
	TIMECODEEN	Input	Enable time-code functionality. If 0 no time-codes will be propagated by the router. When 1 time-code functionality is enabled.	High
	CFGLOCK	Input	Lock configuration port accesses from all ports except port 1. When set to 0 the configuration port can be accessed from all ports (if not individually disabled through register). If set to 1 the configuration area can only be accessed from port 1 (the AHB slave interface is not affected byt this). The configuration enable bit for port 1 does not have any effect in this case.	High
	SELFADDREN	Input	Reset value for selfaddren register bit. This bit enables ports to address themselves i.e a packet received on a port will be transmitted on the same port. If not enabled the packet will be discarded with an invalid address error.	High
	LINKSTAR-TREQ[31:1]	Input	Reset value for the linkstartreq register bit. When set ports will be automatically started (provided they are not disabled) if a packet needs to be transmitted on them.

Table 1456. Signal descriptions

Signal name	Field	Type	Function	Active
RI	AUTODCON-NECT[31:1]	Input	Reset value for the autodconnect register bit. When set ports started with the linkstartreq feature will automatically disconnect after a timeout period of no activity.	
	INSTANCEID[7:0]	Input	Sets the reset value of the instance ID field of the version register.	
	ENBRIDGE[31:0]	Input	Reset value for bridge mode on FIFO ports	
	ENEXTTIME[30:0]	Input	Sets the reset value for the external time selection bit for FIFO interfaces. When 0 a tick-in on the corresponding TICKIN signal causes the internal time-counter to be incremented and the new value to be transmitted. When 1 the value from the TIMEIN signal will be used. In both causes the control flags are taken from TIMEIN[7:6].	High
	AUXTICKIN	Input	Time counter tick input. Increments internal time-counter (or set time-counter to auxtimein) and transmits the new value.	
	AUXTIMEINEN	Input	Select between: internal time-counter or auxtimein	
	AUXTIMEIN[7:0]	Input	The time-code or interrupt- / interrupt-acknowledge-code	
	IRQTIMEOUTRE-LOAD[31:0]	Input	Reset value for interrupt timeout value	
	AHBSO *	Input	ADHOC AHB-slave output	
	INTERRUPTCO-DEEN	Input	Reset value for interrupt enable	
	PEPEN	Input	Reset value for PNP enable	
	TIMECODEFILT	Input	Reset value for Time-code control flag mode (TF)	
	INTERRUPTFWD	Input	Reset value for Distributed interrupt code enable (IC) and Auxiliary distributed interrupt codes enable (AI)	
	SPILLIFN-RDY[31:1]	Input	Reset value for spill-if-not-read	
	TIMECODEREGEN	Input	Reset value for global time-code enable	
	GPI[127:0]	Input	General purpose register input	
	STATICROUTEEN	Input	Reset value for Static routing enable (SR)	
	SPWCLKLOCK	Input	Lock signal for codec clock generation. Only used when using the wrapper (grspwrouterm).	
	IRQGENRE-LOAD[31:0]	Input	Reset value for Interrupt acknowledgment code to interrupt code timer reload (RL)	
	INTERRUPTMODE	Input	Reset value for Enable extended distributed interrupts (EE) - If set to 0, all distributed interrupt codes with bit 5 set to 1 are handled as interrupt acknowledgment codes. If set to 1, all distributed interrupt codes with bit 5 set to 1 are handled as extended interrupt code.	
	TESTD	Input	Test input for SpaceWire data	
	TESTS	Input	Test input for SpaceWire Strobe	
	TESTINPUT	Input	Test input enable

Table 1456. Signal descriptions

Signal name	Field	Type	Function	Active
RO	RXCHARAV[30:0]	Output	Receiver data available vector. One signal per FIFO port.	-
	RXAEMPTY[30:0]	Output	Receiver FIFO almost empty vector. One signal per FIFO port.	-
	TXFULL[30:0]	Output	Transmitter FIFO full vector. One signal per FIFO port.	-
	TXAFULL[30:0]	Output	Transmitter FIFO almost full vector. One signal per FIFO port.	-
	RXCHAR[30:0][8:0]	Output	Receiver FIFO character output vector. One character vector per FIFO port.	-
	AUXTICKOUT	Output	Tick-out signal that is asserted when a valid time-code or interrupt- / interrupt-acknowledge-code has been received.	High
	AUXTIME-OUT[7:0]	Output	Contains the received time-code or interrupt- / interrupt-acknowledge-code when AUXTICK-OUT is asserted.	-
	AUXTICKINDONE	Output	Asserted when a time-code or interrupt- / interrupt-acknowledge-code sent via the AUX-TICKIN signal has been accepted for transmission.	High
	TICKOUT[30:0]	Output	Tick out vector. One signal per FIFO or AMBA port.	High
	TIME-OUT[30:0][7:0]	Output	Time-code output vector. One time-code signal per FIFO or AMBA port.	-
	GERROR	Output	Global error. Asserted high when one or both of LERROR and MERROR are asserted.	High
	LERROR	Output	Asserted when one or more link errors have been detected on the SpaceWire ports. Asserted until the corresponding status bits have been c leared.	High
	MERROR	Output	Asserted when one or more uncorrectable parity errors have been detected in the on-chip memories. Asserted until the corresponding status bits have been cleared.	High
	LINKRUN[30:0]	Output	Each bit is asserted (set to 1) when the corresponding link is in run-state. Bit 0 corresponds to port 1, bit 1 to port 2 etc. This is only valid if the port is configured as a SpaceWire link.	
	PORTERR[31:0]	Output	Bit[n] is asserted when port errors have been detected on the SpaceWire ports[n]. Asserted until the corresponding status bits have been c leared.	High
	SPWEN[30:0]	Output	Signals that SpaceWire port is enabled (power-down nand powerdownrx)	High
	AHBSI *	Output	Ad hoc AHB-slave input	-
	POWER-DOWN[30:0]	Output	TX reset and Link disable	
	POWER-DOWNRX[30:0]	Output	Link disabled	
	GPO[127:0]	Output	General purpose register output	-

Table 1456. Signal descriptions

Signal name	Field	Type	Function	Active
RO	RESET	Output	Signal which indicates that the SpW Router is globally reset. Its value is that of the bit 7 of the Router Configuration/Status register (offset: 0xA00). It shall be used to generate the resets of the core. This process is internally done by the wrapper grspwrouterm if the generic internalrstgen is set to 1.	Low
	RXRST[30:0]	Output	Internal reset generated by each SpW link transmitter for synchronization purpose between transmitter and both its receiver channels. It shall be used to generate the asynchronous and synchronous receiver resets of each port. This process can be skipped by activating the internal reset generation in the wrapper (internalrstgen set to 1).	High
	CLOCKGATE[30:0]	Output	Signal to indicate that the clocks for a specific link can be clockgated. They are used internally by the wrapper if the generic internalrstgen is set to 1.	High
* see GRLIB IP Library User's Manual				

75.12 Signal definitions and reset values

The signals and their reset values are described in table 1457.

Table 1457. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
spw_clk	Input	Transmitter default run-state clock	Rising edge	-
spw_rxd	Input, LVDS	Data input, positive	High	-
spw_rxdn	Input, LVDS	Data input, negative	Low	-
spw_rxs	Input, LVDS	Strobe input, positive	High	-
spw_rxsn	Input, LVDS	Strobe input, negative	Low	-
spw_txd	Output, LVDS	Data output, positive	High	Logical 0
spw_txdn	Output, LVDS	Data output, negative	Low	Logical 1
spw_txs	Output, LVDS	Strobe output, positive	High	Logical 0
spw_txsn	Output, LVDS	Strobe output, negative	Low	Logical 1

75.14 Instantiation

This example of instantiation assumes that the router wrapper is used and the internal reset generators are automatically included. If the user prefers to generate the resets externally, it is advised to use the wrapper as a baseline to understand how some signals are taken into account for each clock domain.

```
-- Since the resets and clockgate are generated internally in the wrapper,
-- the only element from TXCLK and TXCLKN to be used is the bit '0' (spw_clk).
-- The others remain unconnected
txclk_array(0)                          <= spw_clkl;
txclkn_array(0)                         <= spw_clkln;
txclk_array(CFG_SPW_SPWPORTS-1 downto 1)  <= (others => '0');
txclkn_array(CFG_SPW_SPWPORTS-1 downto 1) <= (others => '0');

76 SPWTDP - SpaceWire - Time Distribution Protocol

76.1 Overview

This interface implements the SpaceWire - Time Distribution Protocol (TDP). The protocol provides capability to transfer time values and synchronise them between onboard users of SpaceWire network. The time values are transferred as CCSDS Time Codes and synchronisation is performed through SpaceWire Time-Codes. The core also provides datation services. The core operates in an AMBA APB bus system. The AMBA APB bus is used for configuration, control and status handling. The interface is coupled with a SpaceWire node with AMBA AHB master and RMAP target implementation.

76.2 Protocol

The initiator and target maintain their own time locally. The Time Distribution Protocol provides the means for transferring time of initiator to targets and for providing a synchronization point in time. The time is transferred by means of an RMAP write command carrying a CCSDS Time Code (time message). The synchronization event is signaled by means of transferring a SpaceWire Time-Code. The transfer of the SpaceWire Time-Code is synchronized with time maintained by the initiator. To distinguish which SpaceWire Time-Code is to be used for synchronization, the value of SpaceWire Time-Code is transferred from initiator to target by means of an RMAP write command prior to actual transmission of SpaceWire Time-Code itself. When there is more than one target the CCSDS Time Code need to be transferred to each individual target separately [SPWCUC].

76.3 Functionality

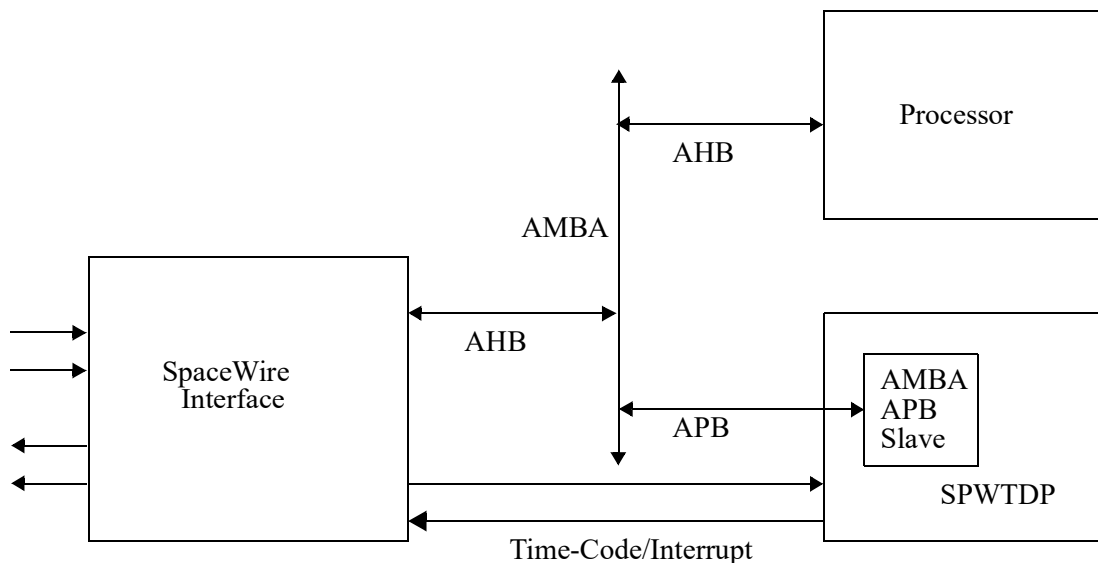
The block diagram below explains the complete system.


Figure 209. Block diagram

The foreseen usage of this core is to distribute and synchronise time between an initiator SPWTDP core and one or more target SPWTDP (slave) cores using the SpaceWire interface for communication between them.

The system can act as initiator (time master) and target being able to send and receive SpaceWire Time-Codes. The initiator requires SpaceWire link interface implements an RMAP initiator. The Target requires SpaceWire link interface implements an RMAP target. The SPWTDP component is a part of this system providing SpaceWire Time-Codes, CCSDS Time Codes, datation, time-stamping of

distributed interrupts, support for transmission of CCSDS Time Codes through RMAP and support for latency measurement and correction. In this implementation the CCSDS Time Codes carried between the SpaceWire network is based on CCSDS Unsegmented Code format (CUC) which is explained below [CCSDS]. The table below shows an example Preamble Field (P-Field) which corresponds to 40 bits of coarse time and 24 bits of fine time.

76.3.1 CCSDS Unsegmented Code: Preamble Field (P-Field)

Table 1460. CCSDS Unsegmented Code P-Field definition

Bit	Value		Interpretation
0	"1"		Extension flag, P-Field extended with 2nd octet
1-3	"010"	Agency-defined epoch (Level 2)	Time code identification
4 - 5	"11"	(number of octets of coarse time) + 1	Detail bits for information on the code
6 - 7	"11"	(number of octets of fine time)	
8	"0"		Extension flag, P-Field not extended with 3rd octet
9-10	"01"	Number of additional octets of the coarse time.	added to octet 1
11-13	"000"	Number of additional octets of the fine time.	added to octet 1
14-15			RESERVED

76.3.2 CCSDS Unsegmented Code: Time Field (T-Field)

For the unsegmented binary time codes described herein, the T-Field consists of a selected number of contiguous time elements, each element being one octet in length. An element represents the state of 8 consecutive bits of a binary counter, cascaded with adjacent counters, which rolls over at a modulo of 256.

Table 1461. Example CCSDS Unsegmented Code T-Field with 32 bit coarse and 24 bit fine time

CCSDS Unsegmented Code											
Preamble Field	Time Field										
	Coarse time							Fine time			
-	2^{31}	2^{24}	2^{23}	2^{16}	2^{15}	2^{8}	2^{7}	2^{0}	2^{-1}	2^{-8}	2^{-9}	2^{-15}	2^{-16}	2^{-24}
0:15	0						31	32		55

The basic time unit is the second. The T-Field coarse time (seconds) can be maximum 56 bits and minimum 8 bits. The T-Field fine time (sub seconds) can be maximum 80 bits and minimum of 0 bits.

The number of bits representing coarse and fine time implemented in this core can be obtained by reading the DPF bits of Datation Preamble Field register.

The coarse time code elements are a count of the number of seconds elapsed from the initial time value. This code is not UTC-based and leap second corrections do not apply according to CCSDS.

76.3.3 Time generation

The core consist of time generator which is the source for time in this system. The core may act as initiator or a target but both have their respective time generator. The Elapsed Time (ET) counter is implemented complying with the CUC T-Field. The number of bits representing coarse and fine time of a ET counter implemented in a design can be obtained by reading the DPF bits of Datation Preamble Field register.

The ET counter can be incremented either using an internal frequency synthesizer or by using an external enable signal. The External ET Increment Enable bit in Configuration 0 register must be enabled if external inputs are to be used.

Increment ET using internal frequency synthesizer:

The counter is incremented on the system clock only when enabled by the frequency synthesizer. The binary frequency required to determine the counter increment is derived from the system clock using a frequency synthesizer (FS). The frequency synthesizer is incremented with a pre-calculated increment value, which matches the available system clock frequency. The frequency synthesizer generates a tick every time it wraps around, which makes the ET time counter to step forward with the precalculated increment value. The output of frequency synthesizer is used for enabling the increment of ET counter. The increment rate of the ET counter and frequency synthesizer counter should be set according to the system clock frequency. The ET counter increment rate is set by providing values to ETINC bits in Configuration 2 register and frequency synthesizer counter is set by providing values to FSINC bits in Configuration 1 register. The following table specifies some example ETINC and FSINC values for some frequencies. The below values are also obtained for Coarse time width 32, Fine time width 24 and Frequency synthesizer width of 30. To calculate for other frequencies and configuration refer the spreadsheet provided along with this document.

*Table 1462.*Example values of ETINC and FSINC for corresponding frequencies

Frequency	ETINC	FSINC
50 MHz	0	360287970
250 MHz	0	72057594
33333333	2	135107990

Increment ET using external input:

The EP register in Configuration 0 specify whether to increment the ET counter based on rising or falling edge of the external enable signal. Also the ETINC bits in Configuration 2 register specify from which bit the ET counter must increment.

The following section describes the cores capabilities if it configured as initiator or target.

76.3.4 Initiator

An initiator is a SpaceWire node distributing CCSDS Time Codes and SpaceWire Time-Codes. It is also an RMAP initiator, capable of transmitting RMAP commands and receiving RMAP replies. There is only one active initiator in a SpaceWire network during a mission phase.

The initiator performs the following tasks

•   Transmission of SpaceWire Time-Codes

The SpaceWire Time-Codes are provided by this component and transmission of those codes to targets should be performed by a SpaceWire interface.

•   Transmission of CCSDS Time Codes through RMAP

•   Datation, time-stamping and latency measurement

76.3.5 Target

A target is a SpaceWire node receiving CCSDS Time Codes and SpaceWire Time-Codes. A target is also an RMAP target, capable of receiving RMAP commands and transmitting RMAP replies. There can be one or more targets in a SpaceWire network.

GRIP

Apr 2024, Version 2024.1

1241

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The target performs the following tasks

- Reception of SpaceWire Time-Codes

The SpaceWire Time-Codes sent from initiator are received by SpaceWire interface and provided to this component in target.

- Reception of CCSDS Time Codes through RMAP

- Qualification of received time messages (CCSDS Time Codes) using SpaceWire Time-Codes

- Initialization and Synchronisation of received CCSDS Time Codes with Elapsed Time counter available in this component

- Datation, time-stamping and latency correction

- Jitter and drift mitigation (the MA bit in Status 0 register specify the availability of this service)

76.3.6 Configuring initiator and target

The core is interfaced via an AMBA Advanced Peripheral Bus (APB) slave interface, providing a register view that is compatible with the Time Distribution Protocol (TDP). The core must be configured according to the requirement either as initiator or target.

- Initializing initiator

The initiator transmits the SpaceWire Time-Codes out of the core only when the Transmit Enable TE bit in Configuration 0 register is enabled. The ET counter in initiator can be initialized (to provide any initial value). Initialization is done by writing a time value into the Command Elapsed Time registers available in the command field, the NC bit in the Control register of command field should be enabled to initialize the time value stored in the Command Elapsed Time registers to be the local time (Transmit Enable TE bit in Configuration 0 register must be enabled). The NC bit in the Control register will disable itself when the time is initialized. The INSYNC bit in Status 0 register will enable when initialization is performed. The MAPPING bits in Configuration 0 register determines the interval between SpaceWire Time-Code transmissions which is explained in detail in the section below.

The target time must be configured with time values from the initiator. The targets register space must be configured and controlled through RMAP by an initiator to achieve time synchronisation. The target time synchronisation is explained in detail under the section initialization and synchronisation of target through RMAP.

76.3.7 SpaceWire Time-Code

SpaceWire Time-Codes are continuously transmitted from an initiator node (time master) to all slave nodes. The transmission of the SpaceWire Time-Code is synchronized with the ET counter in the initiator node. The six bits of the Time-Code time information correspond to six bits of the local ET counter (MAPPING bits in Configuration 0 register determines its exact mapping and interval between SpaceWire Time-Code transmissions). Value of 0b00000 for MAPPING bits in Configuration 0 register will send SpaceWire Time-Code at every Second. When the value is 0b00001 SpaceWire Time-Codes are sent at every 0.5 Seconds interval and so on (maximum value of MAPPING can be 0b11111 but this value cannot be more than the number of bits implemented as fine time). The ET bits with lower weights than the size bits mapped to Time Codes time information bits are all zero at time of SpaceWire Time-Codes transmission. The Table below shows an example Local ET counter and Mapping. If the Coarse time is 32 bits and Fine time is 24 bits and mapping value is 6 then 0 to 31 is coarse(32 bits), 32 to 55 is fine time and mapped SpaceWire Time-Code is 32 to 37.

*Table 1463.*Example Local ET counter with Mapping values

0			25	26	27	28	29	30	31	32	33	34	35	36	37	38				55
Mapping Values									0	1	2	3	4	5	6	7				24
If the Mapping value is 6 then the mapped SpaceWire Time-Codes is 32 to 37										32	33	34	35	36	37

+46 31 7758650 | frontgrade.com/gaisler

*Table 1463.*Example Local ET counter with Mapping values

If the Mapping value is 0 then the mapped SpaceWire Time-Codes is 26 to 31	26	27	28	29	30	31							
If the Mapping value is 5 then the mapped SpaceWire Time-Codes is 31 to 36						31	32	33	34	35	36		
If the Mapping value is 7 then the mapped SpaceWire Time-Codes is 33 to 38								33	34	35	36	37	38

76.3.8 Initialization and synchronisation of target through RMAP

An initiator must provide the time values and set the target in order to get the time synchronized. The below text explains how an initiator can synchronise the target.

The SPWTC in Control register of initiator core component should be configured initially with a SpaceWire Time-Code value at which the time message needed to be transferred. When the Space-Wire Time-Code generated internally using the ET counter matches the SPWTC in Control register a Time Message TM interrupt will be generated (TME bit Time Message Enable should be enabled in the Interrupt Enable register). Based on this interrupt the local time (ET counter) in initiator should be accessed from the Datation registers and used to calculate the time message needed to be transmitted.

- Time message generation

The Time message transmitted using RMAP should be an exact mapping of the Command field (explained under Registers section). The Time message transmitted should write the Command field available in target. Control register available in Command field specify weather the target should be initialized or synchronized, at which SpaceWire Time-Codes it should happen (synchronization event) and details of coarse and fine time available in the time message. The New code NC bit available in Control register should be enabled and if the target should be initialized then Init Sync IS bit in Control register must be enabled otherwise target will be synchronized.

The Command Elapsed Time in time message are calculated from the local time (ET counter) available in the initiator. The local time can be obtained by reading the Datation Field of initiator component. While reading the Datation registers always the total implemented coarse time and fine time must be read in order (from 0 till the implemented Datation Elapsed Time registers). The DPF of Datation Preamble Field register gives the coarse and fine time implemented which gives the total local ET counter (coarse + fine width).

For example if the implementation has 32 bit coarse and 24 bit fine time then it is enough to access the first two Datation Elapsed Time registers (0 and 1). The 32 bits of Datation Elapsed Time 0 and only the most significant 24 bits (31 to 8) of Datation Elapsed Time 1 registers (32 + 24 =56 bits) represents the local time. These 56 bits only be used for Command Elapsed time (time message) calculation.

The SpaceWire Time-Codes at which the Time Message interrupt generated is embedded in the local ET counter. The Command Elapsed time which is transmitted as time message should be an incremented time value of this SpaceWire Time-Code and Command Elapsed time bits with lower weights than the size bits mapped to SpaceWire Time-Code time information bits are all must be zero.

The incremented time value is to make the initialization or synchronisation of time message in target will happen after the reception of qualifying SpaceWire Time-Codes. The qualifying SpaceWire Time-Code is embedded in the Command Elapsed time (part of time message) sent from initiator. This qualifying SpaceWire Time-Code value should also be written in the SPWTC in Control section of the time message.

- Time qualification in target

In target, the Command field will contain the time message when it is written by the initiator through RMAP. When the SPWTC of Control register in Command field matches with a received SpaceWire Time-Code then initialization or synchronization will occur (according to NC bit and IS bit in the Control register) to the local ET counter of the target SPWTDP component. The Time message qualified TCQ bit in the status register will enable itself, this bit will disable itself when the conditions for

GRIP
Apr 2024, Version 2024.1

1243

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

time message qualification is achieved (SPWTC of Control register matches with a received Space-Wire Time-Code) but no new time message is received (NC bit is zero). When the local ET counter is initialized or synchronized the NC bit in the control register will disable itself. The INSYNC bit in Status 0 register will enable when initialization is performed specifying the target is initialized. Initialization completely writes time message values into the implemented local Elapsed time counter and synchronisation verifies whether the time message Command Elapsed Time and local Elapsed Time counter matches till the mapped SpaceWire Time-Code level (with a tolerance of previous value) and only modifies the local Elapsed Time if their is a mismatch. If the target is not implemented with jitter and mitigation unit then the synchronisation forces the target time (ET counter) with the time message received.

For example, the initiator can create time message exactly at 0x00000001 coarse time and 0x040000 fine time (32 bit coarse time and 24 bit fine time, mapping value of 6 i.e. 64 SpaceWire Time-Codes per second, time message is generated at 0b000001 SpaceWire Time-Code), the value in the time message to be sent to the target can be coarse time 0x00000002 and 0x040000 fine time, (32 bit coarse time and 24 bit fine time, mapping value of 6, time message is qualified at the next reception of 0b000001 SpaceWire Time-Code, i.e. after a second). Both SPWTC in Control registers available in the initiator and target can be 0b000001 for this example. The time is synchronized after a second in this example. Depending on the frequency of SpaceWire Time-Codes and data link rate several different combination of ways to achieve time synchronisation is possible.

76.3.9 Latency measurement using Time-Stamps

The incoming and outgoing SpaceWire Distributed Interrupts are time stamped in initiator and target. The initiator calculates latency based on these time stamp values. The time stamped values in target are accessed from initiator through RMAP. The Latency Enable LE bit in Configuration 0 register must be enabled between the two nodes in the SpaceWire network for which the latency is to be calculated. The core supports 32 distributed interrupts and acknowledgment (Interrupt and acknowledgment numbers 0 to 31) or 64 distributed interrupts. The distributed interrupt transmission from initiator (which is the origin for latency calculation) is controlled by a mask register STM available in Configuration 3 register and SpaceWire time code register TSTC available in Time-Stamp SpaceWire Time-Code and Preamble Field Tx register, these registers specifies how often and at which time code distributed interrupt is transmitted and time stamping is performed.

The time stamping can be performed in two methods (only Interrupts or Interrupts and Acknowledgment), the DI bit in Configuration 3 register of SPWTDP component in target should be configured to specify which type of method is used. If only distributed interrupts (no acknowledgment) are used then DI bit should be 0. The transmitted and received distributed interrupts INTX and INRX in the Configuration 0 registers of both initiator and target must be configured with the interrupt number which will be used for the latency measurement. For example if the INTX in initiator Configuration 0 is configured with 0b00100 then the target INRX should be configured with the same value. Similarly if the INTX in target Configuration 0 is configured to be 0b00101 then the initiator INRX should be configured with the same value. Initially initiator sends a distributed interrupt when the conditions are matched (STM and TSTC registers match) and when the target received this distributed interrupt it will send another interrupt which will be received by the initiator. At each end transmission and reception is time stamped (current local time is stored in Time Stamp registers) and interrupt transmitted is INTX and received interrupt is checked whether it received INRX.

If both distributed interrupts and acknowledgment method is to be used then DI bit should be 1. The transmitted and received distributed interrupts INTX and INRX in the Configuration 0 registers of both initiator and target can have the same interrupt number (the acknowledgment number for a particular interrupt will be same as interrupt number). Similar to the previous method at each end transmission and reception is time stamped which will be used for latency calculations.

The Latency calculation can be started in initiator based on DIR (distributed interrupt received) interrupt available in Interrupt Status register (the interrupt should be enabled in the Interrupt Enable register). The latency is calculated form the time stamp registers based on the equation explained below

GRIP
Apr 2024, Version 2024.1
1244
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Latency = ((initiator time stamp Rx - initiator time stamp Tx) - (target time stamp Tx - target time stamp Rx)) /2

By calculating the Latency value repeatedly (at least for about 128 times, more number of times provides increased accuracy) and taking an average of it will provide the final latency value. The initiator should transfer the latency correction information to the Latency Field registers in the target by means of RMAP transfer. When the latency values are written it will be adjusted to local time in the target and the LC bit in Status 0 register is enabled (set to '1'), this status register can be disabled by writing '1' into the corresponding field.

76.3.10 Mitigation of jitter and drift

The Jitter and drift mitigation is performed in target when Jitter Enable JE and Mitigation Enable ME bit in Configuration 0 register is enabled. The process will only start when the target is initialized (the target local ET counter should have initialized through a time message from initiator and INSYNC bit in Status 0 register is enabled). The SPWTDP must be implemented with a mitigation unit for jitter and drift mitigation (the MA bit in Status 0 register specify the availability of this service).

The mitigation unit for jitter and drift is enabled with the mitigation VHDL generic.

76.3.11 External Datation

The external signals latch and save are used to provide external datation services. The Elapsed Time is continuously latched when the latch input signal goes high, the corresponding External datation mask register must be enabled for that particular signal. When save input goes high the latched value will remain same (at when the previous latch condition met) and all the mask bit previously enabled will be cleared. The EDS bit in Status Register 0 will go high when the latch and save condition matches and cleared when the latched elapsed time is read. The purpose of this status register is to ensure that all the implemented coarse and fine time are read. Reading the lowest implemented fine time makes the status register to go low. An output pulse is also produced when conditions for external datation is met. The pulse is driven for one system clock period on the occurrence of external save condition.

If a simpler version of latching the time is needed based on a signal going high at any instance then the latch and save signals can be provided with the same input.

There are four External datation services implemented and each of them has its own mask EDMx, status EDS and time EDxETx registers. All the four External datation services are based on the input latch and save signal vectors. The external datation pulse vector consist of four outputs corresponding to each of the external datation services.

76.3.12 Pulses

The core provides eight external outputs used for clock pulse distribution. The timing of each pulse output is individually derived from the Elapsed Time counter. It is possible to program for each pulse output individually the following parameters:

- periodicity pulse
- width of pulse
- polarity of pulse
- enable/disable pulse generation (reset status is disabled)

The pulse has two parts, the active and the inactive part. The active part always starts the pulse, followed by the inactive part. The polarity or logical level of the active part is programmable. The inactive part takes the logical inversion of the active pulse, and is the default output from the generator when the pulse is not issued or the overall generation is disabled.

GRIP

Apr 2024, Version 2024.1

1245

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The periodicity of the pulse corresponds to one of the ET bits that can be selected in the range 27 to 2-8 seconds, providing a range from 128 seconds to 3,91 ms, i.e. 0,0078 to 256 Hz frequency. See register definition for details.

The width of the active part of the pulse corresponds to one of the ET bits that can be selected in the range 26 to 2-9 seconds, providing a range from 64 seconds to 1,95 ms. See register definition for details.

It is possible to generate a pulse that has a duty cycle of 50%. It is also possible to generate a pulse for which the active part is as short as 2^{-9} seconds, and its period is as high as 27 seconds. The effective duty cycle can be as low as $2^{-9}/27$ for the longest period, up to 50% for the shortest period of 2-8 seconds = 256 Hz. The duty cycle choice becomes more restricted as the frequency increases. Note that it is only possible to reduce the duty cycle in one direction: 50%/50%, 25%/75%... 1%/99%. The active part of the pulse can thus never be more than 50% of the cycle. It should be noted that the active pulse width must be at most 50% of the pulse period.

The pulse outputs are guaranteed to be spike free. If a pulse output is disabled by means of writing to the corresponding register (PDRx) (i.e. writing a zero to the Pulse Enable bit (PE)), the pulse output will be immediately driven to the inversion of the Pulse Level bit (PL), which corresponds to the level of the inactive part of the pulse. It is thus possible to modify immediately the pulse output by disabling it using the PE bit and then changing the PL bit, since the output will always drive the inversion of the PL bit while disabled.

An ongoing pulse output will be immediately disabled (the pulse output will be immediately driven to the inversion of the Pulse Level bit) if any external modification of the ET counter is triggered (for both master and slave) due to initialization/synchronisation or set using APB registers.

76.3.13 Set Elapsed Time using external input

The ET counter can be set using an external enable signal (configurable rising or falling edge, see register SP in Configuration 0 register). To set the ET counter the SE bit in configuration register must be enabled, the value to be loaded into the ET counter must be written into the Command Elapsed Time registers. The ARM bit field in the Status 0 register will set itself to '1' when the first Command Elapsed Time register is written. After the occurrence of the external enable signal the value will be loaded into the ET counter and the ARM bit field in the Status 0 register will set itself to '0'. An interrupt can also be generated when the ET counter is loaded, the corresponding interrupt (Set ET External Interrupt Enable) must be enabled.

76.3.14 Multiple Port

It is possible to transmit or receive SpaceWire Time-Codes to multiple SpaceWire links. The Multiple port enable bit in the Configuration 0 register must be enabled, using the Inport and Outport fields in the Configuration 3 register the corresponding inputs and outputs can be enabled or disabled.

At every system clock (if the system is configured as target) all the enabled ports are monitored for a SpaceWire Time-Code input. If received the SpaceWire Time-Code is compared with the previously received Time-code. If the newly received Time-code is same as the previously received then no modification is performed other than updating the Received port RP register in Status 0. If an incremented Time-code is received then the corresponding Time-code is used for further processing (time qualification etc.). In all other case (Time-code - X or Time-code + X) the received Time code is stored (in previously received Time-code internal register, used for processing the next time-code) and an interrupt is generated if corresponding interrupt (Non consecutive SpaceWire Time-code Interrupt) bit is enabled. For all the Time-Code received the corresponding port in which it is received is updated at Received port RP register in Status 0.

The Inport and Outport fields also control the reception and transmission of Distributed interrupts. While performing latency calculation only one port must be enabled, since distributed interrupts cannot be filtered out based on increments like in SpaceWire Time-Codes.

+46 31 7758650 | frontgrade.com/gaisler

Multiple port transmission can also be disabled and only one port can be used for transmission or reception using SEL register in Configuration 0.

76.3.15 Synchronisation of target using SpaceWire Time-Codes

It is possible to synchronise the target only using SpaceWire Time-Codes. A master sending Space-Wire Time-Codes (using its Elapsed time counter) at regular interval can synchronise the Elapsed time in the target. The frequency of Time-code transmission in the master and the frequency of (when to expect a) Time-code in the target must match, this can be achieved by setting the Mapping fields in the Configuration 0 register. The incoming SpaceWire Time-Codes and the Time-code position mapped in the target Elapsed Time is compared, if they match the bits available after the compared bits are made zero, if the local time map is less than one (External Time-code arrived early) then the bits available after the compared bits are made zero and the other part (including the mapped part) is incremented by one. If the above two cases occurred then the target time is in sync with the master time and the Insync bit in Status 0 register is enabled. If the incoming Time-code is in out of order (Non consecutive) then the synchronisation is stopped, the Insync bit in Status 0 register is disabled (but the local time keeps running) and an interrupt is generated if corresponding interrupt (Non consecutive SpaceWire Time-code Interrupt) bit is enabled.

76.4   Data formats

All Elapsed Time (ET) information is compliant with the CCSDS Unsegmented Code defined in [CCSDS] and repeated hereafter.

76.4.1   Numbering and naming conventions

Convention according to the CCSDS recommendations, applying to time structures:

- The most significant bit of an array is located to the left, carrying index number zero.

- An octet comprises eight bits.

*Table 1464.*CCSDS n-bit field definition

CCSDS n-bit field		
most significant		least significant
0	1 to n-2	n-1

Convention according to AMBA specification:

- The least significant bit of an array is located to the right, carrying index number zero.

- Big-endian support.

*Table 1465.*AMBA n-bit field definition

AMBA n-bit field		
most significant		least significant
n-1	n-2 down to 1	0

Bits	Name	Description
31: 25	RESERVED	
24:	JE	Jitter Correction Enable (only for target)
		The jitter correction process in target will start when this bit is enabled. (Mitigation Enable bit should also be enabled). Reset value: '0'. (valid only when Mitigation unit available)
23: 20	RESERVED	
21:	ST	Synchronisation using SpaceWire Time-Code Enable (only for target) Reset value: '0'.
20:	EP	External ET Increment Polarity.
		To select the rising or falling edge of the external enable signal to increment the Elapsed time. Value '1' Rising edge. Value '0' Falling edge. Reset value: '1'.
19:	ET	External ET Increment Enable. Enable to increment the Elapsed Time based on external signal. When disabled the internal frequency synthesizer is used to increment the Elapsed Time counter. Reset value: '0'.
18:	SP	Set ET External Polarity.
		To select the rising or falling edge of the external enable signal to load the Elapsed Time with the contents of the command field register. Reset value: '1'.
17:	SE	Set ET External Enable.
		Based on the external enable signal load the Elapsed Time with the contents of the command field register. Reset value: '0'.
16:	LE	Latency Enable.
		To calculate latency between an initiator and target this bit must be enabled in both of them. Reset value: '0'.
15:	AE	AMBA Interrupt Enable
		The interrupts (explained in interrupt registers) in this core will generate an AMBA interrupt only when this bit is enabled. Reset value: '0'
14 13	RESERVED	
12: 8	MAPPING	Defines mapping of SpaceWire Time-Codes versus CCSDS Time-code.
		Value 0b00000 will send SpaceWire Time-Codes every Second,
		Value 0b00001 will send SpaceWire Time-Codes every 0.5 Second,
		Value 0b00010 will send SpaceWire Time-Codes every 0.25 Second,
		Value 0b00011 will send SpaceWire Time-Codes every 0.125 Second
		Maximum value it can take is 0b11111 but this value cannot be more than the number of bits implemented as fine time. Reset value: Implementation dependent
7:	TD	Enable TDP when set. Reset value: '0'.
6:	MU	Multiple Port Enable. Reset value '0'.
5: 4	SEL	Select for SpaceWire Time-Codes and Distributed Interrupt transmission and reception, one of 0 through 3. Can be used only when Multiple Port MU is disabled. Reset value: 0b00
3:	ME	Mitigation Enable (only for target)
		The drift correction process in target will start when this bit is enabled. Reset value: '0'.(valid only when Mitigation unit available)
2:	RE	Receiver Enable (only for target) Reset value: '0'.
1	TE	Transmit Enable (only for initiator) Reset value: '0'.
0	RS	Reset core. Makes complete reset when enabled.
		Reset value: '0'.

76.10 Signal descriptions

Table below shows the interface signals of the core (VHDL ports).

Table 1516. Signal descriptions

Signal name	Field	Type	Function	Active
RSTN	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
GRTDPI	tickindone	Input	SpaceWire Time-Code input processed	High
	tickoutraw	Input	SpaceWire Time-Code/Distributed interrupt output event	High
	timeout	Input	SpaceWire Time-Code/Distributed interrupt output	-
	ext_dat_latch	Input	Vector to input external signals on which the Elapsed Time is latched. Used for External datation service.	-
	ext_dat_save	Input	Vector to input external signals on which the Elapsed Time is saved. Used for External datation service.	-
	setet	Input	Input to set ET from Register	-
	ext_et_inc	Input	Input to increment ET	-
GRTDPO	tickinraw	Output	SpaceWire Time-Code/Distributed interrupt input request	High
	timein	Output	SpaceWire Time-Code/Distributed interrupt input	-
	elapsedtime	Output	Elapsed time	-
	enable	Output	TDP enable, this signal reflects the content of the TD bit in the Configuration 0 register.	High
	ext_dat_pulse	Output	Produces an output pulse when conditions for external datation is met. The pulse is driven for one system clock period on the occurrence of external save condition. This vector consist of four outputs corresponding to each external datation services.	-
	pulses	Output	Pulse output	-
DIAG_CTICK	N/A	Output	This tick is generated when SpaceWire Time-Code is transmitted in initiator. This tick is generated when a diagnostic SpaceWire Time-Code is generated from targets fully corrected time.	High
DIAG_JTICK	N/A	Output	The incoming SpaceWire Time-Code tick, to visualize the jitter (only for target)	High

* see GRLIB IP Library User's Manual

The inputs setet and ext_et_inc are re-synchronized internally. All the other inputs does not have internal support to remove meta-stability resulting from clock domain crossings. If the inputs are driven from clock domains other than the clock provided for this core then the clock synchronisation conditions must be dealt externally for these inputs.

76.11 Signal definitions and reset values

The core has no external signals.

77 GRSRIO - Serial RapidIO endpoint with AHB or AXI4 bus master interface

77.1 Overview

The GRSRIO core implements the RapidIO Interconnect Specification Part 1 (I/O Logical Specification) and Part 2 (Message Passing Logical Specification) for data messages, doorbell messages, outbound maintenance messages and I/O operations, as defined in Rev. 2.1. This is done by means of a flexible and configurable DMA engine with a configurable bus master interface.

Additionally the core implements the MECS Time Synchronization Protocol according to Rev. 4.0.

The targeted SRIO endpoint is the SRIOIP-GEN2IP core by Integrated Device Technology. The choice of the SRIOIP-GEN2 end point has several implications on the SRIO:

- CAR and CSR registers defined in I/O and Message Passing Logical Specification are assumed to be already implemented in the end point

- Inbound maintenance request are assumed to be already handled by the end point

Two wrappers are available for the core, one with an AHB AMBA 2.0 Bus Master (grsrio_gen2ahb) to be readily compatible with Frontgrade Gaisler's GRLIB and one with an AXI4 (grsrio_gen2axi) to also support latest System-on-Chip (SoC) architectures.

The DMA engine serves several queues of descriptors placed in memory with two possible modes, selectable at compile time:

- Legacy mode: When *g_hyb_que* is set to "false", descriptors for data messages and I/O operations are 8 words long and the ones for doorbell messages 4. In this configuration, each kind of operation (IO memory access, data message and doorbell message) have separated transmission queues, from 1 up to 32 each. In this configuration, descriptors for data messages and I/O operations are 8 words long, while ones for doorbell messages 4. In this configuration, the core has an interface and a behavior compatible with the GRSRIO Logical Layer IP core Version 1.

- Hybrid-queues mode: When *g_hyb_que* is set to "true", there are just *g_no_hyb_tx* transmission queues, each capable of transmitting all kinds of logical operations. This allows a larger CPU off-load and a lower number of queues required for each software entity. In this configuration, all TX descriptors are 8 words long. RX descriptors for data messages and I/O operations are 8 words long and the ones for doorbell messages 4.

A timestamp functionality is provided for each descriptor. When *g_mecs* is set to "true" the time value is taken by the internal MECS Timestamp Generator, while when *g_mecs* is set to false or the MECS functionality is disabled, the time value is taken from an external source.

The core provides a capability register to allow the software to know what functionalities the core instantiation supports and the number of queues instantiated.

77.2 Operation

77.2.1 Receiving Data messages

Inbound data messages are stored in one or more message reception queues. The desired number of reception queues can be set by VHDL generic *g_no_msg_rx* at compile time.

The inbound data messages are stored to a specific queue depending on their destination ID and mailbox number. The accepted destination ID of a queue can be defined in register RXMSG_DST_ID and the accepted mailbox number in the field RXMSG_CTRL.MBOX. Furthermore, ranges of destination IDs and mailbox numbers can be accepted by also setting the masking register RXMSG_DST_MSK and in the field RXMSG_CTRL.MBOXMSK. For instance, the user could set up five queues, the first four queues accepting messages addressed to mailbox 0 to 3 and the fifth queue accepting messages addressed to all the other ones (4-63). If several message reception queues are configured to accept

GRIP

+46 31 7758650 | frontgrade.com/gaisler

the same destination ID / mailbox number pair, the message queue with the lowest index number, that is currently not busy, will receive the message.

If a message is received, which is addressed to a mailbox number /destination ID combination that is not accepted by any message reception queue, the processing core automatically generates and transmits ERROR responses to the source node.

A single queue can receive only a multi-segment data message per time, but more queues can be set with the same destination ID or destination ID/Mailbox combination, effectively allowing up to 16 transfer between a couple of destination/source IDs.

Each reception queue is a circular buffer that is located in memory. Before activating the queue, the memory start address of the circular buffer must be set in register RXMSG_MADDR(_LSW) and RXMSG_MADDR_MSW (if CFG_AW is set to 64) and its depth in register RXMSG_CONF.CBD. Each queue can be configured to store between 2 and 65,536 message descriptors. Each descriptor has a size of 32 bytes and it is up to the software to reserve the necessary memory space for the whole circular buffer.

Each reception queue can be configured to trigger a set of interrupts: (i) full interrupts that indicate that no more inbound data message can be accepted because the reception queue is full (RXMSG_STAT.IF), (ii) error interrupts that indicate bus errors and timeout errors in case of multi-packet messages (RXMSG_STAT.IE), and (iii) reception interrupts that indicate that a full message was successfully received (RXMSG_STAT.IR).

The GRSRIO logical layer does not distinguish between single (up to 256 bytes) and multi-packet messages (up to 4K) and only one DMA descriptor is used for both types of messages. However, the user must set the maximum allowed message size for the queue in register RXMSG_CONF.MAX_-SIZE.

All following conditions must be true for a message to be accepted by the queue:

- The queue is enabled.

- The queue is not full.

- The destination ID is accepted.

- The mailbox number is accepted.

- The message does not exceed the maximum allowed size.

If no queue is available that can accept the message, the GRSRIO logical layer replies to the destination node with an ERROR response. If there are queues that could accept the packet but they are all full or busy with ongoing multi-segment data messages, the GRSRIO logical layer replies to the destination node with a RETRY response.

The timeout can be configured globally in register TO_CONF and expresses the maximum allowed time span between a DONE response for one message segment and the reception of the next segment. If the timeout elapses, the descriptor will be closed with the Serial RapidIO Error (SE) flag set and an error interrupt is generated if enabled.

The circular buffer management between hardware and software is done via two descriptor pointers. The tail pointer in RXMSG_TLPTR is managed by hardware whereas the head pointer in RXMSG_HDPTR is managed by software.

The software can add one or more descriptors to the circular buffer and then activate them by increasing the head pointer value in RXMSG_HDPTR. Every time the GRSRIO logical layer receives a new message successfully, it will increment the tail pointer to the next descriptor. The software can always check how many free descriptors are left in the buffer by subtracting the tail pointer value from the head pointer value.

In the following, the relevant descriptor words of the message reception queues are described:

77.2.2 Transmitting Data Messages

Outbound data messages are stored in message or hybrid (depending on *g_hyb_que*) transmission queues. The desired number of transmission queues can be set by VHDL generic *g_no_msg_tx* or *g_no_hyb_tx* at compile time. In the latter case the queues are shared with the other transaction types.

If several transmission queues have messages ready to be sent, the one with the highest priority gets to transmit first. If more than one active queues have the highest priority, the arbitration between them is done with a round robin algorithm. However, the following conditions must be true:

- The queue is enabled.

- The message has a priority level that can currently be accepted by the SRIO end point.

Each transmission queue is a circular buffer that is located in memory. Before activating the queue, the memory start address of the circular buffer must be set in register TXMSG_MADDR(_LSW) and TXMSG_ADDR_MSW (or TX_MADDR(_LSW) and TX_MADDR_MSW) and its depth in register TXMSG_CTRL.CBD or TX_CTRL.CBD. Each queue can be configured to store between 2 and 65,536 message descriptors. Each descriptor has a size of 32 bytes and it is up to the software to reserve the necessary memory space for the whole circular buffer.

GRIP

Apr 2024, Version 2024.1

1273

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

Each transmission queue can be configured to trigger a set of interrupts: (i) error interrupts that indicate bus errors, retry errors, and timeout errors (TXMSG_CTRL.IE or TX_CTRL.IE), and (ii) transmission interrupts that indicate that a full message was successfully transmitted (TXMSG_STAT.IT or TX_STAT.IT). The generation of transmission interrupts can be further configured by setting the transmission interrupt mode bit (TXMSG_CTRL.IM or TX_CTRL.IM). If set, a transmission interrupt is always triggered after the transmission queue became empty. If not set, the generation of transmission interrupts depends on the Enable Transmission Interrupt (TI) field of each message descriptor.

Messages or segments of messages are automatically retried until either the packet is accepted by the destination node or until the threshold level defined in the descriptor field RCOUNT is reached. For multi-packet messages, RCOUNT is the number of possible retries for all message segments together. If RCOUNT in the descriptor is set to zero the transmission will be retried until the transmission is successful.

Each transmission queue has a fixed source ID (TXMSG_SRC_ID or TX_SRC_ID), priority (TXMSG_CTRL.PRIO), critical request flow setting (TXMSG_CTRL.CR or TX_CTRL.CR), virtual channel setting (TXMSG_CTRL.VC) and transport type (TXMSG_CTRL.TT or TX_CTRL.TT). For each message individually, the destination ID (DEST_ID), mailbox number (MBOX, XMBOX) and letter number (LET) can be set up in the corresponding descriptor.

Each transmission queue implements a request-to-response timeout mechanism that counts the time between the transmission of a message (or message segment) and a response from the destination node. This timeout can be configured globally in the TO_CONF register. If the timeout elapses, the descriptor will be closed with the Timeout Error (TE) flag set and an error interrupt is generated if enabled.

A transmission queue serves one descriptor at a time. Two packets are sent from the same queue when the descriptor defines more than one packet, and then replies for them are awaited before moving to the next couple. This is done in order to enhance the throughput of transfers up to 4 KB. Receiving a RETRY request when two packets are outstanding will cause both packets to be sent again and when an ERROR response is received the descriptor is written back with the number of segment causing the error.

The circular buffer management between hardware and software is done via two descriptor pointers. The tail pointer in TXMSG_TLPTR or TX_TLPTR is managed by hardware whereas the head pointer in TXMSG_HDPTR or TX_HDPTR is managed by software.

Sending a data message does not increase the internal srcTID counter, as data messages are not identified using this field.

The software can add one or more descriptors to the circular buffer and then activate them by increasing the head pointer value in TXMSG_HDPTR or TX_HDPTR. Every time the GRSRIO logical layer transmits a new message successfully, it will increment the tail pointer to the next descriptor. The software can always check how many descriptors awaiting transmission are left in the buffer by subtracting the tail pointer value from the head pointer value.

In the following, the relevant descriptor words of the message transmission queues are described:

77.2.3 Receiving Doorbell Messages

Inbound doorbell messages are stored in one or more doorbell reception buffers. The desired number of reception buffers can be set by VHDL generic *g_no_dbell_rx* at compile time. Doorbell messages are small enough to be stored directly in the circular buffer and therefore do not need DMA descriptors. Furthermore, descriptors are 4 words long instead of 8 to decrease latency of operations.

The inbound doorbell messages are stored to a specific buffer depending on their destination ID. The accepted destination ID of a buffer can be defined in register RXDBL_DST_ID. Furthermore, ranges of destination IDs can be accepted by also setting the masking field RXDBL_DST_MSK. If several doorbell reception buffers are configured to accept the same destination ID, the doorbell buffer with the lowest index number, that is currently not busy, will receive the doorbell message.

Each reception buffer is a circular buffer that is located in memory. Before activating the buffer, the memory start address of the circular buffer must be set in register RXDBL_MADDR_LSW (and RXDBL_MADDR_MSW if *CFG_AW = 64*) and its depth in register RXDBL_CTRL.CBD. Each

queue can be configured to store between 2 and 65,536 doorbell messages. Each doorbell message buffer entry has a size of 16 bytes and it is up to the software to reserve the necessary memory space for the whole circular buffer.

Each reception buffer can be configured to trigger a set of interrupts: (i) full interrupts that indicate that no more inbound doorbell messages can be accepted because the reception buffer is full (RXDBL_CTRL.IF), (ii) error interrupts that indicate bus errors (RXDBL_CTRL.IE), and (iii) reception interrupts that indicate that a doorbell message was successfully received (RXDBL_CTRL.IR).

All following conditions must be true for a doorbell message to be accepted by the queue:

• The queue is enabled.

• The queue is not full.

• The destination ID is accepted.

If no buffer is available that can accept the message, the GRSRIO logical layer replies to the destination node with an ERROR response. If a buffer is available but full, the GRSRIO logical layer replies to the destination node with a RETRY response.

The circular buffer management between hardware and software is done via two descriptor pointers. The tail pointer in RXDBL_TLPTR is managed by hardware whereas the head pointer in RXDBL_HDPTR is managed by software.

The software can add one or more buffer entries to the circular buffer and then activate them by increasing the head pointer value in RXDBL_HDPTR. Every time the GRSRIO logical layer receives a new doorbell message successfully, it will increment the tail pointer to the next buffer entry. The software can always check how many free buffer entries are left in the buffer by subtracting the tail pointer value from the head pointer value.

The GRSRIO logical layer also allows the forwarding of received doorbell messages to an external port. To enable this feature, the EXTDBL_CONF.DO signal must be set. In addition, the logical layer can be configured to only forward specific doorbell messages. This feature can be enabled by setting the EXTDBL_CONF.DC bit and by setting up a compare value in EXTDBL_FLTR.DBCOMP and a mask value in EXTDBL_FLTR.DBMASK.

In the following, the relevant buffer entry words of the doorbell reception buffers are described:

77.2.4 Transmitting doorbell messages

Outbound doorbell messages are stored in doorbell or hybrid transmission queues (depending on *g_hyb_que*). The desired number of transmission buffers can be set by VHDL generic *g_no_dbell_tx* or *g_no_hyb_tx* at compile time. The descriptor in this case directly contains the SRIO payload, as it is just 2 B long. Furthermore, when *g_hyb_que* is set to false, descriptors are 4 words long instead of 8 to decrease latency of operations. When *g_hyb_que* is set to true TX descriptors of doorbells messages are 8 words long like the ones for the other transaction types.

If several transmission queues have messages ready to be sent, the one with the highest priority gets to transmit first. If more than one active queues have the highest priority, the arbitration between them is done with a round robin algorithm. However, the following conditions must be true:

• The queue is enabled.

• The doorbell message has a priority level that can currently be accepted by the SRIO end point.

Each transmission queue is a circular buffer that is located in memory. Before activating the buffer, the memory start address of the circular buffer must be set in register TXDBL_MADDR_LSW (and TXDBL_MADDR(_MSW)) or TX_MADDR_LSW (and TX_MADDR(_MSW)) and its depth in the register field TXDBL_CTRL.CBD or TX_CTRL.CBD. Each queue can be configured to store between 2 and 65,536 doorbell messages. Each buffer entry has a size of 16 bytes when *g_hyb_que* is set to "false" and 32 bytes when *g_hyb_que* is set to "true". It is up to the software to reserve the necessary memory space for the whole circular buffer.

Each transmission buffer can be configured to trigger a set of interrupts: (i) error interrupts that indicate bus errors, retry errors, and timeout errors (TXDBL_CTRL.IE or TX_CTRL.IE), and (ii) transmission interrupts that indicate that a doorbell message was successfully transmitted (TXDBL_CTRL.IT or TX_CTRL.IT). The generation of transmission interrupts can be further con-

GRIP

Apr 2024, Version 2024.1

figured by setting the transmission interrupt mode bit (TXDBL_CTRL.IM or TX_CTRL.IM). If set, a transmission interrupt is always but only triggered after the transmission buffer became empty. If not set, the generation of transmission interrupts depends on the Enable Transmission Interrupt (TI) setting of the doorbell buffer entry.

Doorbell messages are automatically retried until either the packet is accepted by the destination node or until the threshold level defined in the buffer entry field RCOUNT is reached. If RCOUNT is set to zero they are retried forever.

Each transmission buffer has a fixed source ID (TXDBL_SRC_ID), priority (TXDBL_CTLR.PRIO), critical request flow setting (TXDBL_CTRL.CR), virtual channel setting (TXDBL_CTRL.VC) and transport type (TXDBL_CTRL.TT). For each doorbell message individually, the destination ID (DEST_ID) can be set up in the corresponding buffer entry.

Each transmission buffer implements a request-to-response timeout mechanism that counts the time between the transmission of a doorbell message and a response from the destination node. This timeout can be configured globally in register TO_CONF. If the timeout elapses, the buffer entry will be closed with the Timeout Error (TE) flag set and an error interrupt is generated if enabled. A transmission queue is blocked while it is awaiting a response from the destination node. However, other transmission queues can be serviced in the meanwhile.

Every time a new packet is sent the srcTID field of the packet is increased, also when a transaction is retried.

The circular buffer management between hardware and software is done via two descriptor pointers. The tail pointer in TXDBELLMSG3.TLPTR is managed by hardware whereas the head pointer in TXDBELLMSG3.HDPTR is managed by software.

The software can add one or more buffer entries to the circular buffer and then activate them by increasing the head pointer value in TXDBELLMSG3.HDPTR. Every time the GRSRIO logical layer transmits a new doorbell message successfully, it will increment the tail pointer to the next buffer entry. The software can always check how many buffer entries awaiting transmission are left in the buffer by subtracting the tail pointer value from the head pointer value.

The GRSRIO logical layer also allows the generation of doorbell messages through an external port. To enable this feature, the CORECONF1.DI bit must be set. Pending external doorbell transmission requests have always priority over internal transmission requests.

In the following, the relevant descriptor words of the message transmission queues are described:

77.2.5 Inbound I/O operations

Inbound memory I/O operations can gain direct access to the local memory. The GRSRIO logical layer supports all memory I/O operations except of MAINTENANCE Read, Write and Port-Write Requests since these operations are already handled by the SRIO End-Point. The core provides both memory protection on physical addresses and address translation by means of two independent sets of partitions and windows.

When *CFG_AW* = 32 (local addresses of 32 bits), the physical address is decided according to SRIO Address(33:0), effectively allowing to handle a virtual memory space bigger than the physical one. The values of Address(33:30) are used to decide which TRNSWIN_CONF.WIN_ADDR to use in the final result of the translation. The physical address is then calculated by the following formula:

$$\text{Physical Address} = \text{TRNSLWIN.WIN\_ADDR (window } i) \& \\ \text{SRIO Address((27- RXIO\_CONF.ADDR\_SHIFT):0)}$$

Where *i* is the non negative integer found in Address(33:30), "&" is the concatenation operator and i is the index of the hit translation window.

When *CFG_AW = 64* (local addresses of 64 bits), the physical address is decided according to the SRIO Address(65:0), effectively allowing the handling of a virtual memory space bigger than the physical one. The values of Address(65:62) are used to decide which TRNSWIN_-CONF.WIN_ADDR in the final result of the translation. The physical address is then defined by the following formula:

$$\text{Physical Address} = \text{TRNSLWIN.WIN\_ADDR (window } i) \& \\ \text{SRIO Address((59-RXIO\_CONF.ADDR\_SHIFT):0)}$$

Where *i* is the non negative integer found in Address(65:62) and "&" is the concatenation operator.

The translation windows are all disabled by default and only the ones enabled by setting the respective TRNSWIN.EN to "1" are kept into account for translation. If no enabled translation windows are hit, the physical address is obtained directly assigning the value of SRIO Address(31:0) to the physical address in case of *CFG_AW = 32* and SRIO Address(63:0) to the physical address in case of in case of *CFG_AW = 64*.

Remote memory access is by default deactivated. The software can activate up to four (if *g_8_in_win* is set to "false") or eight (if *g_8_in_win* is set to "true") memory partitions using the switches MEM-PRT.PWE for writing and MEMPRT.PRE for reading each partition. Operations trying to read from a partition where read is not enable or writing in a partition where writing is not enabled are ignored and the GRSRIO logical layer replies an ERROR response to the destination node in such a case.

The start address of each partition is defined in the respective MEMPRT.PART_ADDR. These fields contain the upper 12 bits of such address. The size of each partition can be adjusted by setting a corresponding mask value in the respective MEMPRT.PART_MASK.

A physical address of an inbound memory I/O operation falls into the memory protection partition *i* if it satisfies the following condition:

$$\text{(Physical Address (CFG\_AW-1:CFG\_AW-11)} \textbf{ xor } \text{MEMPRT.PART\_ADDR (partition } i\text{))} \\ \textbf{and } \text{MEMPRT.PART\_MASK (partition } i\text{)= 0x000}$$

In this case, a mask value of 0xFFF defines the smallest possible partition with a size of 1MB and a mask value of 0x000 creates a partition that spans the whole 32-bit wide memory space. In this case, a

GRIP
Apr 2024, Version 2024.1   1281   Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

mask value of 0xFFF defines the smallest possible partition with a size of 4GB and a mask value of 0x000 creates a partition that spans the whole 64-bit wide memory space. In the next release (GEN3) it is planned to have a mask value of 0xFFF to define the smallest possible partition with a size of 1MB and a mask value of 0x000 to define partitions of 4GB.

The software can set up two types of interrupts: Memory access interrupts (RXIO_CTRL.IM) are triggered after each successful memory access, error interrupts (RXIO_CTRL.IE) are triggered in case of bus errors or forbidden memory access error, that is, when the destination node tries to access a memory space, which is either not covered by a partition or which does not allow write or read access.

For debug purposes, the last accessed local memory address is logged in the read-only field RXIO_LACCESS_MSW (if *CFG_AW* is set to 64) and RXIO_LACCES(_LSW).

77.2.6 Transmitting Memory I/O operations

Outbound memory I/O operations are stored in one or more memory I/O or hybrid transmission queues. The desired number of transmission queues can be set by VHDL generic *g_no_io_tx* or *g_no_hyb_tx* at compile time.

If several transmission queues have messages ready to be sent, the one with the highest priority gets to transmit first. If more than one active queues have the highest priority, the arbitration between them is done with a round robin algorithm. However, the following conditions must be true:

- The queue is enabled.

- The memory I/O operation message has a priority level that can currently be accepted by the SRIO end point.

Each transmission queue is a circular buffer that is located in memory. Before activating the buffer, the memory start address of the circular buffer must be set in register TXIO_MADDR_MSW and TXIO_MADDR(_LSW) or TX_MADDR_MSW and TX_MADDR(_LSW) and its depth in the field register TXIO_CTRL.CBD or TX_CTRL.CBD. The queue can be configured to store between 2 and 65,536 memory I/O operation descriptors. Each descriptor has a size of 32 bytes and it is up to the software to reserve the necessary memory space for the whole circular buffer.

Each I/O descriptor for NREAD, NWRITE, NWRITE_R and SWRITE can define a number of operations with contiguous payload from 1 to 4096. This is done in order to be able to send contiguous data up to 1MB with a single descriptor (avoid dead time due to the opening and the closing of descriptor at the end of each operation). In this case the RapidIO address will be increased according to the formula below each time the packet will be sent, although the one contained in the descriptor will not be updated:

$$\text{RapidIO address} = (\text{EXT \& SRIO\_EXT\_ADDR \& SRIO\_ADDR \& b000}) + P_B * I_p$$

Where "&" is the concatenation operator, P_B is the length in bytes of the payload in each operation of the descriptor (defined by the field SIZE of the descriptor), I_p is the number of packets already sent from this descriptor, and EXT, SRIO_EXT_ADDR, SRIO_ADDR are the respective fields in the TX descriptor.

Each queue can be configured to trigger a set of interrupts: (i) error interrupts that indicate bus errors, SRIO errors and timeout errors (TXIO_CTRL.IE or TX_CTRL.IE), and (ii) transmission interrupts that indicate that a memory I/O operation was successfully transmitted (TXIO_CTRL.IT or TX_CTRL.IT). The generation of transmission interrupts can be further configured by setting the transmission interrupt mode bit (TXIO_CTRL.IM or TX_CTRL.IM). If set, a transmission interrupt is only triggered after the transmission queue became empty. If not set, the generation of transmission interrupts depends on the Enable Transmission Interrupt (TI) setting of the descriptor.

Each transmission queue has a fixed source ID (TXIO_SRC_ID or TX_SRC_ID), priority (TXIO_CTRL.PRIO or TX_CTRL.PRIO), critical request flow setting (TXIO_CTRL.CR or TX_CTRL.CR), virtual channel setting (TXIO_CTRL.VC) and transport type (TXIO_CTRL.TT or TX_CTRL.TT).

+46 31 7758650 | frontgrade.com/gaisler

For each memory I/O operation individually, the destination ID (DEST_ID) can be set up in the corresponding descriptor.

Each transmission queue implements a request-to-response timeout mechanism that counts the time between the transmission of a memory I/O operation and a response from the destination node (in case of operations that require a response such as NWRITE_R or atomic transactions). This timeout can be configured globally in register TO_CONF. If the timeout elapses, the descriptor will be closed with the Timeout Error (TE) flag set and an error interrupt is generated if enabled.

A transmission queue serves one descriptor at a time. Anyway, more outstanding packets per queue (two, planned to be extended to 64 in future releases) is blocked while it is awaiting a response from the destination node. However, other transmission queues can be serviced in the meanwhile.

The circular buffer management between hardware and software is done via two descriptor pointers. The tail pointer in TXIO_TLPTR or TX_TLPTR is managed by hardware whereas the head pointer in TXIO_HDPTR or TX_HDPTR is managed by software.

The software can add one or more descriptors to the circular buffer and then activate them by increasing the head pointer value in TXIO_HDPTR or TX_HDPTR. Every time the GRSRIO logical layer transmits a new memory I/O operation successfully, it will increment the tail pointer to the next descriptor. The software can always check how many operations awaiting transmission are left in the buffer by subtracting the tail pointer value from the head pointer value.

Every time a new packet is sent the srcTID field of the packet is increased, except when NWRITE and SWRITE transactions are sent (they have no srcTID field).

The type of the operation is defined in field TYPE, and the read- or write size in field SIZE. The size field is the concatenation of wdptr and rdsize/wrsize (see also RapidIO Interconnect Specification Part 1), the possible values are listed in Table 1546.

- For NREAD operations, the data read from the destination node will be stored at the memory address defined in ADDR.

- For NWRITE, NWRITE_R and SWRITE operations, the data which should be written to the remote node must be stored at the address defined in ADDR.

- For ATOMIC Set, Clear, Increment and Decrement operations, the data returned from the destination node will be stored at the memory address defined in ADDR. It is always fixed to 8 bytes. However, only wdptr and rdsize combinations are allowed that modify 1, 2, or 4 bytes.

- For ATOMIC Test-and-Swap and Swap operations, both the data transmitted to the destination node (the "swap" data) and the data returned from the destination node is stored at the address defined in ADDR. It is always fixed to 8 bytes. But again, only wdptr and wrsize combinations are allowed that modify 1, 2, or 4 bytes.

- For ATOMIC Compare-and-Swap operations, both the data transmitted to the destination node (the "compare" data and the "swap" data) and the data returned from the destination node is stored at the address defined in ADDR. The outgoing data is fixed to 16 bytes, where the first 8 bytes store the "compare" data and the second 8 bytes the "swap" data. The data returned from the destination node has always 8 bytes. Like for the other ATOMIC transactions, only wdptr and wrsize combinations that modify 1, 2, or 4 bytes are allowed.

- For MAINTENANCE Read operations, the data read from the destination node will be stored at the memory address defined in ADDR. It can be 4 or 8 bytes long, therefore the SIZE field must be set to b0100, b1100 or b01011.

77.3 MECS Time Synchronization Protocol

The core, combined with the SRIOGEN2-IP end point, implements the "MECS Time Synchronization Protocol" according to RapidIO specifications Rev 4.0 if *g_mecs* is set to "true". SMECS are not implemented. "Enhanced" MECS events with cmd = i are signaled from and triggered in the end point as changes in the signal level of respectively MECS_CAPTURED_IN[i] and MECS_TRIGGER_OUT[i].

77.4 Bus Master interface

77.4.1 Overview

Atomicity of operations as a target is supported by the AHB Master. Atomicity of operations as a target is currently not supported by the AXI4 Master. For this reason, when the grsrio_gen2axi wrapper is used inbound atomic operations are discarded and flagged as unsupported transaction.

The generic_bm_x is designed to use a standard bus master interface in which the translation of bus master commands to AHB or AXI bus protocol is handled by the component. This way if an IP core is designed to handle memory accesses with the standard bus master interface, which is defined in this document, it can be made compatible to AHB or AXI buses without additional effort. In addition, memory access control is simplified since standard bus interface (AHB,AXI) features like boundary crossing, alignment requirements is handled by the generic_bm_x IP core and no special action needed on the standard bus mater interface. Furthermore, additional bus protocols apart from AHB or AXI might be added in the future. The generic_bm_x core has a variety of configuration options to simplify the memory access logic required for bus master interface and optimize the bus accesses on AHB or AXI bus.

Fig. 210 illustrates the overall block diagram of generic_bm_x. Front-End handles all the handshaking on the bus_master interface. Middle-End handles all the burst related operations and generate standard commands to the back-end interface. Back-end interface generates bus specific burst commands depending on the selected bus protocol type. For each specific bus protocol (AHB,AXI) the back-end component is changed.
Figure 210. Overall block diagram of generic_bm_x

77.4.2 Configuration Options

MAX_SIZE: this generic determines the total maximum possible size of the burst on the bus master interface in terms of **bytes**. It has to be power of two. This generic also determines the width of the bmrd_size and bmwr_size input ports. This generic is fixed to 256 for GRSRIO core.

BM_DW: Data-width of the bus master interface in terms of **bits** and has to be a multiple of 32. This generic is fixed to 128 for GRSRIO core.

BE_DW: Data-width of the back-end bus in terms of **bits**. It can be equal or narrower compared to BM_DW and has to be a multiple of 32.

ADDR_WIDTH: Address width of the front-end and back-end bus.

MAX_BURST_LENGTH: Determines the maximum length of a burst transaction in terms of **number of beats** that is generated on the back-end bus. This generic can be useful if the maximum burst length needs to be limited to have fair arbitration in the system. It should be noted that the total maximum size of the burst in terms of bytes that is generated on the back-end bus depends on the be_dw

and can be calculated with the formula "number_of_beats*(be_dw/8)". Limiting the maximum burst length can reduce the throughput hence it is recommended not be limited unless there is a need, for example due to arbitration fairness on the back-end bus side. In order to calculate the maximum possible burst length the following formula can be used "max_size/(be_dw/8)" and max_burst_length generic can not exceed this value. Also if max_size is bigger than the allowed burst_chop_mask value for the specific bus protocol then max_size can be replaced with maximum burst_chop_mask value since the total allowed burst size in terms of bytes can not exceed maximum burst_chop_mask value.

BURST_CHOP_MASK: Determines when a burst should end a new burst should start on the back-end bus in terms of **byte alignment.** Maximum and default value of this generic depends on the back-end protocol. Maximum value is 1024 bytes for AHB and 4096 bytes for AXI which is determined by the protocol specifications. Reducing the byte alignment might be useful when combined with max_burst_length in cases where the memory that is accessed by the back-end bus has an internal buffer which gives better throughput on specific alignments. For example if max_burst_length is limited to 8 beats on a 32-bit bus and a slave memory gives the best throughput when bursts are aligned to 32-byte boundary than burst_chop_mask can be set to 32. This way, if a burst on the bus_master front and starts with an address which is not aligned to 32-bytes, the first burst will be limited to finish on 32-byte alignment so that the remaining bursts will be always aligned to 32-bytes. It should be noted that, value of this generic is not recommended to be reduced from the default value unless a specific optimization is needed as explained in this chapter , otherwise the throughput will be reduced unnecessarily.

BE_RD_PIPE: When it is set to zero a pipeline stage exists between the read data path of the back-end bus to the read data-path of the bus_master interface. When set to one, this pipeline stage is removed. Setting this value to zero reduces read latency by one for aligned accesses but if the timing requirements do not met it can be set to a non-zero value.

UNALIGN_LOAD_OPT: When set to one, unaligned load optimization is enabled. When the optimization is enabled and a burst access do not finish exactly at the end of the data word of the back-end bus, then instead of generating a separate narrow access for the last word, the entire word is read and the corresponding part is used. This reduces the latency for unaligned burst accesses. But since this optimization reads more data than requested it should not be activated if the data is going to be read from a FIFO-like structure otherwise it can cause data loss.

EXCL_ENABLED: This generic only exists in AHB back-end bus and not compatible with the AXI back-end bus. When set to true it generates locked accesses on the AHB bus. This generic is fixed to true with the AHB back-end. GRSRIO core supports atomic transactions only when using AHB back-end.

77.4.3 Access Alignment

The generic_bm_x IP core does not have any alignment restriction on the bus_master interface. All accesses on the bus_master interface will be translated to access types that are allowed by the back-end bus. If the start address of an access is unaligned relative to the back-end bus, the first accesses on the back-end bus will be narrow accesses until the address reaches to an aligned value. After that a burst access will be generated as much as the size allows. If the ending is not aligned the last accesses will also be narrow accesses. For highest throughput the accesses should be aligned relative to the back-end bus width.

The generic_bm_x IP core will handle the boundary crossing for the back-end bus hence there is no restriction on the start address or the size of the burst on the bus_master interface. But since the burst has to restart on boundary crossing, in order to achieve high throughput with long bursts, the start address should be aligned such a way that boundary crossings are eliminated or minimized.

77.4.4 Endianness

The endianness on the back-end side is always big-endian. On the bus-master interface the most significant byte of the access is always placed to the uppermost bits (relative to the vhdl std_logic_vec-

tor). It should be noted that, the bus_master interface is not byte-invariant. Regardless of the access size or start address, the data word that is outputted do not have any gaps and the most significant byte of the access is placed to the uppermost bits and the remaining data follows to the low order bits.

In order to achieve big-endianness on the AXI back-end bus the bytes are swapped since the AXI protocol is byte-invariant. Following examples shows different access patterns with different back-end bus protocols and data-widths. For all accesses the bit position is relative to the std_logic_vector used in VHDL.

Fig. 211 illustrates a 16Byte access on both AHB and AXI backends, when both BM_DW and BE_DW generics are set to 128. Fig. 212 illustrates a 16 Byte access on both AHB and AXI backends, when BM_DW is set to 128 and BE_DW is set to 64. Fig. 213 illustrates a 2 Byte access on both AHB and AXI backends, when BM_DW is set to 128 and BE_DW is set to 64.

77.4.5 Software Considerations

The bus master interface of the GRSRIO core does not have any alignment restriction. But alignment can be important to achieve low latency and high throughput. In order to improve latency of doorbell messages (where the payload is contained in the descriptor), the descriptor should be aligned to 16 Byte boundary. When transmitting packets with 256 Byte payload, the best throughput can be achieved if data-packet is aligned to 256 Byte boundary since it will avoid boundary crossing on both AHB and AXI.

77.5 Registers

The core is programmed through registers mapped into APB address space. The registers are listed in table and described in detail in the subsequent tables. Addresses not listed in table are reserved. A read access to a reserved register, or reserved field with a register, will always return zero, and a write access has no effect. The register layout used is exemplified in table 1556, and the values used in the reset value row and field type row are explained in tables 1557 and 1558.

To easily support allocation of hardware resources to software entities, the address space for each hardware resource (queues, translation windows, memory protection partitions) are placed on 4KB boundaries.

Internally, the GRSRIO core decodes the address as listed in table 1555:

Table 1555. Decoding of ABP address

Bits	Description
19:17	Type of register block.
16:12	Index of queues/windows/partitions
11:2	Number of register.

The memory map has a size of 1MB and must also be aligned to 1MB boundaries.

Table 1556.<APB address offset> - <Register acronym> - <Register name>

31 24	23 16	15 8	7 0
EF3	EF2	EF1	EF0
<Reset value for EF3>	<Reset value for EF2>	<Reset value for EF1>	<Reset value for EF0>
<Bit-field type for EF3>	<Bit-field type for EF2>	<Bit-field type for EF1>	<Bit-field type for EF0>

31: 24	Example bit-field 3 (EF3) - <Bit-field description>
23: 16	Example bit-field 2 (EF2) - <Bit-field description>
15: 8	Example bit-field 1 (EF1) - <Bit-field description>
7: 0	Example bit-field 0 (EF0) - <Bit-field description>

Table 1557. Reset value definitions

Value	Description
0	Reset value 0. Used for single-bit fields.
1	Reset value 1. Used for single-bit fields.
0xNN	Hexadecimal representation of reset value. Used for multi-bit fields.
n/r	Field not reseted
*	Special reset condition, described in textual description of the bit-field. Used for example when reset value is taken from an input signal.

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 1572.*EXTDBL_CONF - External Doorbell Configuration Register

13: 12	External Outbound Doorbell Message Transport Type (TT). If set to 0b00, the destination ID and source IDs of external outbound doorbell messages are 8-bit wide. If set to 0b01, the fields are 16-bit wide.
11	External Outbound Doorbell Message Virtual Channel Bit (VC). If set, the virtual channel bit of the external outbound doorbell message packet is also set.
10	External Outbound Doorbell Message Critical Request Flow Bit (CR). If set, the CRF bit of the external outbound doorbell message is also set.
9: 8	External Outbound Doorbell Message Priority (PRIO). Priority of the external outbound doorbell message. To avoid deadlock, the highest priority level is not allowed for request packets. If 0b11 is written to this field, it is automatically overwritten by 0b10.
7: 5	RESERVED
4	Ignore Doorbell Buffer (IB). If this bit is set and DO is set and the doorbell info matches DBCOMP (in case DC is also set), the GRSRIO core outputs the doorbell to the external port without storing it to any possibly set up doorbell reception buffer and therefore always returns a DONE response to the destination node. If the bit is not set, the doorbell message is also outputted to the external port, however, the GRSRIO core still tries to store it in a doorbell reception buffer. Then, the response type depends on the doorbell reception buffer. If a buffer is available and the doorbell message was successfully stored, the GRSRIO core returns a DONE response, otherwise a RETRY response.
3	Ignore Full Doorbell Buffer (IFB). In case DO is set and IB is not set but no free doorbell reception buffer is available (see above), the GRSRIO core always returns a DONE response.
2	Enable Doorbell Info Comparison (DC). If set and if DO is set, inbound doorbell messages are only forwarded to the external port if the doorbell info field matches the value in the DBCOMP field.
1	Enable Doorbell Output Signals (DO). If set, inbound doorbell messages are forwarded to the external port.
0	Enable Doorbell Input Signals (DI). If set, outbound doorbell messages can be generated through the external port.

*Table 1573.*EXTDBL_FLTR - Processing Core Configuration Register 2

31	16	15	0
DBMASK		DBCOMP	
0		0	
rw		rw	

31: 16	Doorbell Message Mask Value (DBMASK). If DC and DO are set, inbound doorbell messages are compared with the compare value DBCOMP. If a bit is set in this mask field, the corresponding bit of DBCOMP is compared.
15: 0	Doorbell Message Compare Value (DBCOMP). If DC and DO are set, the doorbell message is only forwarded to the external port if the doorbell info field matches the value in this field.

77.5.2 Transmission Queues Registers

*Table 1579.*TXMSG_CTRL/TXDBL_CTRL/TXIO_CTRL/TX_CTRL - Transmission queue configuration register

31	22	21 20	19	18	17 16	15	10	9	6	5	4	3	2	1	0
RESERVED		PRIO	CR	VC	TT	RESERVED		CBD		IM	IE	IT	ST	TP	EN
0		0	0	0	0	0		0		0	0	0	0	0	0
r		rw	rw	rw	rw	r		rw*		rw	rw	rw	rw	rw*	rw*

31: 22	RESERVED	
21: 20	Priority (PRIO). Priority of the outbound message or IO operation packets. To avoid deadlock, the highest priority level is not allowed for request packets (if 0b11 is written to this field, it is automatically overwritten by 0b10)	
19	Critical Request Flow Bit (CR). If set, the CRF bit of the outbound message or IO operation packet is also set.	
18	Virtual Channel Bit (VC). If set, the virtual channel bit of the outbound message packet is also set.	
17: 16	Transport Type (TT). If set to 0b00, the destination ID and source IDs of this transmission queue are 8-bit wide. If set to 0b01, the fields are 16-bit wide.	
15: 10	RESERVED	
9: 6	Circular Buffer Depth (CBD). Depth of the circular queue of this message transmission queue. A queue can be configured to store between 2 and 65,536 messages: Depth = $2^{(CBD+1)}$. Writing to this field has only an effect when the transmission queue is not enabled, that is, when EN is 0. Note that even if the size of the queue is $2^{(CBD+1)}$, setting the head point directly to this value will not enable the queue as only the least significant CBD+1 bits of the tail pointer will be compared to the CBD+1 least significant bit of the head pointer.	
5	Transmission Interrupt Mode (IM). If set, a transmission interrupt is only generated after the transmission queue became empty, that is, when the tail pointer equals the head pointer. If not set, the generation of transmission interrupts depends on the setting of the corresponding TI bits in the transmission descriptor words.	
4	Enable Error Interrupts (IE). If set, interrupts are generated for any kind of transmission or bus error related to this transmission queue.	
3	Enable Transmission Interrupts (IT). If set, interrupts are generated for successful message or IO operation packets transmission. The way how the interrupts are generated depends on the Transmission Interrupt Mode (IM).	
2	Stop on Transmission Error (ST). If set, the transmission queue is automatically disabled after a transmission error has occurred. The tail pointer is not incremented and is therefore pointing to the descriptor that was processed during the occurrence of the error, allowing the software to quickly initiate some error recovery procedure. The type of transmission error can be read from the descriptor and includes: Serial RapidIO Error, Retry Error, and Timeout Error. If not set, the DMA engine increments the tail pointer and processes the next descriptor (if available) in case of errors.	
1	Enable two-outstanding-packets mode: if this bit is set to 1, when a single descriptor defines more than one packet, two packet will be transmitted without waiting for the reply to the first one. Writing to this field has only an effect when the transmission queue is not enabled, that is, when EN is 0.	
0	Enable Transmission Queue (EN). If set, the DMA engine executes the operations defined in the descriptors queue until the circular buffer is empty, that is, until the tail pointer reaches the head pointer. Then, once the software increments the head pointer again, the transmission is automatically resumed. Writing 1 while the queue is disabled, enables the queue. Writing 0 while the queue is enabled disables the transmission queue. If a transmission is ongoing, the queue is disabled after processing the current descriptor. When disabled and after all memory accesses in conjunction with this descriptor have been completed, this bit clears to 0.

*Table 1580.*TXMSG_STAT/TXDBL_STAT/TXIO_STAT/TX_STAT - Transmission Queue Status Register

7	Two packet sent and one response received (SR): reads 1 when two packet have been sent from a descriptor defining the transmission of more packets and one response has been already received (in two-outstanding-packets mode) (two-outstanding-packets mode)
6	Two packets sent and no responses received (SS): reads 1 when two packet have been sent from a descriptor defining the transmission of more packets and no responses have been received (in two-outstanding-packets mode)
5	One packet sent and one waiting to be sent (SW): reads 1 when one packet has been sent from a descriptor defining the transmission of more packets and the second one is still waiting to be transmitted (in two-outstanding-packets mode)
4	Transmission Interrupt (TI). Indicates a transmission interrupt. Writing 1 clears this bit and the corresponding bit in the Interrupt Level 1 register.
3	Error Interrupt (EI). Indicates an error interrupt. Writing 1 clears this bit and the corresponding bit in the Interrupt Level 1 register.
2	Bus Error (BE). Set when a bus memory access error occurs while a descriptor in this queue is processed. The transmission queue is automatically disabled and the tail pointer is not incremented. Writing 1 clears the bit, writing 0 has no effect.
1	Transmission Error (TE). Set when a transmission error occurs while a descriptor in this queue is processed. The type of transmission error can be read from the descriptor and includes: Serial RapidIO Error, Retry Error, and Timeout Error. Writing 1 clears the bit, writing 0 has no effect.
0	Transmission Active (TA). Indicates that a transmission is ongoing. This bit remains high as long as the GRSRIO core has not closed the current descriptor.

*Table 1581.*TXMSG_SRC_ID/TXDBL_SRC_ID/TXIO_SRC_ID/TX_SRC_ID - Transmission Queue Source ID Register

31 0
SOURCE_ID
0
rw

31: 0	Source Identifier (SOURCE_ID). Source ID of this transmission queue.

*Table 1582.*TXMSG_TLPTR/TX_TLPTR/TXDBL_TLPTR/TXIO_TLPTR - Transmission Queue Tail Pointer Register

31 16	15 0
RESERVED	TLPTR
0	0
r	rw*

31: 16	RESERVED
15: 0	Message Transmission Queue Tail Pointer (TLPTR). The tail pointer is updated by the DMA engine and is therefore read-only during operation. It is incremented by one for each message that was successfully committed to the Serial RapidIO port. Writing to this field has only an effect when the transmission queue is not enabled, that is, when EN is 0. The software can flush a disabled queue by programming both the tail and head pointer to point to the same descriptor.

*Table 1583.*TXMSG_HDPTR/TXDBL_HDPTR/TXIO_HDPTR/TX_HDPTR - Transmission Queue Head Pointer

31 16	15 0
TLPTR_R	HDPTR
0	0
r	rw

31: 16	Transmission Queue Tail Pointer (READ ONLY) (TLPTR_R): read only value of the tail pointer to allow the SW to know both head and tail pointer with just one access and take faster decisions.
15: 0	Transmission Queue Head Pointer (HDPTR). The head pointer is updated by software after setting up the messages or IO operations payload in memory and the corresponding descriptors in the circular buffer.

77.5.3 Message Reception Queues Register

*Table 1586.*RXMSG_CTRL - Message Reception Control Register, Queue i

31	23	22	21	16	15	10	9	6	5	4	3	2	1	0
MAX_SIZE		R	MBOXMSK		MBOX		CBD		IF	IE	IR	ST	R	EN
0		0	0		0		0		0	0	0	0	0	0
rw*		r	rw*		rw*		rw*		rw	rw	rw	rw	r	rw*

31: 23	Maximum allowed message size (MAX_SIZE). Only messages with a size up to MAX_SIZE are accepted in this queue. Maximum size of the message in multiples of 8 bytes: Maximum Size = (MAX_SIZE+1)*8 bytes. Writing to this field has only an effect when the reception queue is not enabled, that is, when EN is 0.
22	RESERVED
21: 16	Mailbox Mask (MBOXMSK). Using this mask field, ranges of mailbox numbers can be accepted. If a bit is set, the corresponding bit of the mailbox field MBOX is compared. The example in the datasheet is wrong: the formula to accept a packet is: (RECEIVED ID XOR QUEUE ID) AND MASK = b000000. This means that to accept mailboxes from 0 to 3, ID must be set to b000000 and MASK must be b111100.
15: 10	Mailbox Number (MBOX). Only messages addressed to the here defined mailbox number are accepted. Writing to this field has only an effect when the reception queue is not enabled, that is, when EN is 0.
9: 6	Circular Buffer Depth (CBD). Depth of the circular buffer of this message reception queue. A queue can be configured to store between 2 and 65,536 messages: Depth = 2^(CBD+1). Writing to this field has only an effect when the reception queue is not enabled, that is, when EN is 0.
5	Enable Full Interrupts (IF). If set, an interrupt is generated each time the reception queue becomes full, that is, when also the FQ bit is set.
4	Enable Error Interrupts (IE). If set, interrupts are generated in case of reception errors or bus errors.
3	Enable Reception Interrupts (IR). If set, interrupts are generated for successful message receptions. Reception interrupts must be enabled for each descriptor individually by setting the corresponding RI bits in the message reception descriptors.
2	Stop on Reception Error (ST). If set, the reception queue is automatically disabled after a reception error has occurred. The tail pointer is not incremented and is therefore pointing to the descriptor that was processed during the occurrence of the error, allowing the software to quickly initiate some error recovery procedure. If not set, the DMA engine increments the tail pointer and processes the next descriptor (if available) in case of errors.
1	RESERVED
0	Enable Reception Queue (EN). If set, the DMA engine executes the reception of messages until the circular buffer is full, that is, until the address of the tail pointer equals the address of the head pointer - 1 (modulo buffer depth). Then, once the software increments the head pointer again, the reception is automatically resumed. Writing 1 while the queue is disabled, enables the queue. Writing 0 while the queue is enabled disables the reception queue. If a reception is ongoing, the queue is disabled after processing the current descriptor. When disabled and after all memory accesses in conjunction with this descriptor have been completed, this bit clears to 0.

*Table 1587.*RXMSG_STAT - Message Reception Status Register, Queue i

77.5.5   I/O Operation Reception Unit Registers

*Table 1602.*RXIO_CONF - I/O Operation Reception Configuration Register

31		3	2	1	0
RESERVED			IE	IM	EN
0			0	0	0
r			rw	rw	rw*

31: 3   RESERVED

2   Enable Error Interrupts (IE). If set, interrupts are generated in case of bus errors or forbidden memory access errors.

1   Enable Memory Access Interrupts (IM). If set, interrupts are generated for successful memory I/O operations.

0   Enable Memory I/O (EN). If set, incoming memory I/O operations are executed by the DMA engine, otherwise packets are automatically rejected and an ERROR response is returned to the destination node (for those memory I/O operations that require a response). Writing 1 while memory I/O operations are disabled, enables them. Writing 0 while memory I/O operations are enabled disables them. If a memory access is ongoing, this access is allowed to finish. Then, once the access has been completed, this bit clears to 0.

*Table 1603.*RXIO_STAT - I/O Operation Reception Status Register

*Table 1603.*RXIO_STAT - I/O Operation Reception Status Register

4	Reception Interrupt (RI). Indicates a reception interrupt. Writing 1 clears this bit and the corresponding bit in the Interrupt Level 1 register.
3	Error Interrupt (EI). Indicates an error interrupt. Writing 1 clears this bit and the corresponding bit in the Interrupt Level 1 register.
2	Bus Error (BE). Set when a bus memory access error occurs while an inbound I/O operation is processed. The I/O reception unit is automatically disabled. Writing 1 clears the bit, writing 0 has no effect.
1	Forbidden Memory Access Error (ME). Set when an inbound I/O operation tries to access a forbidden memory address. Writing 1 clears the bit, writing 0 has no effect.
0	Reception Active (RA). Indicates that a reception is ongoing. This bit remains high as long as the GRSRIO core has not finished the memory access.

*Table 1604.*RXIO_LACCESS_MSW - Most Significant Word of the Last Access Register

This register is only available when *CFG_AW* is set to 64.

31	0
LACCESS_MSW	
0	
r	

31: 0	Most Significant Word of the Last Accessed Address Causing a Memory Error(LACCESS_MSW). The last accessed memory address can be read from this field.

*Table 1605.*RXIO_LACCESS(_LSW) - (Least Most Significant Word of the Last Access Register

31	0
LACCESS(_LSW)	
0	
r	

31: 0	Last Accessed Address (LACCESS(_LSW)). The last accessed memory address can be read from this field. When *CFG_AW = 64* this is the LSW of such address.

*Table 1606.*RXIO_LACCESS(_LSW) - (Least Most Significant Word of the Last Access Register

This register is only available when *CFG_AW* is set to 64.

31	0
LAST_MEM_ERR_ADDR_MSW	
0	
r	

31: 0	Last Accessed Address Causing a Memory Error (LACCESS(_LSW)). The last MSW of the last accessed memory address causing a memory error can be read from this field.

31: 16	Number of Memory Error (NME): Number of memory errors occured since last time RXIO_STAT.ME was cleaned.
15: 0	Number of Reception Interrupts Error (NRI): Number of reception interrupts occured since last time RXIO_STAT.RI was cleaned.

77.5.6 MECS registers

The MECS registers are implemented according to RapidIO specification, Rev. 4.0 and only if *g_mecs* is set to "true". Timestamp Generation Extension Block Header is not implemented, as MECS registers are not implemented together with the other CAR and CSR registers in the SRIOGEN2IP.

*Table 1609.*Timestamp CAR (T_CAR)- offset 0xF004

Table 1610. Timestamp Generator Status CSR (TGS_CSR) - offset 0xF008

3	Timestamp Generator Was Stopped: Indicates if the Timestamp Generator counter has not advanced because it has been set to an earlier time.
	0b0 - Timestamp Generator has advanced continuously since this bit was last cleared
	0b1 - Timestamp Generator has temporarily stopped advancing at least once since this bit was last cleared.
	This bit is cleared by writing "1" to it.
2	Timestamp Generator Stopped: Indicates if the Timestamp Generator counter is not advancing because it is being set to an earlier time.
	0b0 - Timestamp Generator is advancing
	0b1 - Timestamp Generator is temporarily not advancing
1	RESERVED
0	Timestamp Generator Clock Locked (CL): Indicates whether the Timestamp Generator counter is operating from a good clock source.
	0b0 - Timestamp Generator is not operating with a good clock source.
	0b1 - Timestamp Generator is operating with a good clock source.

Table 1611. MECS Tick Interval CSR (MTI_CSR) - (0xF00C)

31								8	7	6	5	4	3	2	1	0
TICK_INT									RES.		LS	LT	LSTHR		SS	SR
0									0		0	0	00		0	0
rw									r		wc	wc	rw		r	rw

31: 8	Tick Interval (TICK_INT):
	For a MECS Master, a MECS shall be sent when time has advanced by this many nanoseconds.
	For an MECS Slave, time has advanced by this many nanoseconds whenever an MECS is received.
	MECS transmission, and MECS timestamp synchronization for received MECS, is disabled when this register is 0.
7: 6	RESERVED
5	Lost TSG Sync Error Status: This field indicates that the device has detected at least "Lost TSG Sync Error Threshold" consecutive ticks have been lost.
	0 - A Lost TSG Sync Error has not been detected
	1 - A Lost TSG Sync Error has been detected
	This bit must be written with 1 to be cleared.
4	Lost Tick Error Status 0 This field indicates if the device has detected at least one lost tick.
	0 - A Lost Tick Error has not been detected
	1 - A Lost Tick Error has been detected
	This bit must be written with 1 to be cleared.
3: 2	Lost TSG Sync Error Threshold: controls the number of MECS/SMECS "ticks" that must be lost before declaring the timestamp generator to be out of sync.
	0b00 - Lost Tick Error Threshold is disabled
	0b01 - If one tick is lost, declare the timestamp generator out of sync
	0b10 - If two ticks are lost, declare the timestamp generator out of sync
	0b11 - If three ticks are lost, declare the timestamp generator out of sync

*Table 1611.*MECS Tick Interval CSR (MTI_CSR) - (0xF00C)

1	SMECS Selection (SS): The device uses MECS and doesn't support SMECS (0)
0	MECS Time synchronization Role: Controls whether a device operates as a MECS Master or MECS Slave.
	0 - The device is operating as a MECS Slave
	1 - The device is operating as a MECS Master

*Table 1612.*MECS Next Timestamp MSW CSR (NMSW_CSR) - offset 0xF0014

31	0
NMSW	
0	
rw	

31: 0	Most significant 32 bits for the timestamp value used to update the Timestamp Generator MSW CSR when a Multicast Event Control Symbol is received by an MECS Slave.
	Most significant 32 bits of the timestamp value compared with the Timestamp Generator value to determine when a Multicast Event Control Symbol must be transmitted by an MECS Master

*Table 1613.*MECS Next Timestamp LSW CSR (NLSW_CSR) - (0xF0018)

31	0
NLSW	
0	
rw	

31: 0	Least significant 32 bits for the timestamp value used to update the Timestamp Generator LSW CSR when Multicast Event Control Symbol is received by an MECS Slave.
	Least significant 32 bits of the timestamp value compared with the Timestamp Generator value to determine when a Multicast Event Control Symbol shall be transmitted by an MECS Master

*Table 1614.*MECS Implementation Specific Settings Register (MECS_S) - (0xF0020)

77.6 External doorbell interface

77.6.1 Outbound doorbell messages

The following timing diagram illustrates how outbound doorbell messages can be generated through the external interface (if this feature is enabled):
Figure 214. Skew and jitter timing waveforms

The doorbell info value must be provided on DBELL_IN_VAL and kept stable together with DBELL_IN_WEN asserted to 1 until the interface acknowledges the transmission by asserting DBELL_IN_ACK. In case of errors, DBELL_IN_SRIO_ERR, DBELL_IN_RETRY_ERR or DBELL_IN_TIMEOUT_ERR is asserted together with DBELL_IN_ACK (in the example above a SRIO error occurred during transmission, that is, an ERROR response has been received from the destination node).

77.6.2 Inbound doorbell messages

The following timing diagram illustrates how inbound doorbell messages are made available to the external interface (if this feature is enabled):
Figure 215. Skew and jitter timing waveforms

GRIP
Apr 2024, Version 2024.1

1314

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The doorbell info value is available at DBELL_OUT_VAL for one clock cycle when DBELL_OUT_PULSE is asserted to 1. DBELL_OUT_PULSE can be used as a write enable signal to a register or memory that stores the doorbell info value for further processing.

77.7 Implementation

77.7.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

77.8 Configuration options

Table 1617 shows the configuration options of the core (VHDL generics).

Table 1617. Configuration options

Generic	Function	Allowed values	Default
g_tech	Selects technology for RAM blocks.	0 - NTECH	DEFMEMTECH
g_use_async_rst	Use asynchronous instead of synchronous resets.	FALSE, TRUE	FALSE
g_data_width	See section 77.4 for details.	32 - 128	32
g_max_burst_length	See section 77.4 for details.	2 - 256	256
g_burst_chop_mask	See section 77.4 for details.	8 - 4096 (AXI) 8 - 1024 (AHB)	4096 (AXI) 1024 (AHB)
g_be_rd_pipe	See section 77.4 for details.	0-1	1
g_unalign_load_opt	See section 77.4 for details.	0-1	0
g_bm_info_print[1]	When it is set to a value apart from 0, prints out bus master configuration information during simulation.	-	1
g_axi_bm_id_width[1]	Determines the ID width for read address/data, write address, and write response channels.	-	5
g_axi_bm_addr_width[1]	Determines the address width for both front-end and back-end of the bus master.	32 - 64	32
g_no_dbell_rx	Number of doorbell reception queues.	1 - 32	4
g_no_dbell_tx[4]	Number of doorbell transmission queues[4]	1 - 32	4
g_no_msg_rx	Number of data message reception queues	1 - 32	4
g_no_hyb_tx[3]	Number of hybrid queues[3]	1-32	4
g_no_io_tx[4]	Number of IO memory access transmission queues[4]	1-32	4
g_no_msg_tx[4]	Number of data message transmission queues[4]	1 - 32	4
g_init_nodes	Number of data nodes initially available in SRIO end point.	0 - 255	72
g_init_crq	Number of CRQ entries initially available in SRIO end point.	0 - 255	64
g_wm_p0	Watermark for priority 0.	0 - 255	72

SRIO_TX_CCOUNT[4:0]	N/A	Input	The value signals the number of data nodes that have been freed by the physical layer.	-
SRIO_TX_HALT	N/A	Input	When asserted, the GRSRIO IP core stops Egress traffic after finishing the current in-flight packet.	High
SRIO_RX_FULL	N/A	Output	Used by the GRSRIO IP core to pause the transfer of packets.	High
SRIO_RX_RELEASE[5:0]	N/A	Output	Indicates the number of ingress FIFO entries that have been freed by the GRSRIO IP core.	-
SRIO_RX_DATA[127:0]	N/A	Input	Inbound UDI packet data bus.	-
SRIO_RX_VALID	N/A	Input	When asserted, SRIO_RX_DATA is valid.	High
SRIO_RX_EOP	N/A	Input	When asserted, SRIO_RX_DATA is the end of the packet	High
SRIO_RX_HWORD[2:0]	N/A	Input	Indicates which half-words of SRIO_RX_DATA are valid.	-
SRIO_RX_STOMP	N/A	Input	Asserted together with SRIO_RX_EOP to flag a packet with CRC error (not supported by GRSRIO IP core)	High

[1] Only available in grsrio_gen2axi.vhd

[2] Only available in grsrio_gen2ahb.vhd

77.10   Clocks

The GRSRIO core operates in the CLK clock domain. Clock domain crossing between the CLK clock domain and the SRIO_CLK clock domain is accomplished by various CDC techniques.

The SRIO end point provides the signal SRIO_TX_CCOUNT[4:0] to the GRSRIO core, which is synchronous to and valid on every clock cycle of SRIO_CLK. Lost samples corrupt the flow control and must therefore be avoided. As a consequence, the AHB clock must be greater than or equal the SRIO clock. Lost samples are reported in CORECONF1.FE.

77.11   Resets

To ensure proper initialisation of synchronous logic related to the clock domain crossing between the SRIO_CLK and CLK clock domain, both the SRIO_RSTN and RSTN reset must be asserted for at least three clock cycles in the slower clock domain.

78   GRSYSMON - AMBA Wrapper for Xilinx System Monitor

78.1   Overview

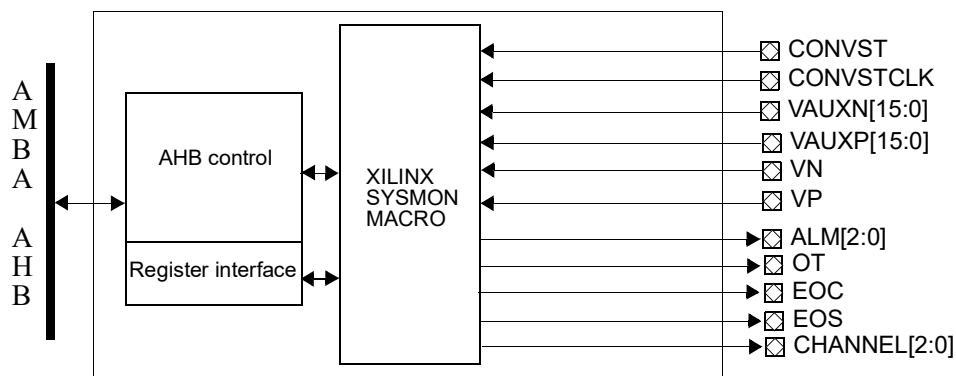
The core provides an AMBA AHB interface to the Xilinx System Monitor present in Virtex-5 FPGAs. All Xilinx System Monitor registers are mapped into AMBA address space. The core also includes functionality for generating interrupts triggered by System Monitor outputs, and allows triggering of conversion start via a separate register interface.


Figure 216. Block diagram

78.2   Operation

78.2.1   Operational model

The core has two I/O areas that can be accessed via the AMBA bus; the core configuration area and the System Monitor register area.

78.2.2   Configuration area

The configuration area, accessed via AHB I/O bank 0, contains two registers that provide status information and allow the user to generate interrupts from the Xilinx System Monitor's outputs. Write accesses to the configuration area have no AHB wait state and read accesses have one wait state. To ensure correct operation, only word (32-bit) sized accesses should be made to the configuration area.

78.2.3   System Monitor register area

The System Monitor register area is located in AHB I/O bank 1 and provides a direct-mapping to the System Monitor's Dynamic Reconfiguration Port. The System Monitor's first register is located at address offset 0x00000000 in this area.

Since the System Monitor documentation defines its addresses using half-word addressing, and AMBA uses byte-addressing, the addresses in the System Monitor documentation should be multiplied to get the correct offset in AMBA memory space. If the Configuration register bit WAL is '0' the address in System Monitor documentation should be multiplied by two to get the address mapped by the AMBA wrapper. A System Monitor register with address n is at AMBA offset 2*n. If the Configuration register bit WAL is '1', all registers start at a word boundary and the address in the System Monitor documentation should be multiplied by four to get the address mapped in AMBA address space. In this case, a System Monitor register with address n is at AMBA offset 4*n.

The wrapper always makes a single register access as the result of an access to the System Monitor register area. The size of the AMBA access is not checked and to ensure correct operation the mapped area should only be accessed using half-word (16-bit) accesses.

If the core has been implemented with AMBA split support, it will issue a SPLIT response to all accesses made to the mapped System Monitor registers. If the core is implemented without AMBA SPLIT support, wait states will be inserted until the System Monitor signals completion of a register access.

For a description of the System Monitor's capabilities and configuration, please refer to the Xilinx Virtex-5 FPGA System Monitor User Guide.

78.3   Registers

The core is programmed through registers mapped into AHB address space. Only 32-bit single-accesses to the registers are supported.

*Table 1620.*GRSYSMON registers

78.4   Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x066. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

78.5   Implementation

78.5.1   Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

78.5.2   Technology mapping

The core instantiates a SYSMON primitive.

78.5.3   RAM usage

The core does not use any RAM components.

78.5.4   Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core provides registers mapped on AHB that can be accessed in both big-endian and little-endian systems.

78.6   Configuration options

Table 1623 shows the configuration options of the core (VHDL generics).

*Table 1623.*Configuration options

Generic name	Function	Allowed range	Default
tech	Target technology	0 - NTECH	0
hindex	AHB slave index	0 - (NAHBSLV-1)	0
hirq	Interrupt line	0 - (NAHBIRQ-1)	0

79   GRUSBDC - USB Device controller

79.1   Overview

The Universal Serial Bus Device Controller provides a USB 2.0 function interface accessible from an AMBA-AHB bus interface. The core must be connected to the USB through an external PHY (shown in figure 235) compliant to either UTMI, UTMI+ or ULPI. Both full-speed and high-speed mode are supported.

Endpoints are controlled through a set of registers accessed through an AHB slave interface. Each of the up to 16 IN and 16 OUT endpoints can be individually configured to any of the four USB transfer types.

USB data cargo is moved to the core's internal buffers using a master or a slave data interface. The data slave interface allows access directly to the internal buffers using AHB transactions and therefore does not need external memory. This makes it suitable for slow and simple functions. The data master interface requires an additional AHB master interface through which data is transferred autonomously using descriptor based DMA. This is suitable for functions requiring large bandwidth.

These two interfaces are mutually exclusive and cannot be present in the same implementation of the core.
Figure 217. GRUSBDC connected to an external PHY device.

79.2   Operation

79.2.1   System overview

Figure 218 shows the internal structure of the core. This section briefly describes the function of the different blocks.

The Speed Negotiation Engine (SNE) detects connection by monitoring the VBUS signal on the USB connector. When a steady 5 V voltage is detected the SNE waits for a reset and then starts the High-speed negotiation. When the Speed negotiation and reset procedure is finished the selected speed mode (full-speed or high-speed) is notified to the Serial Interface Engine (SIE) which now can start operation. The SNE also detects and handles suspend and resume operations.

The SIE is enabled when the SNE notifies that the reset procedure has finished. It then waits for packets to arrive and processes them according to the USB 2.0 specification. The data cargo is stored to an internal buffer belonging to the recipient endpoint.

The AHB Interface Engine AIE is responsible for transferring USB data cargo from the endpoint's internal buffers to the AHB bus using descriptor based DMA through an AHB master interface when configured in master mode or by direct accesses to the AHB slave interface when configured in slave mode.

For received data it is then up to the external (to the device controller) function to continue processing of the USB data cargo after it has been transferred on the AHB bus. The function is the application specific core which determines the functionality of the complete USB device. It sets up endpoints in the device controller and notifies their existence through the appropriate USB descriptors. When the function wants to transmit a packet it either uses the slave interface to write to the endpoint buffers or establishes a DMA transfer.

GRIP

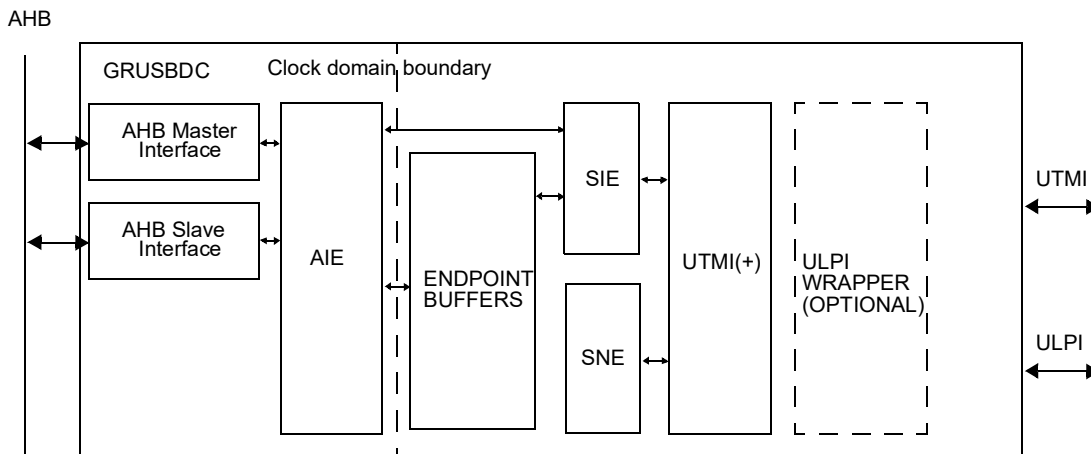
Apr 2024, Version 2024.1   1334   Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler


Figure 218. Block diagram of the internal structure of the core.

79.2.2 PHY interface

The core supports three different interfaces to the external PHY which is used to connect to the USB bus. The supported interfaces are UTMI, UTMI+ and ULPI. UTMI+ is an extension of the UTMI specification with optional additional support for host controllers and on-the-go devices while UTMI only supports devices. There are different so called levels in the UTMI+ specification, each with an added degree of support for hosts and on-the-go. The lowest level and common denominator for all the levels is identical to UTMI and uses the exact same signals. The core only supports devices and thus the support for UTMI+ refers to level 0. The data path to the UTMI/UTMI+ cores can be 8-bits or 16-bits wide and also uni- or bi-directional. All combinations are supported by the core.

The UTMI+ Low Pin Interface (ULPI) specifies a generic reduced pin interface and how it can be used to wrap a UTMI+ interface. The core has UTMI/UTMI+ as the main interface (they are identical) and when ULPI is used an extra conversion layer is added. When ULPI is enabled, the UTMI layer is always in 8-bit mode since this is what is required by the ULPI specification.

79.2.3 Speed Negotiation Engine (SNE)

The SNE detects attach, handles reset, high-speed handshake and suspend/resume operation. It also contains support for the various test-modes, which all USB device have to support.

The attached state is entered when a valid VBUS signal is detected. After this the core waits for a USB reset and then starts the high-speed handshake which determines whether full-speed or high-speed mode should be entered. No bus traffic will be accepted by the core until a valid reset has been detected.

The core supports soft connect/disconnect which means that the pull-up on the D+ line can be controlled from a user accessible register. The pull-up is disabled after reset and thus the function implementation has full control over when the device will be visible to the host.

The SNE also continuously monitors for the suspend condition (3 ms of idle on the USB bus) when the suspend state will be entered. The suspend state is left either through an USB reset or resume signaling. The resume signaling can come from either a downstream facing port (hub or host controller) or the device itself (Remote wakeup). The device controller core can generate remote wakeup signaling which is activated through an user accessible register. If this feature is used the function should indicate this in the descriptor returned to a device GetStatus request.

Transactions are only handled by the SIE if the SNE is in full-speed or high-speed mode. When in suspend, notattached, attached or during the reset process all transactions will be dropped.

The current status of the SNE such as VBUS valid, suspend active, USB reset received and current speed mode can be accessed through a status register. Each of these status bits have a corresponding interrupt enable bit which can be used to generate interrupts when a change occurs in the status bits.

If full-speed only mode is desired the core can be set to not perform the high-speed handshake through a register.

The different test-modes required by the USB standard are also enabled through user accessible registers. When enabled they can only be left by power-cycling the complete core or resetting the device controller (by using the rst signal to the core, not an USB reset).

The test modes are Test_SE0_NAK, Test_J, Test_K and Test_Packet.

In Test_SE0_NAK mode the high-speed receiver is enabled and only valid IN transactions (CRC correct, device and endpoint addresses match, PID is not corrupt) are responded to with a NAK.

Test_J continuously drives a high-speed J state.

Test_K continuously drives a high-speed K state.

Test_Packet repetitively sends a test packet. Please refer to the USB 2.0 standard for the packet contents. Minimum interpacket delay when device is sending two or more consecutive packets seems not to be specified in the standard. The core uses 192 bit times as its minimum delay which is the maximum value of the various minimum delays in the standard for any packet sequence and should therefore be compliant.

The core also supports a functional test-mode where all timeouts in the speed-negotiation engine have been shortened to eight clock cycles. This intended to be used in simulations and for ASIC testers where time and test-vector length respectively are important.

79.2.4 Serial Interface Engine (SIE)

The SIE handles transmission and reception of USB packets. The core will not respond to any transactions until a reset has been received and either full-speed or high-speed mode has been successfully entered.

The SIE always begins with waiting for a token packet. Depending on the type of token, data is either transferred from the core to the host or in the opposite direction. Special tokens are handled without any data transfers. The special tokens are PING and SOF which cause only a handshake to be sent or the frame number to be stored respectively. IN tokens initiate transfers to the host while SETUP and OUT tokens initiate transfers to the device. Packets received in the token stage with other PIDs than those mentioned in this paragraph are discarded.

A data packet is transmitted in the next stage if the token determined that data should be transferred to the host. When the data transmission is finished the core waits for a handshake before returning to the token stage.

If data was determined to be transferred to the device the core waits for and receives a data packet and then sends a handshake in return before entering the token stage again.

More detailed descriptions of the SIE and how it interacts with the core function are found in section 79.5.

79.2.5 Endpoint buffers

Each endpoint has two buffers to which packets are stored. The core automatically alternates between them when a packet has been received/transmitted so that data from one of the buffers can be transferred on the AHB bus while a new packet is being received/transmitted on the USB to/from the second buffer.

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The state of the buffers affects the handshake sent to the host at the end of a transaction. In high-speed mode BULK OUT endpoints and CONTROL OUT endpoints which are not in the SETUP stage support the PING protocol. This means that at the end of an OUT transaction to one of these endpoints the device should return ACK if it could accept the current data and has space for another packet. For the USB device controller this is done if the second buffer for the endpoint is empty when the transaction is ready.

If the second buffer is non-empty a NYET is sent instead. If the current data could not be accepted (both buffers non-empty when the packet arrives) a NAK is returned.

For other endpoint types in high-speed mode and all endpoint types in full-speed mode an ACK is always returned if the data is accepted and a NAK if it could not be accepted.

An endpoint buffer can be configured to be larger than the maximum payload for that endpoint. For IN endpoints the writing of data larger than the maximum payload size to a buffer will result in a number of maximum sized packets being transferred ending with a packet smaller than or equal to the maximum size.

In the OUT direction larger buffers are only used for high-bandwidth endpoints where more than one transaction per microframe can occur for that endpoint. In that case the data from all packets during one microframe is stored in the order it arrives to a single buffer and is then handed over to the AHB interface. All non-high-bandwidth endpoints always store one packet data cargo to a buffer.

The endpoint buffers do not use separate physical RAM blocks in hardware instead they reside consecutively in the same memory space to avoid wasting memory.

79.2.6 AMBA Interface Engine (AIE)

The AIE can either be configured in slave mode or master mode. This is selected in synthesis process with a VHDL generic. Both cannot be present at the same time. The two interfaces will be described separately in this section.

Master interface

In master mode an AHB master interface is included in the core and handles all data transfers to and from the cores internal buffers using DMA operations. The DMA operation is described in detail in section 79.3. There is a separate DMA engine in the IN direction and the OUT direction respectively. They are multiplexed on the single master interface available for the core on the AHB bus. This scheme is used to limit the load on the AHB bus.

If both engines request the bus at the same time the owner will always be switched. That is, if the OUT direction DMA engine currently was allowed to make an access and when finished it still requests the bus for a new transaction and at the same time the IN direction engine also requests the bus, the IN direction will be granted access. If the situation is the same after the next access ownership will be switched back to the OUT engine etc.

The IN engine only reads data (note that this only applies to DATA, descriptor status is written) from the bus and always performs word transfers. Any byte alignment and length can still be used since this will only cause the core to skip the appropriate amount of leading and trailing bytes from the first and last words read.

The OUT engine writes data to the bus and performs both word and byte transfers. If the start transfer for an access is not word-aligned byte writes will be performed until a word boundary is reached. From then and onwards word writes are performed in burst mode until less than 4 bytes are left. If remaining number of bytes is not zero byte writes are performed for the last accesses. The byte accesses are always done as single accesses.

The bursts are of type incremental burst of unspecified length (refer to AMBA specification for more details). The core can only operate in big-endian mode that is the byte at the lowest address in a word is the most significant byte. This corresponds to bits 31 downto 24 in the GRLIB implementation. The

first byte received on the USB will be stored to the msb location. In a single byte the lowest bit index corresponds to the first bit transmitted on the USB.

Slave interface

The slave interface is used for accessing registers and also for data transfers when the core is configured in slave mode. Byte, half-word and word accesses are supported. At least one waitstate is always inserted due to the pipelined nature of the interface but the upper limit is not fixed due to registers being accessed across clock domains. The maximum number of waitstates will thus depend on the difference in clock frequency between the USB and AHB clock domains. An upper bound can be calculated when the clock frequencies have been determined.

79.2.7 Synchronization

There are two clock domains in the core: the AHB clock domain and the USB clock domain. The AHB clock domain runs on the same clock as the AHB bus while the USB domain runs on the UTMI or ULPI clock. The boundary is between then AIE, SIE and Endpoint buffers. All signals between the two domains are synchronized and should be declared as false paths during synthesis.

79.2.8 Reset generation

The main reset (AMBA reset) resets AHB domain registers, whereas the USB reset resets registers in USB clock domain. There is no internal reset generation or synchronization between both AMBA and USB resets, they are independent inputs. If necessary, the reset generation shall be done in a higher instance, externally to this IP.

Endpoint specific registers related to the state of the USB protocol in the SIE are reset when an USB reset is received.

79.2.9 Synthesis

All number of endpoints with up to maximum size payloads cannot be supported due to limitations in the RAM block generator size in GRLIB. The maximum size also varies with technology. Note that large buffers can also have a large timing impact at least on FPGA since the a large RAM buffer will consist of several separate physical block RAMs located at different places causing large routing delays.

As mentioned in section 79.2.7, signals between the clock domains are synchronized and should be declared as false paths.

The complete AHB domain runs at the same frequency as the AHB bus and will be completely constrained by the bus frequency requirement.

The USB domain runs on different frequencies depending on the data path width. In 8-bit mode the frequency is 60 MHz and in 16-bit mode it is 30 MHz. Input and output constraints also need to be applied to the signals to and from the PHY. Please refer to the PHY documentation and/or UTMI/ULPI specification for the exact values of the I/O constraints.

79.2.10 Functional test-mode

A functional test-mode can be enabled in the core using the functesten VHDL generic. The functional test-mode is intended to reduce the number of required test-vectors during functional testing of an ASIC chip. During normal operation it would be required to go through the whole speed detection sequence before being able to start USB transactions. Since the speed detection takes a relatively long time this would make the test-vector amount very large often making it incompatible with existing test equipment.

In functional test-mode the core shortens the speed detection thus making it possible to test the functionality without a long initial delay. The test-mode can be disabled using the FT control register bit.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

79.2.11 Scan test support

The VHDL generic *scantest* enables scan test support. If the core has been implemented with scan test support it will:

- disable the internal RAM blocks when the testen and scanen signals are asserted.

- use the testoen signal as output enable signal.

- use the testrst signal as the reset signal for those registers that are asynchronously reseted.

The testen, scanen, testrst, and testoen signals are routed via the AHB slave interface.

79.3   DMA operation

DMA operation is used when the core is configured in AHB master mode. Each IN and each OUT endpoint has a dedicated DMA channel which transfers data to and from the endpoint's internal buffers using descriptor based autonomous DMA. Each direction (IN and OUT) has its own DMA engine which requests the AHB master interface in contention with the other direction. Also each endpoint in a direction contends for the usage of the DMA engine with the other endpoints in the same direction. The arbitration is done in a round-robin fashion for all endpoints which are enabled and have data to send or receive.

The operation is nearly identical in both directions and the common properties will be explained here while the differences are outlined in the two following sub-sections.

The DMA operation is based on a linked list of descriptors located in memory. Each endpoint has its own linked list. The first word in a descriptor is the control word which contains an enable bit that determines whether the descriptor is active or not and other control bits. The following word is a pointer to a memory buffer where data should be written to or read from for this descriptor. The last word is a pointer to the location of the next descriptor. A bit in the control word determines if the next descriptor pointer is valid or not. If not valid the descriptor fetching stops after the current descriptor is processed and the DMA channel is disabled.

The DMA operation is started by first setting up a list with descriptors in memory and then writing a pointer to the first descriptor to the endpoint's descriptor pointer register in the core and setting the descriptor available bit. The pointer register is updated as the list is traversed and can be read through the AHB slave interface. When the list is ended with a descriptor that has its next descriptor available bit disabled the list must not be touched until the core has finished processing the list and the channel is disabled. Otherwise a deadlock situation might occur and behavior is undefined.

Another way to use the linked list is to always set the next descriptor available bit and instead make sure that the last descriptor is disabled. This way new descriptors can be added and enabled on the fly to the end of the list as long as the descriptor available bit is always set after the new descriptors have

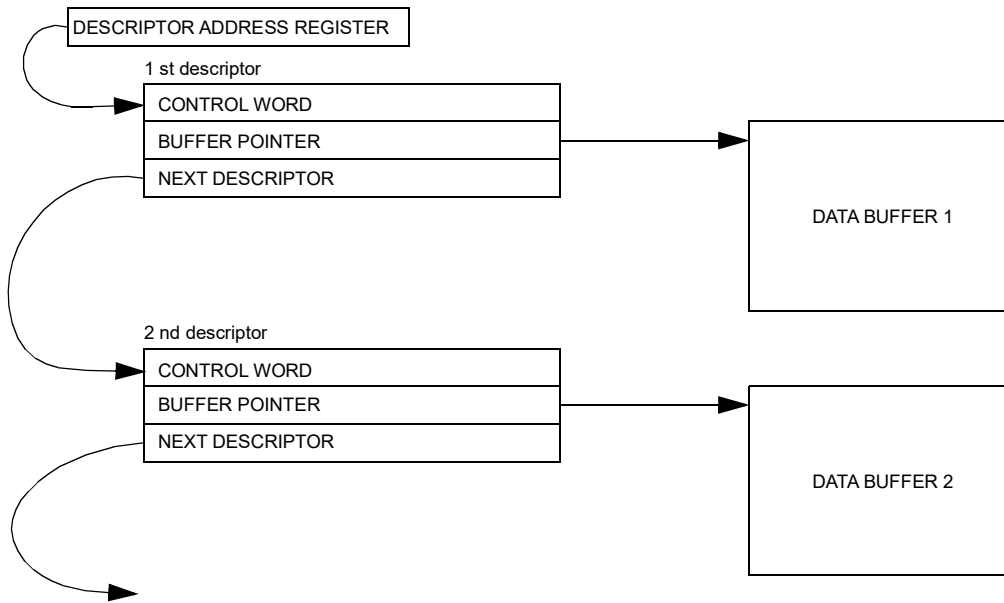
been written to memory. This ensures that no dead lock will occur and that no descriptors are missed. Figure 219 shows the structure of the descriptor linked list.


Figure 219. Example of the structure of a DMA descriptor linked list in memory.

79.3.1 OUT endpoints

The DMA operation for OUT endpoints conforms to the general description in the previous subsection. There are small differences in individual bits and the meaning of the length field. The contents of the different descriptor words can be found in the tables below.

When a descriptor has been enabled it will be fetched by the core when the descriptor available bit is set and as soon as a buffer for the corresponding endpoint contains data received from the USB it will be written to memory starting from the address specified in the buffer pointer word of the descriptor. The contents of a single internal memory buffer is always written to a single descriptor buffer. This always corresponds to a single USB packet except for high-bandwidth isochronous and interrupt endpoints. The number of bytes written is stored in the length field when writing is finished which is indicated by the enable bit being cleared. Then the SETUP status bit will also be valid. When the enable bit is cleared the memory location can be used again.

Interrupts are generated if requested as soon as the writing to memory is finished. The endpoint can also be configured to generate an interrupt immediately when a packet has been received to the internal buffers. This can not be enabled per packet since the core cannot associate a received packet with a specific descriptor in advance. This interrupt is enabled from the endpoint's control register.

When the data has been fetched from the internal buffer it is cleared and can be used by the SIE again for receiving a new packet.

79.3.2 IN endpoints

The DMA operation for IN endpoints conforms to the general DMA description. There are small differences in individual bits and the meaning of the length field. The contents of the different descriptor words can be found in the tables below.

When a descriptor has been enabled and the descriptor available bit is set the core will start processing the descriptor and fetch the number of bytes indicated in the length field to an internal buffer belonging to the endpoint as soon as one is available. An interrupt will be generated if requested when data has been written to the internal buffer and status has been written back to the descriptor. The packet might not have been transmitted on the USB yet.

A separate interrupt is available which is generated when the packet has actually been transmitted. It needs to be enabled from the endpoint's control register and also in the descriptor (using the PI bit) for each packet that should generate the interrupt.

A descriptor with length zero will result in a packet with length zero being transmitted while a length larger than the maximum payload for the endpoint will result in two or more packets with all but the last being of maximum payload in length. The last transaction can be less than or equal to the maximum payload. If the length field is larger than the internal buffer size the data will not written to the internal buffer and status will be immediately written to the descriptor with an error bit set.

When the more bit is set the data from the current descriptor is written to the internal buffer and it then continues to the next descriptor without enabling the buffer for transmission. The next descriptor's data is also read to the same buffer and this continues until a descriptor is encountered which does not have more set.

If the total byte count becomes larger than the internal buffer size the packet is not sent (the data from the internal buffer is dropped) and the ML bit is set for the last descriptor. Then the descriptor fetching starts over again.

79.4 Slave data transfer interface operation

The AHB slave interface is used for data transfers instead of the DMA interface when the core is configured in AHB slave mode. This mode is selected by setting the aiface VHDL generic to 0. In this mode the core's internal buffers containing data to/from USB packets are accessed directly using AHB read and write transfers. This is usually much slower than DMA but much simpler and does not require any external memory, thus suitable for slow devices which need to be small and simple.

As for the DMA mode each endpoint is operated separately using four registers at the same addresses. Two of them, the control and status registers, are the same while the DMA control and the descriptor address registers have been replaced with the slave control and slave write/read data registers. The slave interface does not use descriptors so these four registers provides the complete control of the endpoint.

The details for data transfers in the two different endpoint directions will be explained in separate sections.

79.4.1 OUT slave endpoint

As stated earlier, in slave mode the core's buffers are accessed directly from the AHB bus through the slave interface. For OUT endpoints it has to be checked that data is available in the selected buffer and then reserve it. This is done using the slave control register by writing a one to the CB bit. The CB bit is always automatically cleared when the write access is finished and then the BS, DA and BUFCNT

GRIP
Apr 2024, Version 2024.1

1342

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

read-only bits/fields contain valid information. The BS bit is set to 0 if buffer 0 is currently selected and to 1 if buffer 1 is selected. DA is set to 1 if data is available in the buffer and in that case BUFCNT contains the number of bytes.

If data is available (DA is 1) it can be read from the slave data read register. One byte at a time is read using byte accesses, two bytes using half-word accesses and four bytes using word accesses. No other widths are supported. In each case data is available from bit 31 and downwards regardless of the value of the two least significant address bits. This is summarized in table 1633. The BUFCNT field is continuously updated when reading the buffer so that it can be monitored how many bytes are left.

Table 1633. AHB slave interface data transfer sizes

Size (byte)	AHB transfer size (HSIZE)	Data alignment (HRDATA)
1	byte (000)	31:24
2	half-word (001)	31:16
4	word (010)	31:0

When all the data has been read, a new buffer can be acquired by writing a one to CB. In this case when a buffer is currently reserved and the DA bit is set it will be released when CB is written. If a new buffer was available it will be reserved and DA is set to 1 again. If no new buffer is available DA will be 0 and the process has to be repeated. The current buffer (if one is selected) will be released regardless of whether a new one is available or not. Also, if all data has not been read yet when a buffer change request is issued the rest of the data will be lost.

The core does not have to be polled to determine whether a packet is available. A packet received interrupt is available which can be enabled from the control register and when set an interrupt will be generated each time a packet is stored to the internal buffers. The status of the buffers can also be read through the endpoint's status register without actually reserving the buffer.

One buffer consists of the data payload from one single packet except for high-bandwidth interrupt and isochronous endpoints for which up to three packet data payloads can reside in a single buffer.

A buffer does not have to be read consecutively. Buffers for several endpoints can be acquired simultaneously and read interleaved with each other.

79.4.2 IN slave endpoint

The slave operation of IN endpoints is mostly identical to that for OUT. For IN endpoints it has to be checked that a buffer is free and then reserve it before writing data to it. This is done using the slave control register by writing a one to the EB bit. The EB bit is always automatically cleared when the write access is finished and then the BS, BA and BUFCNT fields are updated. The BS bit is set to 0 if buffer 0 is currently selected and to 1 if buffer 1 is selected. BA is set to 1 if a buffer is available to write data to. BUFCNT contains the number of bytes currently written to the selected buffer. It is cleared to zero when a new buffer is acquired.

If a buffer is available (BA is 1) data can be written through the slave data write register. One byte at a time is written using byte accesses, two bytes using half-word accesses and four bytes using word accesses. No other widths are supported. In each case data should be placed from bit 31 and downwards regardless of the value of the two least significant address bits. This is summarized in table 1634.

Table 1634. AHB slave interface data transfer sizes

Size (byte)	AHB transfer size (HSIZE)	Data alignment (HWDATA)
1	byte (000)	31:24
2	half-word (001)	31:16
4	word (010)	31:0

GRIP
Apr 2024, Version 2024.1
1343
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

When all the data has been written, the buffer is enabled for transmission by writing a one to EB. If a new buffer was available it will be reserved and BA is set to 1 again. If no new buffer is available BA will be 0 and the process has to be repeated. The current buffer (if one is reserved) will be enabled for transmission regardless of whether a new one is available or not.

The core does not have to be polled to determine whether a buffer is available. A packet transmitted interrupt is available which can be enabled from the endpoint control register. Then when enabling a packet for transmission the PI bit in the slave control register can be set which will be cause an interrupt to be generated when this packet has been transmitted and cleared from the internal buffers. The status of the buffers can also be read through the endpoint's status register without actually reserving the buffer.

Maximum payload size packets will be generated from the buffer until the last packet which will contain the remaining bytes.

A buffer does not have to be written consecutively. Buffers for several endpoints can be acquired simultaneously and written interleaved with each other. This will however cause additional waitstates to be inserted.

79.5   Endpoints

An endpoint needs to have both its AHB and USB function configured before usage. The AHB configuration comprises the DMA operation described in the previous section. The USB configuration comprises enabling the endpoint for USB transactions, setting up transfer type (control, bulk, isochronous, interrupt), payload size, high-bandwidth among others. The configuration options are accessed through a register available from the AHB slave interface. See section 79.8 for the complete set of options.

When setting the configuration options the endpoint valid bit should be set. This will enable transfers to this endpoint as soon as a USB reset has been received. If the endpoint is reconfigured the valid bit must first be set to zero before enabling it again. Otherwise the endpoint will not be correctly initialized. When the endpoint is enabled the toggle scheme will be reset and data buffers cleared and buffer selectors set to buffer zero. The maximum payload, number of additional transactions and transfer type fields may only be changed when endpoint valid is zero or when setting endpoint valid to one again after being disabled. Other bits in the endpoint control register can be changed at any time.

No configuration options should be changed when the endpoint is enabled except the halt, control halt and disable bits.

An endpoint can also be halted by setting the halt bit of the endpoint. This will cause all transactions to receive a STALL handshake. When clearing the halt condition the toggle scheme will also be reset as required by the USB standard.

When the endpoint is setup, data transfers from and to the endpoint can take place. There is no difference in how data is transferred on the AHB bus depending on the selected transfer type. This only affects the transfers on the USB. For control endpoints some extra handling is required by the core user during error conditions which will be explained in the control endpoint section.

Packets that are received to an endpoint (independent of endpoint type) with a larger payload than the configured maximum value for the endpoint will receive a STALL handshake and cause the endpoint to enter halt mode.

When a USB reset is detected the CS, ED and EH bits of the endpoint control register will be cleared for all endpoints. The EV bit will also be cleared except for control endpoint 0.

The CB bit in the endpoint control register is for clearing the internal buffers of an endpoint. When set the data will be discarded from the buffers, the data available bits for the corresponding buffers will be cleared and the CB bit is cleared when it is done. This will however not work if a transaction is currently active to the same endpoint so this feature must be used with caution.

GRIP

Apr 2024, Version 2024.1

79.5.1 Control endpoints

Endpoint 0 must always be a control endpoint according to the USB standard and be accessible as soon as a USB reset is received. The core does not accept any transactions until a USB reset has been received so this endpoint can be enabled directly after power up. More control endpoints can be enabled as needed with the same constraints as the default control endpoint except that they should not be accessible until after configuration. If the function controlling the core is slow during startup it might not be able complete configuration of endpoint 0 before a USB reset is received. This problem is avoided in the core because its pull-up on D+ is disabled after reset which gives the function full control of when the device will be visible on the bus.

A control endpoint is a message pipe and therefore transfers data both in the IN and OUT direction. Thus control endpoints must use the endpoint in both directions with the same number in the device controller. This requires both to be configured in the same mode (same transfer type, payload ...). Otherwise device behavior is undefined.

A control transfer is always started with a SETUP transaction which will be received to the OUT endpoint. If the control transfer is a write the subsequent data phase will be in the OUT direction and this data will also be received to the OUT endpoint. The function should read both the setup data and the other data cargo and respond correspondingly. If the request was valid the function should enable a zero length packet for the endpoint in the IN direction which will lead to a valid status stage. If an error is detected it should instead halt the endpoint. There are two alternatives for this: A non-clearing halt which will last even after the next SETUP transaction or a clearing halt which will be removed when the next SETUP is received. The latter is the recommended behavior in the USB standard since the other will require the complete core to be reset to continue operation if the permanent halt appears on the default control endpoint.

The core can detect errors in single transactions which cause the endpoint to enter halt mode automatically. In this case the clearing halt feature will be used for control endpoints.

If a SETUP transaction indicates a control read the data phase will be in the IN direction. In that case the core user should enable data for the endpoint in the IN direction if the request was accepted otherwise the halt feature should be set. The transfer is finished when the host sends a zero length packet to the OUT endpoint.

Note that when entering halt for a control endpoint both the IN and OUT endpoints halt bits should be set.

Each time a control endpoint receives a setup token the buffers in the IN direction are emptied. This is done to prevent inconsistencies if the data and status stage were missing or corrupted and thus the data never fetched. The old data would still be in the buffer and the next setup transaction would receive erroneous data. The USB standard states that this can happen during error conditions and a new SETUP is transmitted before the previous transfer finished. The core user can also clear the buffer through the IN endpoint control register and is encouraged to do this when it detects a new SETUP before finishing the previous transfer. This must be done since the user might have enabled buffers after the core cleared them when receiving the new SETUP.

Whether data received to a descriptor for an OUT endpoint was from a SETUP transaction or an OUT transaction is indicated in a descriptor status bit.

79.5.2 Bulk endpoints

Bulk endpoints are stream pipes and therefore only use a single endpoint in either the IN or OUT direction. The endpoint with the same number in the other direction can be used independently. Data is accessed normally through the AHB interface and no special consideration need to be taken apart from the general endpoint guidelines.

79.5.3 Interrupt endpoints

Interrupt data is handled in the same manner as for bulk endpoints on the AHB interface. The differences only appear on the USB. These endpoints are also of stream type.

Interrupt endpoints support a high-bandwidth state which means that more than one transaction per microframe is performed. This necessitates buffers larger than the maximum payload size. The endpoint should be configured with a buffer larger or equal to the maximum payload times the number of transactions. All transactions will be received to/transmitted from the same buffer. The endpoint is configured as a high-bandwidth endpoint by setting the number of additional transactions to non-zero in the endpoint control register.

79.5.4 Isochronous endpoints

Isochronous endpoints are of stream type are identical to other endpoints regarding the handling on the AHB bus.

A big difference between isochronous endpoints and the other types is that they do not use handshakes. If no data is available when an IN token arrives to an Isochronous endpoint a data packet with length 0 is transmitted. This will indicate to the host that no error occurred but data was not ready. If no packet is sent the host will not know whether the packet was corrupted or not.

When not in high-bandwidth mode only one transaction in the OUT direction will be stored to a single buffer. In high-bandwidth mode all transactions during a microframe are stored to the same buffer.

In the IN direction data is always transferred from the same buffer until it is out of data. For high-bandwidth endpoints the buffer should be configured to be the maximum payload times the number of transactions in size.

Isochronous high-bandwidth endpoints use PID sequencing. When an error is detected in the PID sequence in the OUT direction no data is handed over to AHB domain for the complete microframe.

79.6 Device implementation example in master mode

This section will shortly describe how the USB device controller can be used in master mode.

A function controlling the device controller and implementing the actual application specific device will be needed. It can be either hardware, software or a combination. The only requirement is that it can control the device controller through the AHB bus.

The first thing needed for successful operation is a correctly configured PHY. This is automatically done by the device controller.

After this the device controller waits for attachment to the USB bus indicated by the VBUS becoming valid. This can be notified to the function either by polling or an interrupt. The time of attachment can be controlled by the function through the pull-up enable/disable bit in the core control register. When disabled the USB host will not notice the device even when it is plugged in.

After attachment a USB reset needs to be received before transactions are allowed to be accepted. This can also notified by polling or an interrupt.

Only control endpoint 0 should be accessible after reset. The function is responsible for enabling and configuring at the right time. It can wait until a USB reset has been received but it is easier to enable it immediately after power-up. This can be done since the device controller will not accept any transactions until USB reset has been received. When enabling the endpoint descriptors should also be enabled for both the IN and OUT direction and also the descriptor available bits should be set.

Then the endpoint is ready to accept packets and the function should wait for SETUP packets arriving. It can be notified of packets arriving either through polling or interrupts. The core should process the requests and return descriptors as requested. When a Set address request is received the function should write the new address to the device controller's global control register. It will take effect after

+46 31 7758650 | frontgrade.com/gaisler

the next successful IN transaction for the control endpoint. This should correspond to the status stage of the Set address transfer.

When a Set configuration request is received the function should enable the appropriate interface and endpoints according to the selected configuration. This is done by writing to the various endpoint control registers. The function is responsible for advertising the configurations and interfaces through the descriptors requested by SETUP transactions.

When the endpoints for the selected configuration are enabled the function should also setup the DMA operation. Then it is ready to transmit and receive data through the application specific endpoints. Interrupts can be used to notify that new packets have transferred and then polling will determine which endpoint had a status change.

79.7   Device implementation example in slave mode

This section will shortly describe how the USB device controller can be used in slave mode.

A function controlling the device controller and implementing the actual application specific device will be needed. It can be either hardware, software or a combination. The only requirement is that it can control the device controller through the AHB bus.

The first thing needed for successful operation is a correctly configured PHY. This is automatically done by the device controller.

After this the device controller waits for attachment to the USB bus indicated by the VBUS becoming valid. This can be notified to the function either by polling or an interrupt. The time of attachment can be controlled by the function through the pull-up enable/disable bit in the core control register. When disabled the USB host will not notice the device even when it is plugged in.

After attachment an USB reset needs to be received before transactions are allowed to be accepted. This can also notified by polling or an interrupt.

Only control endpoint 0 should be accessible after reset. The function is responsible for enabling and configuring at the right time. It can wait until a USB reset has been received but it is easier to enable it immediately after power-up. This can be done since the device controller will not accept any transactions until USB reset has been received. When enabling the endpoint packet interrupts should be enabled or the function should start polling the buffer status so that it will notice when packets arrive.

Then the endpoint is ready to accept packets and the function should wait for SETUP packets arriving. When a packet arrives the core should process the requests and return USB descriptors as requested. When a Set address request is received the function should write the new address to the device controller's global control register. It will take effect immediately. It should not be written until the status stage has been finished for the Set address request. It can be determined that the request has finished if a packet transmitted interrupt is enabled for the handshake packet of the request and an interrupt is received.

When a Set configuration request is received the function should enable the appropriate interface and endpoints according to the selected configuration. This is done by writing to the various endpoint control registers. The function is responsible for advertising the configurations and interfaces through the descriptors requested by SETUP transactions.

When the endpoints for the selected configuration are enabled the function should also enable interrupts or start polling these endpoints. Then it is ready to transmit and receive data through the application specific endpoints. Interrupts can be used to notify that new packets have been transferred and then status reads will determine which endpoint had a status change.

79.8.1 OUT Endpoint Control Register

*Table 1636.*0x00,... - EOCTRL - OUT endpoint control register

31 BUFSZ 21	20 PI	19 CB	18 CS	17 MAXPL 7	6 5 NT	4 3 TT	2 EH	1 ED	0 EV
*	0	0	0	NR	NR	NR	0	0	0
r	rw	rw	rw	rw	rw	rw	rw	rw	rw

31: 21	Buffer size (BUFSZ) - Size/8 in bytes of one hardware buffer slot for this endpoint. Two slots are available for each endpoint.
20	Packet received interrupt (PI) - Generate an interrupt for each packet that is received on the USB for this endpoint (packet has been stored in the internal buffers). Reset value: '0'.
19	Clear buffers (CB) - Clears any buffers for the endpoint that contain data if the buffer is not currently active.
18	Control Stall (CS) - Return stall for data and status stages in a control transfer. Automatically cleared when the next setup token is received. Only used when the endpoint is configured as a control endpoint.
17: 7	Maximum payload (MAXPL) - Sets the maximum USB payload (maximum size of a single packet sent to/from the endpoint) size for the endpoint. All bits of the field are not always used. The maximum value for the maximum payload is determined with a generic for each endpoint. Not Reset.
6: 5	Number of transactions (NT) - Sets the number of additional transactions per microframe for high-speed endpoints and per frame for full-speed endpoints. Only valid for isochronous endpoints. Not Reset.
4: 3	Transfer type (TT) - Sets the transfer type for the endpoint. "00"=CTRL, "01" =ISOCH, "10"=BULK, "11"=INTERRUPT. Only OUT endpoints should be set to the CTRL type and then the IN endpoint with the same number will be automatically used. It is important not to use OUT endpoints that do not have a corresponding IN endpoint as a CTRL endpoint. Not Reset.
2	Endpoint halted (EH) - Halt the endpoint. If set, all transfers to this endpoint will receive a STALL handshake. Reset value: '0'.
1	Endpoint disabled (ED) - Disables the endpoint. If set, all transfers to this endpoint will receive a NAK handshake. Reset value: '0'.
0	Endpoint valid (EV) - Enables the endpoint. If not enabled, all transfers to this endpoint will be ignored and no handshake is sent. Reset value; '0'.

79.8.2 OUT Slave Control Register

*Table 1637.*0x04,... - EOSLUCTRL - OUT slave control register.

31 RESERVED 17	16 SE	15 BUFCNT 3	2 DA	1 BS	0 CB
0	0	0	0	0	0
r	r	r	r	r	rw

31: 17	RESERVED
16	Setup packet (SE) - The data was received from a SETUP packet instead of an OUT.
15: 3	Buffer counter (BUFCNT) - The number bytes available(OUT)
2	Data available (DA) - Set to one if a valid packet was acquired when requested using the CB. If no valid packet was available it is set to zero. Reset value: '0'.
1	Buffer select (BS) - Current buffer selected. Read only.
0	Change or acquire buffer (CB) - If no buffer is currently active try to acquire a new one. If one is already acquired, free it and try to acquire a new one.

16	USB reset (UR) - Set each time an USB reset has been detected. Cleared when written with a '1'.
15	Vbus valid (VB) - Set to one when a valid voltage has been detected on the USB vbus line.
14	Speed (SP) - The current speed mode of the USB bus. '0' = high-speed, '1' = full-speed.
13: 11	Additional frames (AF) - Number of additional frames received with the current frame number.
10: 0	Frame number (FN) - The value of the last SOF token received.

79.9 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x021. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

79.10 Implementation

79.10.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. A subset of the registers in the USB clock domain make use of asynchronous reset.

The IP core has two different reset inputs: the AMBA reset and the USB reset. They work independently on their respective clock domains. If reset generation/synchronization is desired, it shall be done in a higher instance, out of the IP.

See also documentation of *prst* VHDL generic.

79.10.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

79.11 Configuration options

Table 1650 shows the configuration options of the core (VHDL generics). Buffer sizes are given in bytes and determines the sizes of one hardware buffer for the endpoint. Two buffers are available for each endpoint. The buffer size must be equal to or larger than the desired maximum payload size. In the case of high-bandwidth endpoints the buffer size must be equal to or larger than the maximum payload times the number of transactions per (micro) frame.

*Table 1650.*Configuration options

Generic	Function	Allowed range	Default
hsindex	AHB slave index.	0 - NAHBSLV-1	0
hirq	AHB interrupt number	0 - NAHBIRQ-1	0

o14	Buffer size for OUT endpoint 14.	8, 16, 24, ... , 3072	1024
o15	Buffer size for OUT endpoint 15.	8, 16, 24, ... , 3072	1024
oepol	Select polarity of output enable signal. 1 selects active high and 0 selects active low.	0 - 1	0
keepclk	This generic determines wheter or not the USB transceiver will be suspended and have its clock turned off during USB suspend. Set this generic to 1 if the clock should not be turned off. This might be needed for some technologies that can't handle that the USB clock is turned off for long periods of time.	0 - 1	0
sepirq*	Set this generic to 1 if three seperate interrupt lines should be used, one for status related interrupts, one for IN endpoint related interrupts, and one for OUT endpoint related interrupts. The irq number for the three different interrupts are set with the hirq (status), irqi (IN), and irqo (OUT) generics. If sepirq = 0 then only interrupts with irq number hirq will be generated.	0 - 1	0
irqi*	Sets the irq number for IN endpoint related interrupts. Only used if sepirq generic is set to 1.	0 - NAHBIRQ-1	1
irqo*	Sets the irq number for OUT endpoint related interrupts. Only used if sepirq generic is set to 1.	0 - NAHBIRQ-1	2
functesten	Enable functional test mode. This is used to skip the USB high-speed detection sequence to reduce the number of test vectors during functional testing.	0 - 1	0
scantest	Set this generic to 1 if scan test support should be implemented.	0 - 1	0
nsync	Number of stages for the internal clock-domain-crossing synchronization registers.	1 - 2	1

* The values of these generics are stored in the first User-Defined word of the core's AHB plug-n-play area as follows: bit 0 = sepirq, bits 7:4 = irqi, bits 11:8 = irqo. Please see the AHBCTRL section of GRLIB IP Core User's Manual.

80 GRUSB_DCL - USB Debug Communication Link

80.1 Overview

The Universal Serial Bus Debug Communication Link (GRUSB_DCL) provides an interface between a USB 2.0 bus and an AMBA-AHB bus. The core must be connected to the USB through an UTMI, UTMI+, or ULPI compliant PHY. Both full-speed and high-speed mode are supported. The GRUS-B_DCL rely on the GRUSBDC core for handling the USB communication and communication with the PHY. The GRUSB_DCL implements the minimum required set of USB requests to be Version 2.0 compliant and a simple protocol for performing read and write accesses on the AHB bus. Figure 220 show how the GRUSB_DCL can be connected to a PHY. For more information on the GRUSBDC and the connection to the USB PHY please refer to the GRLIB IP Core User's Manual.
Figure 220. USBDCL connected to an external UTM.

80.2 Operation

80.2.1 System overview

The internal structure of the GRUSB_DCL can be seen in figure 221. The GRUSB_DCL is constructed with two internal AHB busses for communication with the GRUSBDC and one external AHB master interface for reading and writing the external AHB bus. Since the GRUSBDC is connected with point-to-point links there is no need for a conventional AHB arbiter on the internal bus.

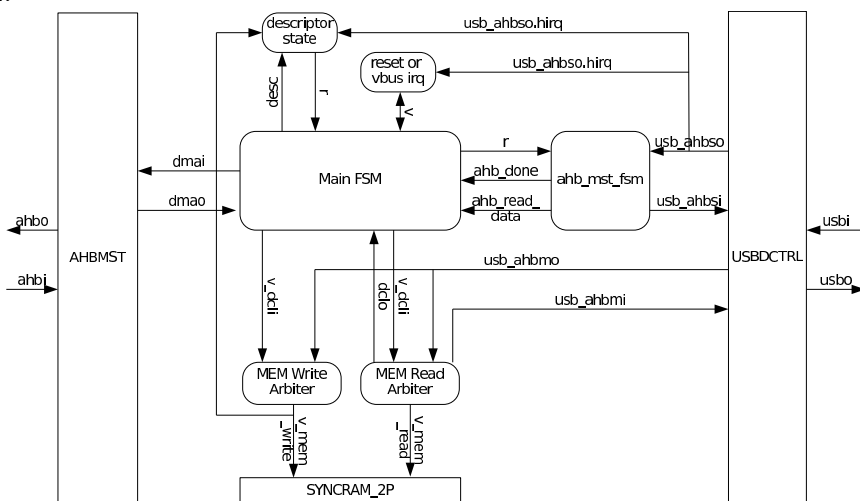
The GRUSBDC is configured with two bidirectional endpoints with endpoint zero (EP0) being the default USB control endpoint and endpoint one (EP1) the communication endpoint for the DCL protocol. The GRUSBDC is configured to use DMA and its descriptors as well as the DMA buffers are stored in a local memory with separate read and write ports (SYNCRAM_2P). The two ports makes it possible for the GRUSBDC and the internal workings of the GRUSB_DCL to access the memory in parallel. Arbitration for the read and write port is implemented as two separate procedures. The main functionality of the GRUSB_DCL is implemented in the main FSM procedure. The FSM can be seen in figure 222.


Figure 221. Block diagram of the internal structure of the GRUSBDCL. Blocks with rounded corners are implemented as VHDL procdures while squares represent VHDL entities.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

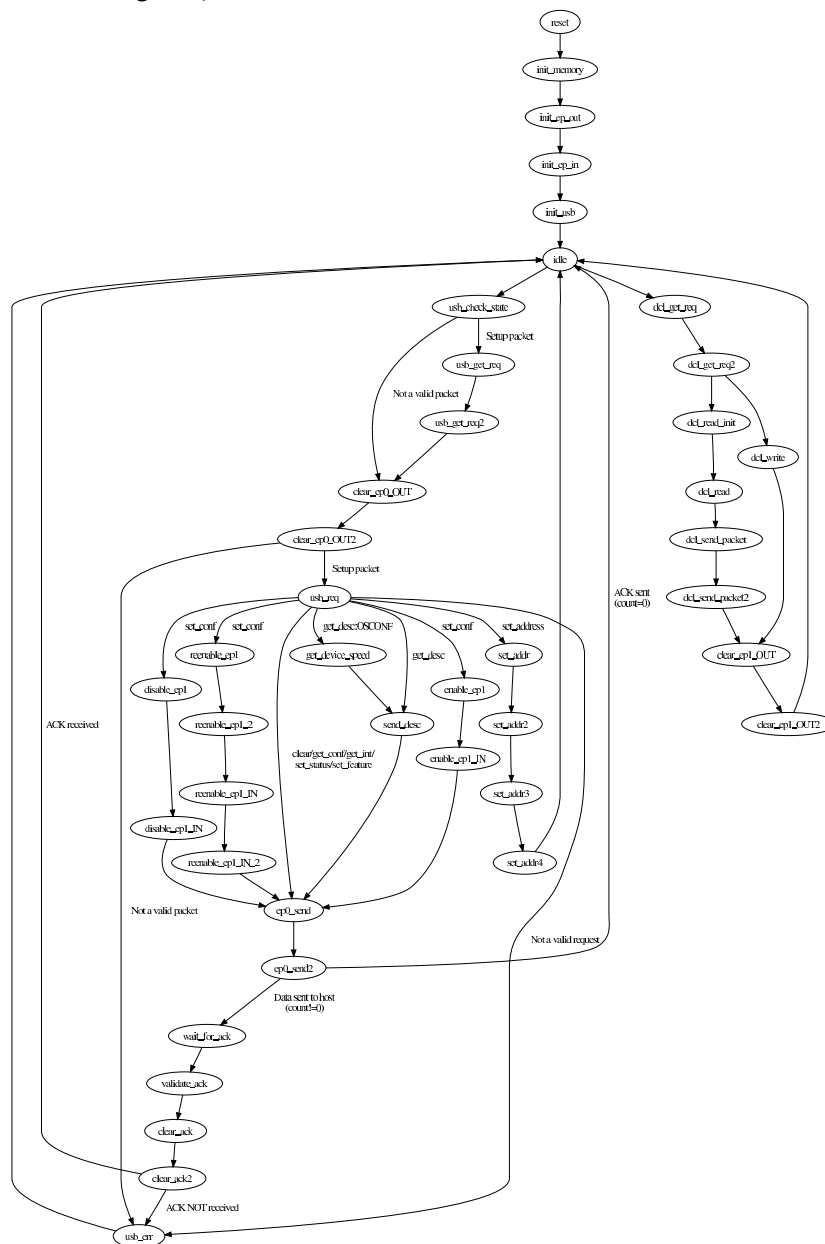
Upon reset the FSM begins with setting up the DMA descriptors in the local memory and then configures the GRUSBDC such that it becomes active. The FSM then waits for incoming requests on either EP0 or EP1. For EP0 each request is validated and then appropriate action is taken according to the USB Version 2.0 standard. For undefined requests the GRUSB_DCL returns an error by stalling EP0. For EP1 the DCL request is fetched and either data is written to the AHB buss from the local memory or data is read from the AHB and stored in the local memory. In the case of the AHB is being read the data is then sent on EP1 IN. To keep track of the state of the DMA descriptors the FSM has help from the descriptor-state procedure. The descriptor-state procedure uses the IRQ from the GRUSBDC to identify incoming packets on either EP0 or EP1. By storing the last accessed address by the GRUSBDC to the local memory the descriptor-state procedure can tell which EP that has been updated. The FSM in turn signals the procedure telling it when a DMA descriptor/buffer has been read/write. A small FSM (ahb_mst_fsm) is also used when the main FSM wants to update the state of the GRUSBDC through the AHB slave interface. Finally, the reset-or-vbus-irq procedure listens on irqs from the USBDC that informs the core that a USB reset or that a change on the VBUS has occured. In that case the core stops what ever it was doing and moves into the USB default state (no addresse set and not configured).


Figure 222. The main FSM of the GRUSBDCL. The FSM can be divided into three major parts i) the initialization (reset to idle), ii) handling of USB requests (seen to the left of idle), and iii) handling of DCL requests (seen to the right of idle).

+46 31 7758650 | frontgrade.com/gaisler

80.2.2 Protocol

The protocol used for the AHB commands is very simple and consists of two 32-bit control words. The first word consists of the 32-bit AHB address and the second consists of a read/write bit at bit 31 and the number of words to be written at bits 16 downto 2. All other bits in the second word are reserved for future use and must be set to 0. The read/write bit must be set to 1 for writes.

Figure 223 shows the layout of a write command. The command should be sent as the data cargo of an OUT transaction to endpoint 1. The data for a command must be included in the same packet. The maximum payload is 512 B when running in high-speed mode and 64 B in full-speed mode. Since the control information takes 8 B the maximum number of bytes per command is 504 B and 56 B respectively. Subword writes are not supported so the number of bytes must be a multiple of four between 0 and 504.

The words should be sent with the one to be written at the start address first. Individual bytes should be transmitted msb first, i.e. the one at bits 31-24.

There is no reply sent for writes since the USB handshake mechanism for bulk writes guarantees that the packet has been correctly received by the target.
Figure 223. Layout of USBDCL write commands.

Figure 224 shows the layout of read commands and replies. In this case the command only consists of two words containing the same control information as the two first words for write commands. However, for reads the r/w bit must be set to 0.

When the read is performed data is read to the buffer belonging to IN endpoint 1. The reply packet is sent when the next IN token arrives after all data has been stored to the buffer. The reply packets only contains the read data (no control information is needed) with the word read from the start address transmitted first. Individual bytes are sent with most significant byte first, i.e. the byte at bit 31 downto 24.
Figure 224. Layout of USBDCL read commands and replies.

+46 31 7758650 | frontgrade.com/gaisler

80.2.3 AHB operations

All AHB operations are performed as incremental bursts of unspecified length. Only word size accesses are done.

80.3 Registers

The core does not contain any user accessible registers.

80.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x022. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

The USB vendor identifier is 0x1781 and product identifier is 0x0AA0.

80.5 Implementation

80.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. A subset of the registers in the USB clock domain make use of asynchronous reset.

The IP core has two different reset inputs: the AMBA reset and the USB reset. They work independently on their respective clock domains. If reset generation/synchronization is desired, it shall be done in a higher instance, out of the IP.

See also documentation of *syncprst* VHDL generic.

80.5.2 Scan test support

The VHDL generic *scantest* enables scan test support for both the GRUSB_DCL and GRUSBDC. When the scanen and testen signals in the AHB master input record are high the GRUSB_DCL will disable the internal RAM blocks.

See GRUSBDC section of GRLIB IP Core User's Manual for details on the scan support for GRUSBDC.

80.5.3 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

80.6 Configuration options

Table 1653 shows the configuration options of the core (VHDL generics).

*Table 1653.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB master index.	0 - NAHBMST-1	0
memtech	Memory technology used for blockrams (endpoint buffers).	0 - NTECH	0
uiface	Please see GRUSBDC section in the GRLIB IP Core User's Manual.		
dwidth	Please see GRUSBDC section in the GRLIB IP Core User's Manual.		
oepol	Please see GRUSBDC section in the GRLIB IP Core User's Manual.		
keepclk	Please see GRUSBDC section in the GRLIB IP Core User's Manual.		
functesten	Please see GRUSBDC section in the GRLIB IP Core User's Manual. If this generic is non-zero, the core will sample the value of its functesten input signal during reset. This value will then be used when assigning the Functional Testmode field in the GRUSBDC control register. The functesten input can be useful during netlist simulation as functional test mode reduces simulation time. If this generic is set to zero, the value of the functesten input will be disregarded and the Functional Testmode field will always be written with '0'.		
burstlength	Sets the maximum burst length in 32-bit words. The core will not burst over a burstlength word boundary.	8	1 - 512
scantest	Set this generic to 1 if scan test support should be implemented.	0 - 1	0

80.7 Signal descriptions

Table 1654 shows the interface signals of the core (VHDL ports).

*Table 1654.*Signal descriptions

Signal name	Field	Type	Function	Active
UCLK	N/A	Input	USB UTMI/ULPI Clock	-
URST	N/A	Input	USB Reset	Low
USBI	*	Input	USB Input signals	-
	functesten	Input	Functional test enable. If the core has been implemented with support for functional test mode (VHDL generic *functesten*), this signal will be sampled during core reset. Its value will then be used to set the functional testmode enable bit in the GRUSBDC core's control register.	High
USBO	*	Output	USB Output signals	-
HCLK		Input	AMBA Clock	-
HRST		Input	AMBA Reset	Low
AHBMI	**	Input	AHB master input signals	-
AHBMO	**	Output	AHB master output signals	-

GRLIB IP Core

81   GRUSBHC - USB 2.0 Host Controller

81.1   Overview

The Frontgrade Gaisler USB 2.0 Host Controller provides a link between the AMBA AHB bus and the Universal Serial Bus. The host controller supports High-, Full-, and Low-Speed USB traffic. USB 2.0 High-Speed functionality is supplied by an enhanced host controller implementing the Enhanced Host Controller Interface revision 1.0. Full- and Low-Speed traffic is handled by up to 15 (USB 1.1) companion controllers implementing the Universal Host Controller Interface, revision 1.1. Each controller has its own AMBA AHB master interface. Configuration and control of the enhanced host controller is done via the AMBA APB bus. Companion controller registers are accessed via an AMBA AHB slave interface. Figure 225 shows a USB 2.0 host system and the organization of the controller types. Figure 226 shows an example with both host controller types present.

The controller supports both UTMI+ and ULPI transceivers and can handle up to 15 ports.
Figure 225. Block diagram of USB 2.0 host system

81.2   Operation

81.2.1   System overview

Depending on the core's configuration it may contain both controller types, one enhanced host controller, or up to 15 standalone universal host controllers. If both controller types are present, each universal host controller acts as a companion controller to the enhanced host controller.

The enhanced host controller complies with the Enhanced Host Controller Interface with the exception of the optional Light Host Controller Reset, which is not implemented.

The universal host controller complies with the Universal Host Controller Interface, with exceptions. The HCHalted field in the USB Command register is implemented as Read Only instead of Read/Write Clear. The Port Status/Control registers have been extended with Over Current and Over Current Change fields. Changes to both registers have been done in accordance with contemporary implementations of the interface. Both changes match the description of corresponding bits in the EHCI specification.

81.2.2   Protocol support

The enhanced host controller has full support for High-Speed traffic as defined in the USB Specification, revision 2.0. In addition Asynchronous Park Mode is supported, and the controller has a NAK counter.

The universal host controller supports Full- and Low-Speed traffic.

81.2.3   Descriptor and data buffering

The enhanced host controller prefetches one frame of isochronous descriptors. All payload data for a transaction is fetched before the transaction is executed. The enhanced host controller has a 2048 byte buffer for descriptors and a 2048 byte buffer for payload data, which can hold data for two transactions.

The universal host controller does not prefetch descriptors. Depending on controller configuration a transaction on the bus may be initiated before all payload data has been fetched from memory. Each universal host controller has a 1024 byte buffer for payload data. A transfer descriptor in UHCI may describe a transaction that has a payload of 1280 bytes. The USB specification limits the maximum allowed data payload to 1023 bytes and the controller will not transfer a larger payload than 1023 bytes. If a descriptor has a, legal, larger payload than 1023 bytes, the controller will only attempt to transfer the first 1023 bytes before the transaction is marked as completed.

In the event that the host controller has just one port, the universal host controller and the enhanced host controller will share the data payload buffer. Thus only two 2048 byte buffers are required.

81.2.4   Endianness

The core always accesses the least significant byte of a data payload at offset zero. Depending on the core's configuration, registers may be big endian, little endian, or byte swapped little endian.

81.2.5   RAM test facilities

The VHDL generic *ramtest* adds the possibility to test the RAM by mapping the core's internal buffers into the register space. If the core is implemented with RAM test facilities the universal host controller maps the packet buffer at offset 0x400 - 0x7FF. An enhanced host controller will map the packet buffer at offset 0x1000 - 0x17FF and the transaction buffer at 0x1800 - 0x1FFF. Note that the VHDL generics *uhchmask* and *ehcpmask* must be modified to allow access to the increased number of registers. The three least significant bits of the universal host controller's mask must be set to zero. The enhanced host controller's mask must have its five least significant bits set to zero.

+46 31 7758650 | frontgrade.com/gaisler

When the *ramtest* generic is set to one an extra register called *RAM test control* register is added to both the universal and the enhanced controller. This register is described in section 81.8.1 and 81.8.2. To perform the RAM tests the user should first make sure that both the universal host controller and enhanced host controller are in their respective idle state. Note that if the core has only one port then the enhanced controller and the universal controller share the packet buffer. The shared buffer can be tested through both of the controllers but the controller performing the test must be the current owner of the port. For information on how to enter idle state and change ownership of the port please see section 81.8. When the controllers are in their idle states the enable bit in the *RAM test control* register should be set to one.

Once RAM test is enabled the whole RAM can be tested by first filling the buffers by writing to the corresponding register addresses and then setting the start bit in the *RAM test control* register. When the start bit is set the controller will, in order to access to the RAM from all its ports, read and write the whole packet buffer from the USB domain. If the core uses dual port RAM (see section 81.10.2 for more information on RAM usage) the same thing is done with the transaction buffer (if it is the enhanced controller that is performing the test). When the core uses double port RAM both the read and write port of the transaction buffer is located in the AHB domain, and therefore both the read and write port is tested during read and write accesses to register space. When the transfers are finished the core will clear the start bit and the data can then be read back through register space and be compared with the values that were written. When the core is implemented with dual port RAM individual addresses in the packet buffer and transaction buffer can be written and read without using the start bit. When using double port RAM only the transaction buffer can be read without using the start bit. However when individual addresses are accessed the buffers are only read/written from the AHB domain.

81.3 Port routing

Port routing is implemented according to the EHCI specification but functions regardless of whether the core is configured with or without an enhanced host controller. The VHDL generic prr enables or disables Port Routing Rules. With Port Routing Rules enabled, each port can be individually routed to a specific universal host controller via the VHDL generics portroute1 and portroute2. If Port Routing Rules is disabled the n_pcc lowest ports are routed to the first companion controller, the next n_pcc ports to the second companion controller, and so forth. The HCSP-PORTROUTE array is communicated via the portroute VHDL generics, which are calculated with the following algorithm:

$$\text{portroute1} = 2^{26}*CC_8 + 2^{22}*CC_7 + 2^{18}*CC_6 + 2^{14}*CC_5 + 2^{10}*CC_4 + 2^6*CC_3 + 2^2*CC_2 + CC_1 \,/\, 4$$

$$\text{portroute1} = 2^{26}*CC_{15} + 2^{22}*CC_{14} + 2^{18}*CC_{13} + 2^{14}*CC_{12} + 2^{10}*CC_{11} + 2^6*CC_{10} + 2^2*CC_9 + CC_1 \bmod 4$$

where CC_P is the companion controller that port P is routed to. Companion controllers are enumerated starting at 1.

When the enhanced host controller has not been configured by software, or when it is nonexistent, each port is routed to its companion controller. This allows a universal host controller to function even if the host system does not have support for the enhanced host controller. Please see the EHCI specification for a complete description of port routing.

81.4 DMA operations

Both host controller types have configurable DMA burst lengths. The burst length in words is defined by the VHDL generic bwrd. The value of bwrd limits how many words a controller may access in memory during a burst and not the number of memory operations performed after bus access has been granted. When writing a data payload back to memory that requires half-word or byte addressing the number of memory operations may exceed bwrd by one before the bus is released. If a host controller

GRIP
Apr 2024, Version 2024.1
1369
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

is given a byte-aligned data buffer its burst length may exceed the bwrd limit with one word when fetching payload data from memory.

The universal host controller uses a burst length of four words when fetching descriptors. This descriptor burst length is not affected by the bwrd VHDL generic. The universal host controller may be configured to start transactions on the USB before all data has been fetched from memory. The VHDL generic uhcblo specifies the number of words that must have been fetched from memory before a USB transaction is started. Since the USB traffic handled by the universal host controller can be expected to have significantly lower bandwidth than the system memory bus, this generic should be set to a low value.

81.5   Endianness

The core works internally with little endian. If the core is connected to a big endian bus, endian conversion must be enabled. When the VHDL generic endian_conv is set, all AMBA data lines are byte swapped. With endian_conv correctly set the core will start accessing data payloads from byte offset zero in the buffer, this is the first byte that is moved on the USB. The VHDL generic endian_conv must be set correctly for byte and halfword accesses to work. Therefore it is not possible to change the byte order of the buffer by configuring the controller for a little endian bus when it is connected to a big endian bus or vice versa.

The VHDL generics be_regs and be_desc are used to place the controller into big endian mode when endian conversion is enabled. These configuration options have no effect when the core is connected to a little endian bus, as determined by the value of VHDL generic endian_conv. The VHDL generic be_regs arranges the core's registers in accordance with big endian addressing. In the enhanced host controller this will only affect the placement of the register fields CAPLENGTH and HCIVERSION, the HCSP-PORTROUTE array, and - if implemented - the PCI registers *Serial Bus Release Number Register* and *Frame Length Adjustment Register*. In the universal host controller be_regs will affect the placement of all registers. When be_regs is set, the bus to the register interface is never byte swapped. Tables 1656 - 1658 below illustrate the difference between big endian, little endian, and little endian layout with byte swapped (32 bit) WORDs on two 16 bit registers. Register R1 is located at address 0x00 and register R2 is located at address 0x02.

1370

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The VHDL generic be_desc removes the byte swapping of descriptors on big endian systems. Tables 1659 and 1660 below list the effects of endian_conv and be_regs on a big endian and a little endian system respectively.

*Table 1659.*Effect of endian_conv, be_regs, and be_desc on a big endian system

endian_conv	be_regs	be_desc	System configuration
0	-	-	Illegal. DMA will not function.
1	0	0	Host controller registers will be arranged according to little endian addressing and each DWORD will be byte swapped. In-memory transfer descriptors will also be byte swapped. This is the correct configuration for operating systems, such as Linux, that swap the bytes on big endian systems.
1	0	1	Host controller registers are arranged according to little endian addressing and will be byte swapped. Transfer descriptors will not be byte swapped.
1	1	0	Host controller registers will be arranged according to big endian addressing and will not be byte swapped. In memory transfer descriptors will be byte swapped.
1	1	1	Host controller registers will be arranged according to big endian addressing. In memory transfer descriptors will not be byte swapped.

*Table 1660.*Effect of endian_conv, be_regs and be_desc on a little endian system

endian_conv	be_regs	be_desc	System configuration
0	-	-	Host controller registers will be placed as specified in the register interface specifications.
1	-	-	Illegal. DMA will not function.

81.6   Transceiver support

The controller supports UTMI+ 8-bit, UTMI+ 16-bit, and ULPI transceivers. All connected transceivers must be of the same type. Note that the transceiver type is fixed and the core can therefore not change between 8-bit and 16-bit UTMI+ interface during operation. Transceiver signals not belonging to the selected transceiver type are not connected and do not need to be driven. When using ULPI transceivers the default, and recommended, configuration is to use an external source for USB bus power (VBUS) as well as external VBUS fault detection. However the core can be configured to support configurations where the ULPI transceiver handles VBUS generation and fault detection internally, and configurations where VBUS generation is external to transceiver but fault detection is handled internally. Also the active level of the VBUS fault indicator can be configured. The configuration is handled by the vbusconf generic. If UTMI+ transceivers are used it does not matter to the core how VBUS generation and fault detection is handled as long as the VBUS enable signal and VBUS fault indicator are connected to the core's drvvbus and vbusvalid signals respectively. The UTMI+ specification defines these two signals to be active high, however in order to support different types of USB power switches and fault detectors the core can be configured to have active low drvvbus and vbusvalid signals. This configuration is also handled by the vbusconf generic. The UTMI+ interface is described in *USB 2.0 Transceiver Macrocell Interface (UTMI) Specification* and *UTMI+ Specification Revision 1.0*. The ULPI interface is described in *UTMI+ Low Pin Interface (ULPI) Specification Revision 1.1*.

81.7   PCI configuration registers and legacy support

The VHDL generic *pcidev* is used to configure the core to be used as a PCI device. If the core is configured to be used as a PCI device then the PCI registers *Serial Bus Release Number Register* and *Frame Length Adjustment Register* are implemented in the enhanced controller. The *Serial Bus Release Number Register* is also implemented for the universal controller. See *Enhanced Host Controller Interface Specification (EHCI) for Universal Serial Bus revision 1.0* and *Universal Host Controller Interface (UHCI) Design Guide revision 1.1* for details.

Legacy support is not implemented.

81.8 Registers

81.8.1 Enhanced host controller

The core is programmed through registers mapped into APB address space. The contents of each register is described in the *Enhanced Host Controller Interface Specification (EHCI) for Universal Serial Bus revision 1.0. A* register called *RAM test control* is added when the VHDL generic *ramtest* is set to one. The *RAM test control* register is not part of the EHCI interface and is described below. Also registers mapped to the packet buffer and transaction buffer are added if RAM test facilities are implemented.

81.9   Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler), the enhanced host controller has device identifier 0x026, the universal host controller has device identifier 0x027. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

81.10   Implementation

81.10.1 Clocking and reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set. The core does not support *grlib_async_reset_enable*.

The core has two clock domains; a system clock domain and a USB clock domain. The USB clock domain always operates in either 60 MHz or 30 MHz, depending on the transceiver interface. All signals that cross a clock domain boundary are synchronized to prevent meta-stability.

The IP core has two different reset inputs, according to the two existing clock domains: the AMBA reset and the USB reset. They work independently on their respective clock domains. If reset generation/synchronization is desired, it shall be done in a higher instance, out of the IP, as this is not performed internally.

The reset input can be asserted and deasserted asynchronously or synchronously. All registers that in the system clock domain that require a reset value are synchronously reseted. It is assumed that the

reset input is held asserted until the system clock input is stable. In order to insure that no unwanted USB activity take place, a few registers in the USB clock domain are asynchronously reseted. Once the USB clock starts to toggle, all other registers in the USB domain that require a reset value will be reset as well.

Some ULPI transceivers require the data bus to be kept low by the core during transceiver reset, this behaviour is controlled by the *urstdrive* input signal.

81.10.2 RAM usage

The core maps all usage of RAM on either the *syncram_dp* component (dual port) or the *syncram_2p* component (double port), both from the technology mapping library (TECHMAP). Which component that is used can be configured with generics. The default, and recommended, configuration will use *syncram_dp*. A universal host controller requires one 256x32 *syncram_dp*, or two 256x32 *syncram_2p* for its packet buffer. The extra amount of *syncram_2p* needed comes from the fact that the packet buffer is both read and written from the AHB clock domain and the USB clock domain. It can not be guaranteed that a synchronization scheme would be fast enough and therefore one buffer for data beeing sent and one buffer for data beeing received are needed. An enhanced host controller requires one 512x32 *syncram_dp* (or two 512x32 *syncram_2p*, for the same reason discussed above) for its packet buffer and two 512x16 *syncram_dp/syncram_2p* for its transaction buffer. The transaction buffer is not doubled when using *syncram_2p*, instead synchronization and arbitration logic is added. When the core is instantiated with only one port, the enhanced host controller and universal host controller will share the packet buffer and the core only requires one 512x32 *syncram_dp* (or two 512x32 *syncram_2p*) for the packet buffer. Table 1672 below shows RAM usage for all legal configurations.

*Table 1672.*RAM usage for USB Host Controller core

Enhanced Host Controller present	Number of Universal Host Controllers	Number of ports	RAM component	RAM 256x32	RAM 512x32	RAM 512x16
No	x*	Don't care	syncram_dp	x*	0	0
No	x*	Don't care	syncram_2p	x**	0	0
Yes	1	1	syncram_dp	0	1	2
Yes	1	1	syncram_2p	0	2	2
Yes	x*	> 1	syncram_dp	x*	1	2
Yes	x*	> 1	syncram_2p	x**	2	2

* The number of required 256x32 *syncram_dp* equals the number of instantiated universal host controllers.

** The number of required 256x32 *syncram_2p* equals the double amount of instantiated universal host controllers.

81.10.3 ASIC implementation details

When synthesizing the core for ASIC it might be required to use DC Ultra to reach the desired performance of the AMBA interface.

81.10.4 Scan test support

The VHDL generic *scantest* enables scan test support. If the core has been implemented with scan test support it will:

• disable the internal RAM blocks when the testen and scanen signals are asserted.

• use the testoen signal as output enable signal.

• clock all registers with the clk input (i.e. not use the USB clock).

• use the testrst signal as the reset signal for those registers that are asynchronously reseted.

The testen, scanen, testrst, and testoen signals are routed via the AHB master interface.

81.10.5 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

81.11 Configuration options

Table 1673 shows the configuration options of the core (VHDL generics).

Table 1673. Configuration options

Generic name	Function	Allowed range	Default
ehchindex	Enhanced host controller AHB master index	0 - NAHBMST-1	0
ehcpindex	Enhanced host controller APB slave index	0 - NAPBSLV-1	0
ehcpaddr	Enhanced host controller ADDR field of the APB BAR.	0 - 16#FFF#	0
ehcpmask	Enhanced host controller MASK field of the APB BAR. Note that if the *ramtest* generic is set to 1 then the allowed range for this generic changes to 0 - 16#FE0#. If the pcidev generic is set to 1 then the allowed range for *ehcpmask* is 0 - 16#FC0#	0 - 16#FFF#	16#FFF#
ehcpirq	Enhanced host controller interrupt line	0 - NAHBIRQ-1	0
uhchindex	Universal host controller AHB master index. If the core contains more than one universal host controller the controllers will be assigned indexes from uhchindex to uhchindex+n_cc-1.	0 - NAHBMST-1	0
uhchsindex	Universal host controller AHB slave index. If the core contains more than one universal host controller the controllers will be assigned indexes from uhc_hsindex to uhchsindex+n_cc-1.	0 - NAHBSLV-n_cc	0
uhchaddr	Universal host controller ADDR field of the AHB BAR. If the core contains more than one universal host controller the controllers will be assigned the address space uhchaddr to uhchaddr + n_cc.	0 - 16#FFF#	0
uhchmask	Universal host controller MASK field of the AHB BAR. Note that if the *ramtest* generic is set to 1 then the allowed range for this generic changes to 0 - 16#FF8#	0 - 16#FFF#	16#FFF#
uhchirq	Universal host controller interrupt line. If the core contains more than one universal host controller the controller will be assigned interrupt lines uhc_hirq to uhchirq+n_cc-1.	0 - NAHBIRQ-1	0
tech	Technology for clock buffers	0 - NTECH	inferred
memtech	Memory Technology used for buffers.	0 - NTECH	inferred
nports	Number of USB ports	1 - 15	1
ehcgen	Enable enhanced host controller	0 - 1	1
uhcgen	Enable universal host controller(s)	0 - 1	1
n_cc	Number of universal host controllers. This value must be consistent with nports and n_pcc, or portroute1 and portroute2, depending on the value of the generic prr. This value must be at least 1, regardless the value of generic uhcgen.	1 - 15	1

+46 31 7758650 | frontgrade.com/gaisler

*Table 1673.*Configuration options

Generic name	Function	Allowed range	Default
n_pcc	Number of ports per universal host controller. This value must be consistent with n_cc and nports: nports <= (n_cc * n_pcc) < (nports + n_pcc) when Port Routing Rules is disabled. The only allowed deviation is if (nports mod n_cc) < n_pcc in which case the last universal host controller will get (nports mod n_cc) ports. This generic is not used then Port Routing Rules (prr) is enabled.	1 - 15	1
prr	Port Routing Rules. Determines if the core's ports are routed to companion controller(s) with n_cc and n_pcc or with the help of portroute1 and portroute2.	0 - 1	0
portroute1	Defines part of the HCSP-PORTROUTE array	-	0
portroute2	Defines part of the HCSP-PORTROUTE array	-	0
endian_conv	Enable endian conversion. When set, all AMBA data lines are byte swapped. This generic must be set to 1 if the core is attached to a big endian bus, it must be set to 0 if the core is attached to a little endian bus.	0 - 1	1
be_regs	Arrange host controller registers according to big endian addressing. When set no endian conversion is made on the AMBA data lines connected to the host controller registers, regardless of endian_conv. Valid when endian_conv is enabled.	0 - 1	0
be_desc	Disable byte swapping of in-memory descriptors. Valid when endian_conv is enabled.	0 - 1	0
uhcblo	Universal Host Controller Buffer Limit Out. A universal host controller will start OUT bus transactions when uhcblo words of payload data has been fetched from memory. Note that if the core uses the UTMI+ 16 bit interface this generic must have a value larger than 2.	1 - 255	2
bwrd	Burst length in words. A universal host controller has a fixed, not affected by bwrd, burst length of four words when fetching transfer descriptors. See comments under section 81.2 DMA operations.	0 - 256	16
utm_type	Transceiver type: 0: UTMI+ 16 bit data bus 1: UTMI+ 8 bit data bus 2: ULPI	0 - 2	2

*Table 1673.*Configuration options

Generic name	Function	Allowed range	Default
vbusconf*	Selects configuration for USB power source and fault detection (external and internal below is from the USB transceivers point of view): ULPI transceivers: 0: ULPI transceiver generates VBUS internally and no external fault indicator present 1: External power source but no external fault indicator. Transceiver implement the optional ULPI pin DrvVbusExternal but not ExternalVbusIndicator. 2: External power source and external active high fault indicator. Transceiver implement both the optional ULPI signals DrvvbusExternal and ExternalVbusIndicator. 3: External power source and external active low fault indicator. Transceiver implement both the optional signals DrvvbusExternal and ExternalVbusIndicator. 4: External power source, but transceiver does not implement the optional ULPI signal DrvVbusExternal. Active low drvvbus output from Host Controller will be used. Don't care if ExternalVbusIndicator is implemented, not used. 5: External power source, but transceiver does not implement the optional ULPI signal DrvVbusExternal. Active high drvvbus output from Host Controller will be used. Don't care if ExternalVbusIndicator is implemented, not used. UTMI+ transceivers: 0: vbusvalid and drvvbus are both active low 1: vbusvalid is active low, drvvbus is active high 2: vbusvalid is active high, drvvbus is active low 3: vbusvalid and drvvbus are both active high	0 - 3	3
ramtest	When set each controller maps its internal buffers into the controller's register space.**	0 - 1	0
oepol	The polarity of the output enable signal for the data input/output buffers, 0 means active low and 1 means active high.	0 - 1	0
scantest	Scan test support will be included if this generic is set to 1.	0 - 1	0
memsel	Selects if dual port or double port memories should be used for the host controllers' internal buffers. Dual port memories are used if this generic is set to 0 (or MEMSEL_DUALPORT). Double port memories are used if this generic is set to 1 (or MEMSEL_DOUBLEPORT). It is strongly recommended to use dual port memories in the host controllers. Double port memories should only be used on technologies that lack support for dual port memories or where the area overhead for dual port memories preventively large.***	0 - 1	0
pcidev	This generic should be set to one if the core is to be used as a PCI device. If set to 1 the core will hold its interrupt signal(s) high until cleared by software. Also a few PCI registers will be added. See section 81.7 and 81.8 for details on the registers. Note that if this generic is set to 1 then the allowed range for *ehcpmask* changes to 0 - 16#FC0#.	0 - 1	0

82 GRVERSION - Version and Revision information register

82.1 Overview

The GRVERSION provides a register containing a 16 bit version field and a 16 bit revision field. The values for the two fields are taken from two corresponding VHDL generics. The register is available via the AMBA APB bus.

82.2 Registers

The core is programmed through registers mapped into APB address space.

Table 1677. GRVERSION registers

APB address offset	Register
0x00	Configuration Register

82.2.1 Configuration Register

31	16	15	0
VERSION		REVISION	
*		*	
r		r	

31-16: VERSION Version number
15- 0: REVISION Revision number

82.3 Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x03A. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

82.4 Implementation

82.4.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

82.5 Configuration options

Table 1679 shows the configuration options of the core (VHDL generics).

Table 1679. Configuration options

Generic name	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar.	0 - 16#FFF#	0
pmask	Mask field of the APB bar.	0 - 16#FFF#	16#FFF#

83 GRWATCHDOG - Watchdog module with separate clock domain

83.1 Overview

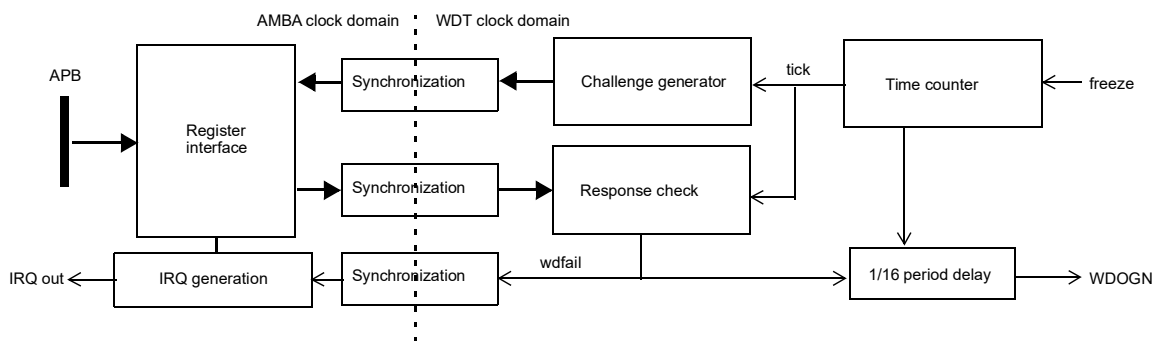
This core implements a watchdog timer intended to detect when a processor has crashed or become non-responsive. The timer consists of a down-counter, that runs in a separate clock domain from the on-chip bus system. Running it in another clock domain allows catching cases where the system clock stops functioning (for example, due to PLL malfunction).


Figure 227. Functional block diagram of GRWATCHDOG

83.2 Operation

83.2.1 Challenge / Response protocol

The watchdog operates by a continuous cycle of posting an value (challenge), waiting for a pre-determined amount of time, and then checking that the correct response value was written in by software. If the value is correct, another challenge value is produced and the cycle repeats. If the value is incorrect, the watchdog will assert a watchdog triggered signal.

Both the challenge and response are 8-bit values. The response is formed by rotating the value two bit positions to the left and inverting the lower two bits. The formula for producing the correct response for a certain challenge is, in C syntax:

resp = ((chal & 0x3f) << 2) | ~((chal & 0xc0) >> 6);

The intent of this challenge/response protocol is to ensure that the writes to the watchdog are made intentionally by software and not by stray DMA accesses or through accidental writes by software via corrupted pointers. While a stray write to the watchdog's register space could by accident get the response right once it is very unlikely to produce the right response several times.

83.2.2 Watchdog triggered signal

When a challenge/response cycle fails, the watchdog will trigger. In order to allow for a controlled shutdown whenever possible, the watchdog triggers in two stages. First, a watchdog triggered indiciation is sent to the AMBA clock domain. This can be read out through the status register, and optionally an interrupt can be generated. The second stage occurs after an additional 1/16:th of the watchdog period time has passed, then the active-low watchdog triggered signal (wdogn) will go low, and will stay low until the core is reset.

The watchdog module itself does not take any further action beyond asserting the watchdog output signal. The signal would normally be used to trigger a system reset, either on-chip or through an external signal on board level.

GRIP

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

83.2.3 Timer freeze

The core has a timer freeze control signal that suspends the watchdog counter. This is intended to be used to stop the watchdog timer during software debugging. Note that accidentally raising this signal could defeat the watchdog functionality, it is therefore recommended to ensure that this signal is low when not debugging (for example by gating it with a debug-enable input signal).

83.3 Implementation

83.3.1 Synchronization

The core uses the syncreg component from the techmap library for the synchronization registers. For all signals from the system clock domain into the watchdog clock domain, three-stage synchronization registers are used. For the tranfer of data from the watchdog clock domain into the system, a handshaking protocol is used and the cdcbus component is used for the data bus capture.

The timer freeze signal is internally synchronized into the wdt_clk domain.

83.3.2 Endianness

This core has only an APB register interface that supports one access size (32 bits), and is therefore not impacted by endianness issues.

83.3.3 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

83.4 Registers

The bridge provides a configuration register area accessed over the APB bus. For forward compatibility, reserved fields should be written either with 0 or with the last read-out value, and reserved registers should not be accessed at all.

*Table 1682.*Configuration registers for GRWATCHDOG

Register address offset	Name	R/W	Reset value	Notes
0x00	Hardware configuration register	R	-	1

84   GRWIZL - WizardLink codec with DMA engine and Bus Master Interface

84.1   Overview

GRWIZL provides an interface between the system bus (such as AHB or AXI) and a High Speed Serial Link (HSSL). The IP has been designed to inter-operate with the WizardLink transceiver family from Texas Instrument, in particular the TLK2711 transceiver. However, the IP can be used with other SerDes devices (Serializer / Deserializer).

The IP core consists of a WizardLink codec and a DMA engine for autonomous data transfers. Compared to SpaceFibre, the codec is much simpler and most of the higher-layer functionality has been removed, since WizardLink is not a closed standard. Therefore, it is the responsibility of upper layers (i.e. configurable commands in the DMA engine or software) to assign a specific functionality to the control words supported in the serial communication.

The design of the WizardLink codec is based on the lowest layer of the SpaceFibre codec, namely the interface layer. It handles the clock-domain-crossing synchronization mechanism between the core clock, the transmitter clock and the clock recovered by the receiver. If enabled, the codec can additionally perform 8b10b encoding (transmission) and decoding (reception), as well as comma detection and word synchronization.

The DMA engine is in charge of autonomously transferring packets between the codec and external working memory via a generic bus master interface. The core is configured and controlled via a set of registers accessed over an AHB slave interface. The generic bus master interface can easily be converted into the desired bus standard. There are wrappers available adapting the generic bus master interface to either AMBA AHB 2.0 or AXI4.

GRWIZL requires an external SerDes for the connection to the high speed serial link, either on the chip or external to the chip. In total, there are up to four clock domains: the system clock for the AMBA and DMA layers, the WizardLink codec clock, the WizardLink transmitter clock (optional) and the WizardLink recovered clock for the receiver.

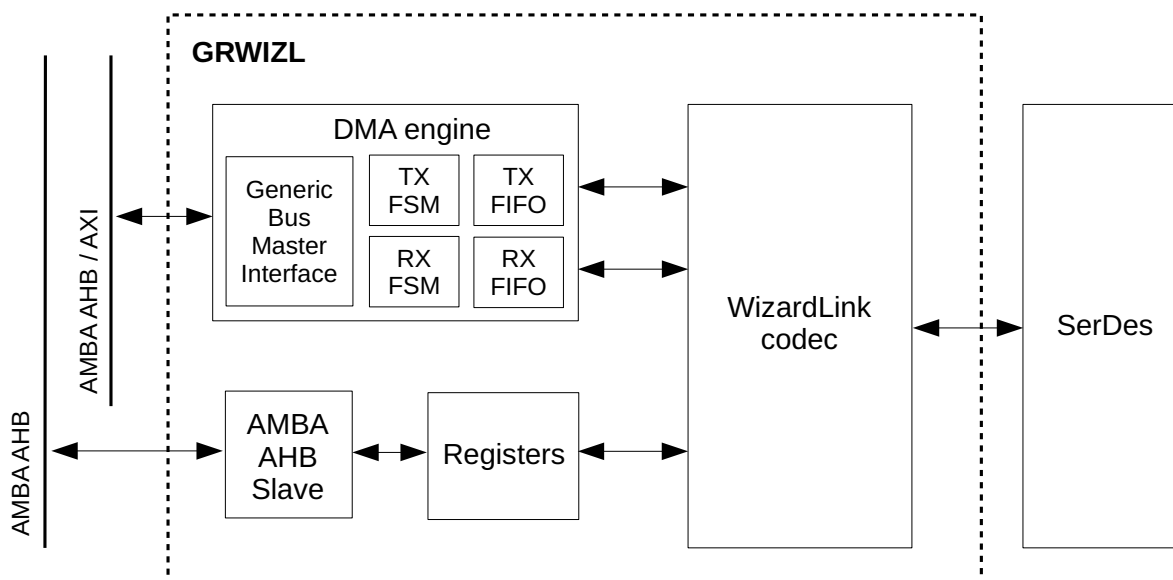
The block diagram of GRWIZL can be seen in the figure below:


Figure 228. GRWIZL block diagram

84.2 Operation

84.2.1 Functional description

The main sub-blocks of the IP are the WizardLink codec, the DMA engine and the IP registers accessed through the AHB slave interface. Note that the SerDes is not part of the IP, but it is always required in order to achieve the typical high bit-rates of the High Speed Serial Links.

The core of the IP is the WizardLink codec. It has been designed to inter-operate the TLK2711 transceiver, but it supports other models of transceivers. The codec can be split into two basic layers:

- Interface Layer. This layer serves as the interface between the Physical and the Lane layers. It is in charge of the symbol synchronization, 8B/10B encoding, cross-domain crossing and polarity inversion, among other tasks.

- Lane Layer. Functions here are those typically related to the Data-Link layer, according to the OSI model. Idle words are inserted and extracted, and reception errors are also detected. Note that, due to the open nature of the standard, the codec does not follow any specific sequence to establish the link.

Additionally, the codec features internal TX and RX buffers to hold data words and K-flags for both transmission and reception. The depth of these buffers is configurable at implementation time via VHDL generics. The TX and RX buffers are directly interfaced by the Lane Layer.

Transmission and reception of packets are based on descriptors. There are two descriptor tables: one for transmission and another for reception. Once a descriptor has been read and verified by the DMA channel, the packet can be fetched from external memory and transmitted using the codec (transmitter) or read from the codec and stored into external memory (receiver). Packets and descriptors are read and written through the generic bus master interface.

The DMA engine also contains an RX and a TX FIFO for 32-bit word alignment and for burst support. The FIFOs serve as the interface between the FSMs and the codec. Once a complete packet has been read by the WizardLink codec (transmission) or written to external memory (reception), the FIFO is emptied, ready for the next packet. As is the case of the codec buffers, the size of these FIFOs can be configured at implementation time via generics.

The bus master interface present in the IP is generic, so that the user can connect a wrapper in order to adapt it to their custom protocol. Wrappers for AMBA 2.0 AHB and AXI4 are readily available from Frontgrade Gaisler.

In order to enhance protocol support in hardware, the DMA engine includes programmable commands that allow the user to transmit and receive control words without needing to set up descriptors. The core can generate interrupts when these commands are transmitted or received. This is an optional feature that can be used to easily insert and extract control words that do not necessarily belong to a WizardLink packet, for instance when starting or stopping the link, or as part of a custom flow control mechanism. The core currently supports up to 8 programmable commands.

GRWIZL includes the registers to configure and control the IP. These registers are accessible through the AMBA AHB slave interface.

GRWIZL will generate AMBA interrupts under certain circumstances:

- Link events

- Errors during read/write accesses through the bus master interface

- Transmission and reception of packets

- Transmission and reception of programmable commands

The user can configure which events shall cause interrupts both at IP level (by an AHB register) and per individual packet (a specific bit in the descriptor).

84.2.2 Protocol support

The WizardLink codec has been designed to interface the TLK2711 transceiver with minimal protocol overhead. Other SerDes models are supported by the IP.

84.2.3 Endianness

The core is designed for big-endian and little-endian systems.

When connected to an AHB bus, GRWIZL automatically detects the endianness of the system by reading a dedicated sideband signal included in the AMBA records. If the AXI wrapper is used instead, the endianness is configured via the VHDL generic *lendian*. When accessing the bus, the data may be swapped depending on the selected endianness and the type of data involved in the transfer:

- Words belonging to TX and RX descriptors are never swapped and shall be read and written using 32-bit accesses. These words shall be located at the same address offsets (0x0, 0x4, 0x8 and 0xC) regardless of the endianness.

- Data and K-flags in WizardLink packets are treated as a stream of bytes, i.e. the bytes will be located in the same memory positions in both big- and little-endian systems. If *addr* is the address configured in the corresponding field of a descriptor, the first byte shall be located at *addr*, the second byte at *addr+1*, and so on. This implies that GRWIZL will internally swap the data words in little-endian configurations when accessing the AMBA bus.

84.3 WizardLink codec

This section provides guidelines for configuring and controlling the internal WizardLink codec.

84.3.1 Configuration

The generics of the WizardLink codec are mainly related to the interface with the SerDes.

Communication over High Speed Serial Links normally requires 8B/10B encoding. However, some SerDes may already incorporate the encoding; otherwise this can be performed inside the codec by setting the generic *use_8b10b*.

Depending on the SerDes interface, the IP can be configured to have a 20- or 40-bit wide interface with the generic *sel_16_20_bit_mode*. If the narrow interface of 20 bits is chosen, the generic *use_sep_txclk* shall be enabled, and the transmitter clock input signal (wizl_txclk) shall be provided.

The lane layer contains TX and RX FIFOs used to buffer the words to transmit or received, respectively. The memory data width is fixed (36 bits: 32 of data plus 4 of K-codes), whereas the depth of the FIFOs is configurable via the generics *depth_tx_buf* and *depth_rx_buf*.

84.3.2 Control

The WizardLink communication is controlled by means of the Codec Control Register (CTRL). This register allows to enable or disable the transmitter and receiver side of the codec and the SerDes, as well as the internal loopback mode of the codec.

In loopback mode, the IP loops the data on both sides: codec (lane layer) and SerDes (interface layer). This implies that any data transmitted by the lane layer is automatically looped back to the receiver but not propagated to the SerDes, whereas any data received by the SerDes is automatically retransmitted over the High Speed Serial Link but not passed to the lane layer of the codec.

Since the control characters and words of WizardLink are not specified, there are registers to customize the protocol according to the needs of a particular application. Some of the most important registers are listed below:

GRIP
Apr 2024, Version 2024.1

1394

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Synchronization comma. Since the 8b10b encoding supports different possibilities for the comma character, the user shall specify the pattern to be used by the codec to perform comma detection. It is assumed that the comma is always a control character (i.e. its K-flag is set to 1).

- EOP (End of Packet) and EEP (Error Packet) markers. Defining at least the EOP is mandatory in order to establish boundaries between consecutive packets. If EEP is not desired it can simply be set to the same value as EOP, so it will never be detected by the IP (EOP takes precedence). It is assumed that EOP and EEP are always control characters (i.e. their K-flags are always set to 1).

- IDLE words. When the IP does not have any word to transmit, it will continue sending IDLE words in order to keep the link active. The user shall specify both the data and the corresponding K-codes of this word.

The control characters and words need to be configured by the user before asserting the transmitter and receiver enable bits of the Codec Control Register in order to avoid transmitting invalid words via the high speed serial link.

84.3.3 Status

The codec provides several signals to inform about its internal status. These signals are mapped to the Codec Status Register (STS). Among others, the following signals are available:

- RX Error counter and counter overflow flag.

- RX overrun.

Note that, unlike in SpaceWire or SpaceFibre, there is no built-in mechanism for flow control. This means that the internal RX FIFO of the codec may get full if the DMA engine cannot keep up with the high speed serial link. As stated before, it is responsibility of the user to configure the application to deal with these situations, either by adding a flow control mechanism in software or by ensuring that the DMA engine can handle the incoming traffic at the target speed.

The capability registers contain information regarding how the IP was generated. Most generics can be read back by reading the Codec Capability Register.

84.4 DMA engine

84.4.1 Transmit channel

A WizardLink packet consists of data bytes and their corresponding K-flags. Data and K-flags are located in different areas in memory, and both shall be provided by the user. Since WizardLink does not associate any functionality with the control characters (bytes with their K-flag asserted) and words, by default this shall be done in software in order to support any application using WizardLink with a custom set of commands.

Transmission of packets is handled by means of descriptors. TX descriptors indicate where the packet is to be fetched from and control several aspects of the transmission process, such as interrupt generation and how the hardware pointers handling the descriptors shall be updated.

The core reads descriptors from an area in memory pointed to by the Transmit Descriptor Table Address Register. The register consists of a base address and a descriptor selector. The base address points to the beginning of the area and must start on an address that is aligned to the size of the descriptor table.

The number of descriptors in the table can be configured by the generic *num_txdesc*. Accepted values are 64, 128, 256 and 512. The number of bits allocated to the base address and descriptor selector in the Transmit Descriptor Table Address Register depends on the value of this generic. A TX descriptor consists of four 32-bit words (16 bytes). Therefore, the size of the descriptor table can be determined as *num_txdesc * 16* bytes. The number of TX descriptors can also be obtained by reading the DMA Capabilities Register.

GRIP

Apr 2024, Version 2024.1

1395

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

To transmit packets, one or more descriptors have to be initialized in memory. Each descriptor shall specify the number of words to transmit and the location of both the data and K-flags. Note that not only the data, but also the K-flags shall be provided by the user in order to support any WizardLink application with custom control words and characters, even if the packet only consists of data characters with their K-flags deasserted.

The TX descriptor contains two different address fields for the data and the K-flags, respectively. The data length is unique, as there shall be a K-flag (one bit) per data byte. If the length field is zero, the packet is skipped and the descriptor is updated. The maximum data length is 32 MiB - 1. When the pointer and length fields have been configured the descriptor enable bit should be set to validate the descriptor. This must always be done last. The other control bits must also be set before enabling the descriptor.

Once the TX descriptors have been written to the descriptor table, the user shall flag this by setting the New Transmit Descriptor bit (NTD) in the Descriptor Control Register. The transmission will start as soon as the transmitter is enabled in the DMA Control Register. The user can also clear the TX descriptor table by setting the Clear Transmit Descriptor bit (CTD) in the Descriptor Control Register. Note that this will not abort any ongoing transmission if a previous descriptor had already been validated by the IP.

The transmission finite-state machine controls the exchange of data between external memory via the AMBA bus and the WizardLink codec. Firstly the FSM fetches the TX descriptor from memory and decodes it. The descriptor is validated, meaning that the enable bit shall be set. If so, the FSM proceeds to fetch the data bytes and K-flags provided that the packet length is not zero. If the enable bit of the descriptor was 0, the FSM automatically clears the TX descriptor available bit in the Descriptor Control Register.

When fetching the content of the packet, the FSM will interleave a read access of 128 K-flags (16 bytes) with 128 bytes of data. This process is repeated until the complete packet has been read out from memory. The FSM will then wait until the WizardLink codec has finished the transmission.

Once the transmission ends, GRWIZL overwrites the first word of the TX descriptor in order to clear the descriptor enable bit, which indicates that the IP has already used the descriptor. An AMBA interrupt will be generated if enabled.

The DMA Status Register contains valuable information regarding the transmission process. The TX Active bit indicates that the transmit FSM is enabled and may be in a status other than idle: a transmission may be ongoing. Disabling the transmit channel will not have any effect until the ongoing operation ends (if there is any). The TX packet bit indicates that a packet has been successfully fetched from memory and transmitted, and the descriptor has been updated accordingly.

The transmit channel will continue reading descriptors and transmitting packets until it encounters a disabled TX descriptor, or until the transmit descriptor table is cleared by the user. New descriptors can be activated in the table on the fly (while transmission is active). Each time a set of descriptors is added the NTD bit shall be set again, as the TX Descriptor Available (TDA) bit is automatically cleared when the DMA engine finds a descriptor disabled.

The internal pointer used to keep the current position in the descriptor table can be read and written through the AHB interface. This pointer is set to zero during reset and is incremented each time a descriptor is used. It wraps automatically when the limit for the descriptor table is reached, or it can be set to wrap earlier by setting a bit in the current descriptor.

The descriptor table register can be updated with a new table anytime when the transmitter is not active. A status bit is available in the DMA Status Register. A value of '0' in the TX Active bit (TA) shall be read to consider it safe to modify the TX descriptor table. Once that happens, the user may change the location of the descriptor table, the content of the current table or the pointer to the next descriptor to be fetched by the core.

84.4.2 TX descriptors

Transmit descriptors consist of four 32-bit words that set up the transmission of the packets. The tables below depict each word in a TX descriptor and further explains every field:

Table 1690. GRWIZL TX descriptor word 0 (offset 0x0)

31	30	29	28	0
IE	WR	EN	RESERVED	

31	Interrupt enable (IE) - If set, an interrupt will be generated when the packet has been transmitted and the transmission interrupt enable bit in the Interrupt control register is set.
30	Wrap (WR) - If set, the descriptor pointer will wrap and the next descriptor read will be the first one in the table (at the base address). Otherwise the pointer is increased with 0x10 to use the descriptor at the next higher memory location.
29	Enable TX descriptor (EN) - When all control fields (address, length, wrap) are set, this bit should be set. While the bit is set the descriptor should not be touched since this might corrupt the transmission. The core clears this bit when the transmission has finished.
28: 0	RESERVED

Table 1691. GRWIZL TX descriptor word 1 (offset 0x4)

31	25	24	2	1	0
RESERVED		DATALEN			RES

31: 25	RESERVED
24: 2	Data length (DATALEN) - Number of 32-bit words of packet data. If set to zero, no packet will be sent. This also defines the number of K-flags to fetch: four bits per data word.
1: 0	RESERVED

Table 1692. GRWIZL TX descriptor word 2 (offset 0x8)

31	0
KFLAGSADDR	

31: 0	K-flags address (KFLAGSADDR) - Address from where K-flags are read. No alignment restriction.

Table 1693. GRWIZL TX descriptor word 3 (offset 0xC)

31	0
DATAADDR	

31: 0	Data address (DATAADDR) - Address from where data is read. No alignment restriction.

84.4.3 Receive channel

A WizardLink packet consists of data bytes and their corresponding K-flags. After receiving a WizardLink packet, the core will store the data and K-flags in different areas of memory. Since WizardLink does not associate any functionality with the control characters (bytes with their K-flag asserted) and words, by default the incoming data shall be interpreted in software in order to support any application using WizardLink with a custom set of commands.

As in transmission, reception of WizardLink packets is handled by means of descriptors. In this case, the descriptor indicates where the packet is to be stored, both the data and the K-flags. Some additional control bits are available as well to handle the interrupt generation and how the descriptor pointer shall be updated once the next reception finishes. Optionally, the user may specify the expected length of the data by writing the data length field. Otherwise, the packet length is determined once the EOP or EEP markers are received.

GRIP
Apr 2024, Version 2024.1

1397

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The core reads the descriptors from an area in memory pointed to by the Receive Descriptor Table Address Register. The register consists of a base address and a descriptor selector. The base address points to the beginning of the area and must start on an address that is aligned to the size of the descriptor table.

The number of descriptors in the table can be configured by the generic *num_rxdesc*. Accepted values are 128, 256, 512 and 1024. The number of bits allocated to the base address and descriptor selector in the Receive Descriptor Table Address Register depends on the value of this generic. An RX descriptor consists of four 32-bit words (16 bytes). Therefore, the size of the descriptor table can be determined as *num_rxdesc * 16* bytes. The number of RX descriptors can also be obtained by reading the DMA Capabilities Register.

WizardLink packets are received by the codec regardless of whether a descriptor has been fetched. The data and K-flags are internally written to a temporary buffer, waiting for the DMA channel to read its content and store it in external memory. For the latter to happen, RX descriptors shall be initialized so that they can be fetched and validated by the DMA engine.

Similarly to the transmitter, RX descriptors include two pointers to the locations where the data and K-flags shall be stored, respectively. Once the pointers are set and the control bits (wrap bit, interrupt enable, data length) configured, the enable bit should be set to validate the descriptor. This must always be done last to avoid reading a corrupt descriptor.

In this case, however, the length of the packet determines how the reception is terminated. If set to 0, the reception only finishes once either EOP or EEP are detected by the IP, and this field is subsequently updated by the core with the resulting packet length. Otherwise, the core will ignore the EOP and EEP markers and will store as many words as specified via the data length before ending the reception and updating the descriptor. Note that the number of K-flags stored in memory can easily be inferred from the total length as four bits per word of data.

Once the RX descriptors have been written to the descriptor table, the user shall set the New Receive Descriptor bit (NRD) in the Descriptor Control Register. The storage of the packet will then start as soon as the receiver is enabled in the DMA Control Register. The user can also clear the RX descriptor table by setting the Clear Receive Descriptor bit (CRD) in the Descriptor Control Register. Note that this will not abort any ongoing reception if a previous descriptor had already been validated by the IP.

The reception finite-state machine controls the exchange of data between the WizardLink codec and the external memory, which is accessed via the AMBA bus. Firstly the FSM fetches the RX descriptor from memory and decodes it. The descriptor is validated, meaning that the enable bit shall be set. If so, the DMA engine checks if the codec has received data. If the enable bit of the descriptor was 0, the FSM automatically clears the RX descriptor available bit in the Descriptor Control Register.

When the codec output FIFO contains at least 128 bytes of data, or the EOP/EEP has already been detected by the codec, the DMA engine starts a burst access of up to 128 data bytes. This is followed by another access to memory in order to store the K-flags associated with the data just written. These accesses are interleaved until the complete packet has been written to external memory.

Once the reception ends, GRWIZL overwrites the first word of the RX descriptor with the corresponding status bits: length of the packet received, EEP detected and whether the packet was truncated due to maximum length violation. It also clears the descriptor enable bit, which indicates that the IP has already used the descriptor. An AMBA interrupt will be generated if enabled.

The DMA Status Register contains valuable information regarding the reception process. The RX Active bit indicates that the receive FSM is enabled and may be in a status different from idle: it may have already started processing a packet. Disabling the receive channel will not have any effect until the ongoing operation ends (if there is any). The RX packet bit indicates that a packet has been received and stored in external memory, and the descriptor has been updated accordingly.

The receive channel will continue reading descriptors and storing packets until it encounters a disabled RX descriptor, or until the receive descriptor table is cleared by the user. New descriptors can be

GRIP
Apr 2024, Version 2024.1

1398

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

activated in the table on the fly (while reception is active). Each time a set of descriptors is added the NRD bit shall be set again, as the RX Descriptor Available (RDA) bit is automatically cleared when the DMA engine finds a descriptor disabled.

The internal pointer used to keep the current position in the descriptor table can be read and written through the AHB interface. This pointer is set to zero during reset and is incremented each time a descriptor is used. It wraps automatically when the limit for the descriptor table is reached, or it can be set to wrap earlier by setting a bit in the current descriptor.

The descriptor table register can be updated with a new table anytime when the receiver is not active, i.e. the RX Active (RA) bit in the DMA Status Register shall be set to 0. In that case, the user may safely change the location of the descriptor table, the content of the current table or the pointer to the next descriptor to be fetched by the core.

84.4.4 RX descriptors

Receive descriptors consist of four 32-bit words that set up the storage of the packets received by the codec. The tables below depict each word in an RX descriptor and further explains every field:

Table 1694. GRWIZL RX descriptor word 0 (offset 0x0)

31	30	29	28	27	26 25	24	2 1 0
IE	WR	EN	TR	EP	RES	PKTLEN	RES

31	Interrupt enable (IE) - If set, an interrupt will be generated when a packet has been received and the reception interrupt enable bit in the Interrupt control register is set.
30	Wrap (WR) - If set, the descriptor pointer will wrap and the next descriptor read will be the first one in the table (at the base address). Otherwise the pointer is increased with 0x10 to use the descriptor at the next higher memory location.
29	Enable RX Descriptor (EN) - Set to one to activate this descriptor. This means that the descriptor contains valid control values and the memory area pointed to by the packet address field can be used to store a packet. When all control fields are set, this bit should be set. While the bit is set the descriptor should not be touched since this might corrupt the reception. The core clears this bit when the reception has finished.
28	Packet truncated (TR) - Set by the core when the reception has finished if the length of the packet exceeds the maximum length. The rest of the packet is spilled.
27	EEP termination (EP) - Set by the core to indicate that the packet ended with an Error End of Packet control character.
26: 25	RESERVED
24: 2	Packet length (PKTLEN) - Number of 32-bit words of packet data, excluding the K-flags. When the descriptor is set up, this field determines how the reception shall terminate. If set to 0 by the user, the reception finishes whenever the IP detects EOP or EEP within the packet data. Otherwise, the reception finalizes once the DMA engine has received the number of words programmed in this field. The core updates this field with the resulting packet length when setting the EN bit to 0, once the reception has finished.

31: 0	Data address (DATAADDR) - The address pointing to the buffer which will be used to store the data bytes of the packet received.

84.4.5 Packet maximum length filter (RX only)

GRWIZL features a mechanism to limit the size of the incoming packets that will be stored in memory.

The RX Maximum Length Register defines the maximum number of 32-bit words that will be accepted by the core for a given WizardLink packet. If the length of a packet exceeds the value of the register, the Truncate bit in the RX descriptor is set and the rest of the packet is spilled, i.e. not stored in external memory. It is mandatory to configure this register prior to starting a reception, otherwise the default length is zero and no words are accepted.

Note that this filter is only active when the IP expects the WizardLink packet to be terminated with either EOP or EEP, meaning that the user shall set the data length to 0 when initializing the RX descriptor.

84.4.6 Address filters (RX only)

GRWIZL features an optional mechanism to filter packets based on their address. When a Wizard-Link packet is received, the first data byte with its K-flag deasserted is interpreted as the packet local address. An acceptance filter is applied to this address in order to decide whether the packet shall be accepted (stored in memory) or ignored (read from the WizardLink codec but never written to external memory).

The filter consists of 2 bytes: an address code and a mask, which are configured in the Address Register. The WizardLink packet address is compared with the address code after applying the mask: those bits set to 1b in the corresponding position of the mask are ignored. The following condition must be fulfilled in order to accept a WizardLink packet:

$$PKTADDR \text{ and not } ADDR.MASK = ADDR.CODE \text{ and not } ADDR.MASK$$

Setting all bits of the mask to 1b disables the filter, and all packet addresses are therefore accepted.

84.4.7 Programmable commands

GRWIZL features a built-in mechanism to transmit and receive custom commands without the need of setting up descriptors. These commands can be configured using the AHB registers, both their data bytes and associated K-flags. The transmission and reception is controlled via AHB registers as well. This mechanism can be used to map control commands that are typically not part of the data payload of a packet. Examples of this are commands used during link establishment, packet acknowledgment, timestamps and flow control.

The first step is to configure the commands relevant to a given application. The IP supports up to 8 programmable commands, although the user does not need to initialize all of them. After configuring their data and K-flag patterns (similarly to how it is done for the IDLE control word, which is mandatory), GRWIZL is ready to transmit the commands and filter them in reception.

GRIP
Apr 2024, Version 2024.1

1400

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The transmission of a command can be triggered by setting the corresponding bit in the Programmable Command TX Register. The TX Request field (PROGTX.REQ) consists of as many bits as programmable commands. The user may set one or more bits simultaneously. If multiple bits are set, commands in lower indices take precedence and are transmitted first. Once a command is transmitted, the corresponding bit is cleared by the IP.

The reception of custom commands works similarly. After configuring the commands, the user shall enable which commands can be automatically detected and filtered by the IP. This is done via the Programmable Command RX Enable Register. The Enable field (PROGEN.EN) has one bit per programmable command. Only commands whose enable bit is set are filtered by the IP. The status can be monitored by checking the Programmable Command RX Register. The flags in the RX.STS field are cleared when written to 1b. Note that when a custom command is received, it is removed from the data stream and therefore not stored in external memory.

Optionally, the transmission and reception of programmable commands can trigger an interrupt. The Programmable Command IRQ Enable Register can be used to specify which commands shall generate interrupts in both transmission and reception. Additionally, the user can separately enable transmission and reception interrupts by means of the TXC and RXC fields in the Interrupt Control Register, respectively.

The table below shows the correspondence between the indices in the control registers (PROGTX, PROGRX, PROGEN and PROGIRQ) and the registers used to configure each programmable command:

Table 1698. Correspondence between indices in the control registers and programmable command registers

Index in control registers (PROGTX, PROGRX, PROGEN, PROGIRQ)	Command data register	Command K-flags register field
0	PROGCMD0 (AHB offset 0x40)	PROGKF.KF0
1	PROGCMD1 (AHB offset 0x44)	PROGKF.KF1
2	PROGCMD2 (AHB offset 0x48)	PROGKF.KF2
3	PROGCMD3 (AHB offset 0x4C)	PROGKF.KF3
4	PROGCMD4 (AHB offset 0x50)	PROGKF.KF4
5	PROGCMD5 (AHB offset 0x54)	PROGKF.KF5
6	PROGCMD6 (AHB offset 0x58)	PROGKF.KF6
7	PROGCMD7 (AHB offset 0x5C)	PROGKF.KF7

84.4.8 Bandwidth throttling (TX only)

There may be cases where the remote node cannot process the incoming data at the rated link speed, which is typically in the range of gigabits per second. To alleviate this situation the Idle Counter Register can be used to interleave IDLE control words between two consecutive data words, thus throttling the bandwidth in transmission.

When set to a value other than 0, this register defines the number of IDLE control words inserted between data words. The receiver in the remote end is expected to filter these IDLE words so that the actual data can be handled at the desired rate. When the register is set to 0, this mechanism is disabled and IDLE control words are only sent when the IP does not have anything else to transmit.

84.4.9 Deactivating the TX and RX channels

A prerequisite for transmitting and receiving packets is to set TX enable (TE) and RX enable (RE) in the DMA control register, respectively. However, it is important to point out that these control bits are only checked when the FSM is in idle state, meaning that once a transmission or reception starts, the

DMA engine will attempt to finish it even if the corresponding channel is disabled in the middle of the transfer.

It is therefore essential to monitor the DMA Status Register in order to know whether the TX and RX channels are effectively switched off before the IP may be safely reconfigured. Two bits are available for this purpose: TX Active (TA) and RX Active (RA). Note that these status bits will be set to 1 if the corresponding channel (TX or RX) is enabled, even if the FSM is idle.

Therefore, the procedure to safely change the configuration of the IP is:

- Disable the TX and/or RX channel by setting the Transmitter Stop (TS) or Receiver Stop (RS) bits in the DMA Control Register.

- Monitor the TA and/or RA bit of the DMA Status Register until cleared.

- Reconfigure the IP, including the address and content of the descriptor tables.

- Re-enable the TX and/or RX channel by setting the Transmitter Enable (TE) / Receiver Enable (RE) bits in the DMA Control Register.

84.5 External FIFO interfaces

GRWIZL can implement an external FIFO interface to directly expose the WizardLink codec data to the ports of the IP. This functionality is enabled via the VHDL generic *numextwc*. When set to 1, this FIFO interface allows the user to directly access the data interface of the WizardLink codec inside GRWIZL, thus bypassing the DMA engine altogether.

By default, this functionality is disabled and the codec is managed by the DMA layer by means of hardware descriptors. To turn it on, the Bypass DMA bit shall be set in the WizardLink Codec Control Register (CCTRL.BD). The user may dynamically configure this feature, meaning that the DMA bypass mode can be turned off and on in run time.

To reconfigure this feature in run time it is always recommended to keep both DMA transmitter and receiver off while switching in order to guarantee that ongoing packets are handled properly.

The transmission and reception of programmable commands is automatically disabled when the DMA engine is bypassed, which means that all commands and data words except for the IDLE command must be handled externally. IDLE commands are still inserted and extracted by the internal WizardLink codec in order to keep the link active.

This feature is identical to the one present in the SpaceFibre IP, so please refer to the GRSPFI section of this user's manual for further information regarding timing of the FIFO signals.

84.6 AMBA interfaces

This section explains the AMBA interfaces present in the GRWIZL codec, as well as the AMBA interrupts that the IP may generate, and how to configure them.

84.6.1 Bus master interface

The DMA engine has a generic bus master interface to fetch and store descriptors and WizardLink packets from/to external memory. The generic approach is chosen for maximum flexibility, so that the user can connect a wrapper adapting the bus master to any custom protocol. Frontgrade Gaisler provides wrappers for AHB 2.0 and AXI4.

Both transmitter and receiver share the bus master interface. The receiver has priority over the transmitter when it comes to accessing the bus, in order not to delay the reception of packets and thus preventing potential loss of data due to buffer overrun.

The size of the read or write access depends on the operation being performed:

- **Fetching a descriptor**: the descriptor size is the same for both transmission and reception. The IP will initiate a read access of 16 bytes to get a complete descriptor.

GRIP
Apr 2024, Version 2024.1

1402

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- **Storing the data bytes of a WizardLink packet** (RX): when the packet is being read from the codec by the DMA engine, a write access will be performed over the bus master interface as soon as there are at least 128 bytes available or the end of the packet has been detected. This means that the size of the write access may vary between 1 and 128 bytes.

- **Storing the K-flags of a WizardLink packet** (RX): after writing a block of up to 128 bytes of data to memory, the core stores their corresponding K-flags. Since each data byte is associated with a single K-flag bit, the write access consists of up to 16 bytes (128 K-flags).

- **Fetching the data bytes of a WizardLink packet** (TX): the data is read from memory in blocks of up to 128 bytes. If there are less than 128 bytes pending, then the size is set to the remaining bytes. Therefore the size of the read burst may vary between 1 and 128 bytes.

- **Fetching the K-flags of a WizardLink packet** (TX): in this case the core reads the flags in a fixed read burst of 16 bytes (128 K-flags, one per data byte). If less than 128 data bytes shall be transmitted, the K-flags read in excess are simply discarded by the core.

- **Updating a descriptor**: once the transmission or reception finishes, the descriptor is updated with the status of the transaction. However, only the first word of the descriptor is overwritten: that implies a fixed write access of 4 bytes for both transmission and reception.

84.6.2 AHB slave interface

GRWIZL has a single AHB slave interface to access the registers of the core. These registers are used to configure and control the IP. The size of write and read accesses over the AHB interface is always 32 bits.

The IP has 2 major clock domains: the AMBA clock, used by the DMA engine and the AMBA interface, and the WizardLink core clock, which relates to the internal codec and its interface with the DMA FIFOs. Therefore, the internal registers are split into both clock domains. All accesses to registers implemented in the WizardLink core clock domain are properly handled by means of cross domain crossing synchronization techniques.

The register address offsets can help determine if the register is implemented in the AMBA clock domain or in the WizardLink clock domain:

- 0x00 - 0x7F: registers implemented in the WizardLink clock domain. These registers are closely related to the control and status of the codec, including the mapping for control characters and words defined for the current application (comma, EOP, EEP, IDLE command, etc.).

- 0x80 - 0xFF: registers implemented in the AMBA clock domain. These registers are related to the DMA channel, interrupt handling and external memory management (i.e. descriptor tables).

Due to the internal cross domain crossing techniques, there will be a delay when accessing registers implemented in the WizardLink clock domain; waitstates are inserted in order to delay the reply from the internal core to guarantee the integrity of the signals.

84.6.3 AMBA interrupts

GRWIZL triggers AMBA interrupts upon certain events. The IP is highly configurable when it comes to selecting which events shall produce an interrupt. This section describes how the interrupts are handled and monitored.

The DMA Control Register shall be used to configure 3 types of interrupts:

- WizardLink packet transmitted.

- WizardLink packet received.

- Error while reading or writing over the bus master interface of the DMA channel.

- Link event: overrun, RX error counter overflow

- Transmission of a programmable command

- Reception of a programmable command

In addition to the control bits above, the TX and RX descriptors include an Interrupt Enable bit used to mask / unmask the generation of interrupts only for the current packet. This means that a TX / RX interrupt is only generated if enabled in both the DMA Control Register and the TX / RX descriptor. This does not apply to the other interrupts, as those are solely enabled in the DMA Control Register.

The user can read the DMA Status Register to know which event has caused an interrupt. In case it was a bus master error, further information is provided: which descriptor was being processed as well as a 4-bit code to identify when the bus error occurred (fetching the descriptor, storing the packet, etc.). Please refer to the chapter covering the Register definition to learn how these fields are encoded.

84.7   Implementation

84.7.1   Reset

The core changes its reset behavior depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

GRWIZL will feature a synchronous reset if the parameter *grlib_async_reset_enable* is not set in the GRLIB configuration package. Otherwise, it will implement an asynchronous reset if *grlib_async_reset_enable* is set.

84.7.2   Endianness

The core automatically changes its endianness behavior depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for both big-endian and little-endian systems.

84.7.3   Clocking scheme

As explained throughout this section, there are up to 4 clock domains in the IP. These paragraphs describe their use and how they shall be generated and connected.

- AMBA clock (clk): the DMA and AMBA layers of the IP operate in this clock domain. It shall be connected to the AMBA clock of the system where the IP is instantiated.

- WizardLink clock (wizl_clk): used by the core logic, including the WizardLink codec and the interface between the DMA FIFOs and the codec. Some AHB registers are also implemented in this domain. This clock is normally generated from the SerDes output transmitter clock by using a Clock Conditioning Circuit. The target frequency shall be the HSSL line rate divided by 40 (i.e. it assumes a 40-bit SerDes interface). This is dependent on the specific SerDes device used. Example: if the link operates at 2.5 Gbps, the target frequency shall always be 62.5 MHz. If the SerDes transmitter clock is 125 MHz, then the multiplication factor of the CCC shall be 0.5.

- WizardLink transmitter clock (wizl_txclk): this clock is used by the transmitter logic within the codec if using a narrow SerDes interface (16/20 bits; both generics *use_sep_txclk* and *sel_16_20_bit_mode* set to 1). The target frequency shall be the HSSL line rate divided by 20 (i.e. a 20-bit SerDes interface, twice the frequency of the core clock). Is is normally generated from the SerDes output transmitter clock. In the example above, the frequency of this clock shall be 125 MHz and could be generated from the SerDes TX clock with a multiplication factor of 1.

- WizardLink RX recovered clock (wizli.se_rx_clk): if the data received from the SerDes is not synchronous to the core clock, the SerDes recovered RX clock shall be connected to this input. If the data is already synchronous, for instance because the SerDes comprises its own elastic buffer, this clock shall be connected to the core clock directly.

Any exchange of signals between clock domains, especially between the AMBA and core clocks, is protected by clock domain crossing techniques in order to avoid metastability problems in the IP.

Please note that the core clock and the AMBA clock have separate reset signals; the user shall ensure that these resets are properly synchronized with their respective clocks if a synchronous reset scheme is chosen.

84.7.4 Relation between GRWIZL and GRHSSL

GRHSSL is a High Speed Serial Link controller providing support for both SpaceFibre and Wizard-Link. The IP can be configured to implement either or both codecs by means of VHDL generics. When both protocols are implemented, the user shall select which codec is active at a time via AHB registers. The selected core will be in charge of driving the SerDes and bus master interfaces.

GRWIZL internally uses the GRHSSL IP and configures it so that only WizardLink is instantiated. Generics relevant to WizardLink are exposed in the top-level entity, whereas those related to SpaceFibre are tied to predefined values in order to guarantee that the SpaceFibre layer is not present in the design.

84.8 Registers

The core is programmed through registers mapped into AHB address space. Only 32-bit single accesses to the registers are supported. Registers within the range 0x00-0x7F are implemented in the WizardLink clock domain, whereas the range 0x80-0xFF is related to the AMBA/DMA layer.

3	Bypass DMA engine (BD). When this bit is set, WizardLink data are directly exposed via the external FIFO ports of the IP (EXTWCI, EXTWCO), thus bypassing the DMA engine. If not set, WizardLink data are handled by the DMA engine by means of hardware descriptors. This bit is only available if the generic *numextwc* is set to 1.
2	Loop-back mode (LB). The WizardLink codec has an internal loop-back feature that can be enabled / disabled with this bit.
1	SerDes Transmit Enable (TE). If set, the codec reads the words passed by the DMA layer and transmits them over the high-speed serial link. This control bit is also visible as an output of the IP and shall be connected to the Transmission Enable port of the SerDes, if it exists.
0	SerDes Receive Enable (RE). If set, the codec parses the words received over the high-speed serial link to extract IDLE and RX error words from the data stream, while the rest is passed on to the DMA layer. This control bit is also visible as an output of the IP and shall be connected to the Reception Enable port of the SerDes, if it exists.

	0x0000	
	r	

15	8	7	0
Reserved		IRQ	
0x00		0x00	
r		rw	

7: 0   Programmable command IRQ enable (EN). When a bit in this register is set, the core will request the generation of an interrupt to the DMA layer when the corresponding programmable command has been transmitted or received by the core. TX and RX interrupts can be masked separately in the Interrupt Control Register.

84.8.13 Programmable Commands K-flags Register

Table 1712. 0x30 - PROGKF - Programmable Commands K-flags Register

31	28	27	24	23	20	19	16
KF7		KF6		KF5		KF4	
0x0		0x0		0x0		0x0	
rw		rw		rw		rw	

15	12	11	8	7	4	3	0
KF3		KF2		KF1		KF0	
0x0		0x0		0x0		0x0	
rw		rw		rw		rw	

31: 28   K-flags pattern for the programmable command 7 (KF7). It defines the command together with the data pattern specified in the Programmable Command 7 Register. The MSB bit corresponds to the byte transmitted first.

27: 24   K-flags pattern for the programmable command 6 (KF6). It defines the command together with the data pattern specified in the Programmable Command 6 Register. The MSB bit corresponds to the byte transmitted first.

23: 20   K-flags pattern for the programmable command 5 (KF5). It defines the command together with the data pattern specified in the Programmable Command 5 Register. The MSB bit corresponds to the byte transmitted first.

19: 16   K-flags pattern for the programmable command 4 (KF4). It defines the command together with the data pattern specified in the Programmable Command 4 Register. The MSB bit corresponds to the byte transmitted first.

15: 12	K-flags pattern for the programmable command 3 (KF3). It defines the command together with the data pattern specified in the Programmable Command 3 Register. The MSB bit corresponds to the byte transmitted first.
11: 8	K-flags pattern for the programmable command 2 (KF2). It defines the command together with the data pattern specified in the Programmable Command 2 Register. The MSB bit corresponds to the byte transmitted first.
7: 4	K-flags pattern for the programmable command 1 (KF1). It defines the command together with the data pattern specified in the Programmable Command 1 Register. The MSB bit corresponds to the byte transmitted first.
3: 0	K-flags pattern for the programmable command 0 (KF0). It defines the command together with the data pattern specified in the Programmable Command 0 Register. The MSB bit corresponds to the byte transmitted first.

84.8.14 Programmable Command Registers

Table 1713. 0x40, 0x44... 0x5C - PROGCMD - Programmable Command Registers

31	16
CMD	
0x0000	
rw	

15	0
CMD	
0x0000	
rw	

31: 0	Data pattern for the programmable command (CMD). This register configures a programmable command in conjunction with the corresponding field in the Programmable Command K-flag Register. Commands 0 - 7 are associated with AHB offsets 0x40 - 0x5C, respectively. The most significant byte is transmitted first.

84.8.15 DMA Capabilities Register

Table 1714. 0x80 - DMACAP - DMA Capabilities Register

31	30					16
WIZ	Reserved					
1	0x0000					
r	r					

15				4	3	2	1	0
Reserved					NTXD		NRXD	
0x000					-		-	
r					r		r	

31	WizardLink protocol implemented (WIZ). Read-only bit to indicate that GRWIZL is present in the design.
3: 2	Number of TX descriptors (NTXD). It shows the size of the TX descriptor table. Value determined by the VHDL generic *num_txdesc*. Encoding: 00b: 64 descriptors 01b: 128 descriptors 10b: 256 descriptors 11b: 512 descriptors
1: 0	Number of RX descriptors (NRXD). It shows the size of the RX descriptor table. Value determined by the VHDL generic *num_rxdesc*. Encoding: 00b: 128 descriptors 01b: 256 descriptors 10b: 512 descriptors 11b: 1024 descriptors

84.8.16 DMA Control Register

Table 1715. 0x84 - DMACTRL - DMA Control Register

31				16
Reserved				
0x0000				
r				

15	4	3	2	1	0
Reserved		TS	RS	TE	RE
0x000		0	0	0	0
r		w	w	w	w

3	Transmitter Stop (TS). If set to 1b, GRWIZL will disable the transmitter as soon as the Transmit FSM enters IDLE state. Any pending TX enable request is cleared.
2	Receiver Stop (RS). If set to 1b, GRWIZL will disable the receiver as soon as the Receive FSM enters IDLE state. Any pending RX enable request is cleared.
1	Transmitter Enable (TE). If set to 1b, GRWIZL will enable the transmitter as soon as the Transmit FSM enters IDLE state. Any pending TX stop request is cleared.
0	Receiver Enable (RE). If set to 1b, GRWIZL will enable the receiver as soon as the Receive FSM enters IDLE state. Any pending RX stop request is cleared.

84.8.17 DMA Status Register

Table 1716. 0x88 - DMASTS - DMA Status Register

31	24	23	22	21	20	19	18	17
Reserved		TXC	RXC	LE	TO	Reserved		BEDESC
0x00		0	0	0	0	00		0x000
r		wc	wc	wc	wc	r		wc

	8	7		4	3	2	1	0
BEDESC		BECODE			TX	RX	TA	RA
0x000		0x0			0	0	0	0
wc		wc			wc	wc	r	r

23	Programmable command TX status (TXC). If set, the codec has flagged the transmission of a programmable command whose individual IRQ bit is also set. The DMA layer generates an interrupt if enabled in the Interrupt Control Register.
22	Programmable command RX status (RXC). If set, the codec has flagged the reception of a programmable command whose individual IRQ bit is also set. The DMA layer generates an interrupt if enabled in the Interrupt Control Register.
21	Link event (LE). If set, the codec has detected an event in the WizardLink communication, such as RX overrun or error counter overflow. The DMA layer generates an interrupt if enabled in the Interrupt Control Register.
20	AHB Register Timeout (TO). Set when the DMA engine has reached the internal timeout (256 AMBA clock cycles) while waiting for a reply when accessing the AHB registers implemented in the codec clock domain.
17: 8	Bus Master Error - Descriptor (BEDESC). This field identifies the descriptor selected when an error occurred during an access through the bus master interface. Cleared when the BECODE field is written to a value other than 0x0.
7: 4	Bus Master Error - Code (BECODE). This field specifies what type of error occurred when accessing the bus. Writing a value other than 0x0 to this field clears the content of all the bus master error-related fields: BEDESC and BECODE. Encoding:
	0x0: No errors
	0x1: Fetching RX descriptor
	0x2: Storing data bytes of a WizardLink packet (RX)
	0x3: Storing K-flags of a WizardLink packet (RX)
	0x4: Updating RX descriptor
	0x5: Fetching TX descriptor
	0x6: Fetching K-flags of a WizardLink packet (TX)

0x7: Fetching data bytes of a WizardLink packet (TX)

0x8: Updating TX descriptor

3	Packet transmitted (TX). If set to 1b, the DMA engine has fetched and passed a complete WizardLink packet on to the codec, and the associated descriptor has been updated. Cleared to 0b when written.
2	Packet received (RX). If set to 1b, the DMA engine has read a complete WizardLink packet from the codec and written it to external memory, and the associated descriptor has been updated. Cleared to 0b when written.
1	Transmitter Active (TA). If set to 1b, the transmitter FSM is active. This may imply that the Transmitter Enable bit in the DMA Control Register is set, or that the DMA engine is still completing an ongoing operation before being disabled.
0	Receiver Active (RA). If set to 1b, the receiver FSM is active. This may imply that the Receiver Enable bit in the DMA Control Register is set, or that the DMA engine is still completing an ongoing operation before being disabled.

84.8.18 WizardLink Enable Register

Table 1717. 0x8C - WIZLEN - WizardLink Enable Register

31		16
	Reserved	
	0x0000	
	r	

15		1	0
	Reserved		EN
	0x0000		-
	r		rw

0	WizardLink Enable (EN). This bit is used to enable the WizardLink mode of operation if GRWIZL is implemented together with other protocols as part of the GRHSSL IP. If WizardLink is the only protocol implemented, this bit will read as 1b and writing will have no effect.

84.8.19 Interrupt Control Register

Table 1718. 0x90 - IRQ - Interrupt Control Register

31						16
		Reserved				
		0x0000				
		r				

15	6	5	4	3	2	1	0
Reserved		TXC	RXC	LE	BME	TX	RX
0x000		0	0	0	0	0	0
r		rw	rw	rw	rw	rw	rw

5	Programmable Command Transmission Interrupt Enable (TXC). If set, GRWIZL will generate an AMBA interrupt upon transmitting a programmable command with its individual IRQ enable bit set.
4	Programmable Command Reception Interrupt Enable (RXC). If set, GRWIZL will generate an AMBA interrupt upon receiving a word matching an enabled programmable command with its individual IRQ enable bit set.
3	Link Event Interrupt Enable (LE). If set to 1b, GRWIZL will generate an AMBA interrupt when the core detects an event in the WizardLink communication, such as RX overrun or error counter overflow.
2	Bus Master Error Interrupt Enable (BEI). If set to 1b, GRWIZL will generate an AMBA interrupt when an error is detected during an access over the bus master interface.
1	Transmit Interrupt Enable (TI). If set to 1b, GRWIZL will generate AMBA interrupts after transmitting a packet and updating the corresponding descriptor. Note that the Interrupt Enable bit in the descriptor associated with the packet shall also be set to 1b.
0	Receive Interrupt Enable (RI). If set to 1b, GRWIZL will generate AMBA interrupts after storing a packet and updating the corresponding descriptor. Note that the Interrupt Enable bit in the descriptor associated with the packet shall also be set to 1b.

84.8.20 TX Descriptor Table Address Register

Table 1719. 0xA0 - TXDADDR - TX Descriptor Table Address Register

31	x+1
TXADDR	
All 0b	
rw	

x		4	3		0
TXDESCSEL			Reserved		
All 0b			0x0		
rw			r		

31: x+1	TX Descriptor Table Address (TXADDR). Sets the base address of the descriptor table. The number of bits of this field depends on the size of the DMA transmit descriptor table, determined by the generic *num_txdesc*. The value of x is calculated as follows: $x = log_2(num\_txdesc) + 3$.
x: 4	TX Descriptor Selector (TXDESCSEL). Offset within the descriptor table. Shows which descriptor is currently used by the core. For each new descriptor read, the selector will increase by 16 and eventually wrap to zero again. The number of bits of this field depends on the size of the DMA transmit descriptor table, determined by the generic *num_txdesc*. The value of x is calculated as follows: $x = log_2(num\_txdesc) + 3$.

84.8.21 RX Descriptor Table Address Register

Table 1720. 0xA4 - RXDADDR - RX Descriptor Table Address Register

31	x+1
RXADDR	
All 0b	
rw	

x		4	3		0
RXDESCSEL			Reserved		
All 0b			0x0		
rw			r		

31: x+1	RX Descriptor Table Address (RXADDR). Sets the base address of the descriptor table. The number of bits of this field depends on the size of the DMA receive descriptor table, determined by the generic *num_rxdesc*. The value of x is calculated as follows: $x = log_2(num\_rxdesc) + 3$.
x: 4	RX Descriptor Selector (RXDESCSEL). Offset within the descriptor table. Shows which descriptor is currently used by the core. For each new descriptor read, the selector will increase by 16 and eventually wrap to zero again. The number of bits of this field depends on the size of the DMA receive descriptor table, determined by the generic *num_rxdesc*. The value of x is calculated as follows: $x = log_2(num\_rxdesc) + 3$.

84.8.22 Descriptor Control Register

Table 1721. 0xA8 - DCTRL - Descriptor Control Register

31	30	29							16
TDA	RDA	Reserved							
0	0	0x0000							
r	r	r							

15						4	3	2	1	0
Reserved							CTD	CRD	NTD	NRD
0x000							0	0	0	0
r							w	w	w	w

31	Transmit Descriptor Available (TDA). Read-only bit indicating whether the TX descriptor table contains descriptors yet to be fetched and processed. Cleared when the core finds a disabled descriptor (Descriptor Enable bit set to 0b inside the descriptor) or when a bus master error occurs during transmission.
30	Receive Descriptor Available (RDA). Read-only bit indicating whether the RX descriptor table contains descriptors yet to be fetched and processed. Cleared when the core finds a disabled descriptor (Descriptor Enable bit set to 0b inside the descriptor) or when a bus master error occurs during reception.
3	Clear Transmit Descriptor Table (CTD). Write-only bit that, when set, clears the content of the TX Descriptor Table. It takes effect only when the DMA channel is in IDLE state.
2	Clear Receive Descriptor Table (CRD). Write-only bit that, when set, clears the content of the RX Descriptor Table. It takes effect only when the DMA channel is in IDLE state.
1	New Transmit Descriptor Available (NTD). Write-only bit to indicate that new descriptors have been added to the TX Descriptor table. It takes effect only when the DMA channel is in IDLE state.
0	New Receive Descriptor Available (NRD). Write-only bit to indicate that new descriptors have been added to the RX Descriptor table. It takes effect only when the DMA channel is in IDLE state.

84.9 Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0C7 (GRWIZL). For description of vendor and device identifiers see GRLIB IP Library User's Manual.

84.10 Configuration options

Table 1722 shows the configuration options of the core (VHDL generics).

Table 1722. Configuration options

Generic name	Function	Allowed range	Default
tech	Technology for the internal memories.	0 - NTECH	inferred (0)
hmindex	AHB master index. Only present in the AHB wrapper.	0 - NAHBMST-1	0
hsindex	AHB slave index.	0 - NAHBSLV-1	0
haddr	Addr field of the AHB bar.	0 - 16#FFF#	0
hmask	Mask field of the AHB bar.	0 - 16#FFF#	16#FFF#
hirq	Interrupt line used by GRWIZL.	0 - NAHBIRQ-1	0
use_8b10b	If set, internal 8B10B encoding and decoding is activated.	0 - 1	1
use_sep_txclk	If set, the SerDes transmission clock is decoupled from the WizardLink core clock. An additional transmit buffer is instantiated for this reason.	0 - 1	0
sel_16_20_bit_-mode	If set, the SerDes interface is 16+2 bit (without 8B10B) or 20 bit (with 8B10B) wide instead of 36/40 bit. If set, *use_sep_txclk* must also be set.	0 - 1	0
num_txdesc	Size of the TX descriptor table in number of descriptors.	64, 128, 256, 512	64
num_rxdesc	Size of the RX descriptor table in number of descriptors.	128, 256, 512, 1024	128
depth_dma_fifo	Depth of the DMA FIFOs. Sets the number of entries in the 144-bit transmitter and receiver FIFOs.	16 - 256	32
depth_tx_buf	Log(Depth) of the codec internal TX buffer, expressed as number of address bits.	1 - 32	10
depth_rx_buf	Log(Depth) of the codec internal RX buffer, expressed as number of address bits.	1 - 32	10
use_async_rxrst	Force asynchronous reset in the recovered clock domain, regardless of the general GRLIB settings.	0 - 1	0
ft_core_buf	Enable fault-tolerance against SEU errors for the codec internal TX and RX buffers. Possible options are byte parity protection (ft = 1), TMR registers (ft = 2), SEC-DED BCH (ft = 4) or technology specific protection (ft = 5). If set to 0, no protection is implemented.	0 - 5	0
ft_core_if	Enable fault-tolerance against SEU errors for the clock-domain-crossing FIFOs in the Interface Layer of the codec. The core supports the same configurations as above.	0 - 5	0
ft_dma	Enable fault-tolerance against SEU errors for the TX/RX FIFOs in the DMA layer. The core supports the same configurations as above.	0 - 5	0
scantest	Enable Scan Test support.	0 - 1	0
ahbbits	Width of AHB read/write data buses and maximum access size. Only present in the AHB wrapper.	32, 64, 128	AHBDW
lendian	Select endianness of the system: 0 for big-endian, 1 for little-endian. Only present in the AXI wrapper.	0 - 1	1
numextwc	If set, implement an external FIFO interface that can be used to bypass the DMA engine when transmitting and receiving WizardLink data.	0 - 1	0

         );
```

85 I2C2AHB - I^{2}C to AHB bridge

85.1 Overview

The I^{2}C slave to AHB bridge is an I^{2}C slave that provides a link between the I^{2}C bus and AMBA AHB. The core is compatible with the Philips I^{2}C standard and external pull-up resistors must be supplied for both bus lines.

On the I^{2}C bus the slave acts as an I^{2}C memory device where accesses to the slave are translated to AMBA accesses. The core can translate I^{2}C accesses to AMBA byte, halfword or word accesses. The core makes use of I^{2}C clock stretching but can also be configured to use a special mode without clock stretching in order to support systems where master or physical layer limitations prevent stretching of the I^{2}C clock period.

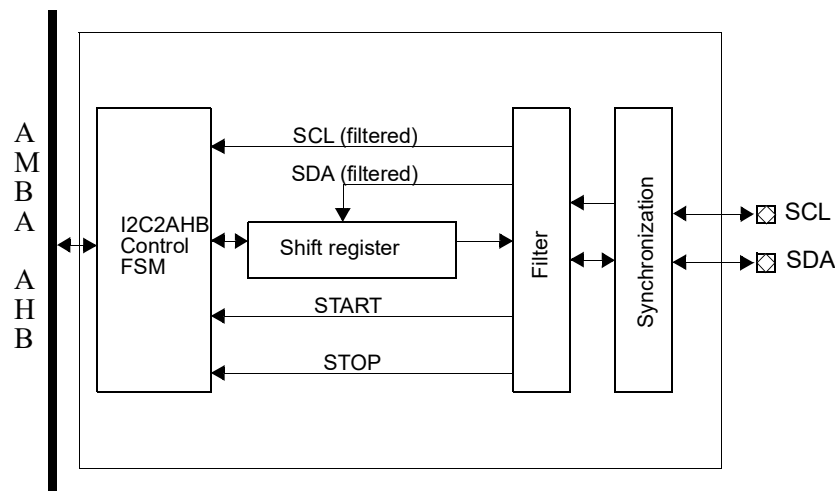
GRLIB also contains another I^{2}C slave core, without an AHB interface, where the transfer of each individual byte is controlled by software via an APB interface, see the I2CSLV core documentation for more information.


Figure 229. Block diagram, optional APB interface not shown

85.2 Operation

85.2.1 Transmission protocol

The I^{2}C-bus is a simple 2-wire serial multi-master bus with collision detection and arbitration. The bus consists of a serial data line (SDA) and a serial clock line (SCL). The I^{2}C standard defines three transmission speeds; Standard (100 kb/s), Fast (400 kb/s) and High speed (3.4 Mb/s).

A transfer on the I^{2}C-bus begins with a START condition. A START condition is defined as a high to low transition of the SDA line while SCL is high. Transfers end with a STOP condition, defined as a low to high transition of the SDA line while SCL is high. These conditions are always generated by a master. The bus is considered to be busy after the START condition and is free after a certain amount of time following a STOP condition. The bus free time required between a STOP and a START condition is defined in the I^{2}C-bus specification and is dependent on the bus bit rate.

Figure 230 shows a data transfer taking place over the I^{2}C-bus. The master first generates a START condition and then transmits the 7-bit slave address. The bit following the slave address is the R/$\overline{W}$ bit which determines the direction of the data transfer. In this case the R/$\overline{W}$ bit is zero indicating a write operation. After the master has transmitted the address and the R/$\overline{W}$ bit it releases the SDA line. The receiver pulls the SDA line low to acknowledge the transfer. If the receiver does not acknowledge the

GRIP

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

transfer, the master may generate a STOP condition to abort the transfer or start a new transfer by generating a repeated START condition.

After the address has been acknowledged the master transmits the data byte. If the R/$\overline{\text{W}}$ bit had been set to '1' the master would have acted as a receiver during this phase of the transfer. After the data byte has been transferred the receiver acknowledges the byte and the master generates a STOP condition to complete the transfer.

Figure 230. Complete I^{2}C data transfer

If the data bit rate is too high for a slave device or if the slave needs time to process data, it may stretch the clock period by keeping SCL low after the master has driven SCL low. Clock stretching is a configurable parameter of the core (see sections 85.2.4 and 85.2.6).

85.2.2 Slave addressing

The core's I^{2}C addresses are set with VHDL generics at implementation time. If the core has been implemented with the optional APB interface, then the I^{2}C addresses can be changed via registers available via APB.

The core responds to two addresses on the I^{2}C bus. Accesses to the I2C memory address are translated to AMBA AHB accesses and accesses to the I^{2}C configuration address access the core's configuration register.

85.2.3 System clock requirements and sampling

The core samples the incoming I^{2}C SCL clock and does not introduce any additional clock domains into the system. Both the SCL and SDA lines first pass through two stage synchronizers and are then filtered with a low pass filter consisting of four registers.

START and STOP conditions are detected if the SDA line, while SCL is high, is at one value for two system clock cycles, toggles and keeps the new level for two system clock cycles.

The synchronizers and filters constrain the minimum system frequency. The core requires the SCL signal to be stable for at least four system clock cycles before the core accepts the SCL value as the new clock value. The core's reaction to transitions will be additionally delayed since both lines are taken through two-stage synchronizers before they are filtered. Therefore it takes the core over eight system clock cycles to discover a transition on SCL.

+46 31 7758650 | frontgrade.com/gaisler

85.2.4 Configuration register access

The I^{2}C configuration register is accessed via a separate I^{2}C address (I^{2}C configuration address). The configuration register has the layout shown in table 1725.

Table 1725. I2C2AHB configuration register

7	6	5	4	3	2	1	0
Reserved		PROT	MEXC	DMAACT	NACK	HSIZE	

7:6	Reserved, always zero (read only)
5	Memory protection triggered (PROT) - '1' if last AHB access was outside the allowed memory area. Updated after each AMBA access (read only)
4	Memory exception (MEXC) - '1' if core receives AMBA ERROR response. Updated after each AMBA access (read only)
3	DMA active (DMAACT) - '1' if core is currently performing a DMA operation.
2	NACK (NACK) - Use NACK instead of clock stretching. See documentation in section 85.2.6.
1:0	AMBA access size (HSIZE) - Controls the access size that the core will use for AMBA accesses. 0: byte, 1: halfword, 2: word. HSIZE = "11" is illegal.

Reset value: 0x02

Reads from the I^{2}C configuration address will return the current value of the configuration register. Writes to the I^{2}C configuration address will affect the writable bits in the configuration register.

85.2.5 AHB accesses

All AMBA accesses are done in big endian format. The first byte sent to or from the slave is the most significant byte.

To write a word on the AHB bus the following I2C bus sequence should be performed:

1. Generate START condition

2. Send I2C memory address with the R/$\overline{\text{W}}$ bit set to '0'.

3. Send four byte AMBA address, the most significant byte is transferred first

4. Send four bytes to write to the specified address

5. If more than four consecutive bytes should be written, continue to send additional bytes, otherwise go to 6.

6. Generate STOP condition

To perform a read access on the AHB bus, the following I2C bus sequence should be performed:

1. Generate START condition

2. Send I2C memory address with the R/$\overline{\text{W}}$ bit set to '0'.

3. Send four byte AMBA address, the most significant byte is transferred first

4. Generate (repeated) START condition

5. Send I2C memory address with the R/$\overline{\text{W}}$ bit set to '1'.

6. Read the required number of bytes and NACK the last byte

7. Generate stop condition

During consecutive read or write operations, the core will automatically increment the address. The access size (byte, halfword or word) used on AHB is set via the HSIZE field in the I2C2AHB configuration register.

The core always respects the access size specified via the HSIZE field. If a write operation writes fewer bytes than what is required to do an access of the specified HSIZE then the write data will be dropped, no access will be made on AHB. If a read operation reads fewer bytes than what is specified by HSIZE then the remaining read data will be dropped at a START or STOP condition. This means,

GRIP
Apr 2024, Version 2024.1

1422

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

for instance, that if HSIZE is "10" (word) the core will perform two word accesses if a master reads one byte, generates a repeated start condition, and reads one more byte. Between these two accesses the address will have been automatically increased, so the fist access will be to address *n* and the second to address *n+4*.

The automatic address increment means that it is possible to write data and then immediately read the data located at the next memory position. As an example, the following sequence will write a word to address 0 and then read a word from address 4:

1. Generate START condition

2. Send I2C memory address with the R/$\overline{\text{W}}$ bit set to '0'.

3. Send four byte AMBA address, all zero.

4. Send four bytes to write to the specified address

5. Generate (repeated) START condition

6. Send I2C memory address with the R/$\overline{\text{W}}$ bit set to '1'.

7. Read the required number of bytes and lack the last byte

8. Generate stop condition

The core will not mask any address bits. Therefore it is important that the I^2C master respects AMBA rules when performing halfword and word accesses. A halfword access must be aligned on a two byte address boundary (least significant bit of address must be zero) and a word access must be aligned on a four byte boundary (two least significant address bits must be zero).

The core can be configured to generate interrupt requests when an AHB access is performed if the core is implemented with the APB register interface, see the APB register documentation for details.

85.2.6 Clock stretching or NACK mode

The core has two main modes of operation for AMBA accesses. In one mode the core will use clock stretching while performing an AHB operation and in the other mode the core will not acknowledge bytes (abort the I^2C access) when the core is busy. Clock stretching is the preferred mode of operation. The NACK mode can be used in scenarios where the I^2C master or physical layer does not support clock stretching. The mode to use is selected via the NACK field in the I^2C configuration register.

When clock stretching is enabled (NACK field is '0') the core will stretch the clock when the slave is accessed (via the I2C memory address) and the slave is busy processing a transfer. Clock stretching is also used when a data byte has been transmitted, or received, to keep SCL low until a DMA operation has completed. In the transmit (AMBA read) case SCL is kept low before the rising edge of the first byte. In the receive case (AMBA write) the ACK cycle for the previous byte is stretched.

When clock stretching is disabled (NACK field is '1') the core will never stretch the SCL line. If the core is busy performing DMA when it is addressed, the address will not be acknowledged. If the core performs consecutive writes and the first write operation has not finished the core will now acknowledge the written byte. If the core performs a read operation and the read DMA operation has not finished when the core is supposed to deliver data then the core will go to its idle state and not respond to more accesses until a START condition is generated on the bus. This last part means that the NACK mode is practically unusable in systems where the AMBA access can take longer than one I^2C clock period. This can be compensated by using a very slow I^2C clock.

85.2.7 Memory protection

The core is configured at implementation time to only allow accesses to a specified AHB address range (which can be the full 4 GiB AMBA address range). If the core has been implemented with the optional APB register interface then the address range is soft configurable and the reset value is specified with VHDL generics.

The VHDL generics *ahbaddrh* and *ahbaddrl* define the base address for the allowed area. The VHDL generics *ahbmaskh* and *ahbmaskl* define the size of the area. The generics are used to assign the memory protection area's address and mask in the following way:

Protection address, bits 31:16 (*protaddr[31:16]*): ahbaddrh
Protection address, bits 15:0 (*protaddr[15:0]*): ahbaddrl
Protection mask, bits 31:16 (*protmask[31:16]*): ahbmaskh
Protection mask, bits 15:0 (*protmask[15:0]*): ahbmaskl

Before the core performs an AMBA access it will perform the check:

   (((incoming address) xor (protaddr)) and protmask) /= 0x00000000

If the above expression is true (one or several bits in the incoming address differ from the protection address, and the corresponding mask bits are set to '1') then the access is inhibited. As an example, assume that *protaddr* is 0xA0000000 and *protmask* is 0xF0000000. Since *protmask* only has ones in the most significant nibble, the check above can only be triggered for these bits. The address range of allowed accessed will thus be 0xA0000000 - 0xAFFFFFFF.

The memory protection check is performed at the time when the core is to perform the AHB access. It is possible to start a write operation and transmit an illegal address to the core without any errors. If additional bytes are transmitted (so that a HSIZE access can be made) the core will NACK the byte that triggers the AHB access.

For a read operation the core will NACK the I^2C memory address of the first AHB access of the read in case the access would be to restricted memory. If consecutive bytes are read from the core and one of the later accesses lead to restricted memory being accessed, then the core will abort all operations and enter its idle state. In this case junk data will be returned and there is no way for the core to alert the master that memory protection has been triggered.

The core will set the configuration register bit PROT if an access is attempted outside the allowed address range. This bit is updated on each AHB access and will be cleared by an access inside the allowed range. Note that the (optional) APB status register has a PROT field with a slightly different behavior.

85.3   Registers

The core can optionally be implemented with an APB interface that provides registers mapped into APB address space.

Table 1726.I^2C slave registers

APB address offset	Register
0x00	Control register
0x04	Status register
0x08	Protection address register
0x0C	Protection mask register
0x10	I2C slave memory address register
0x14	I2C slave configuration address register

85.3.1 Control Register

*Table 1727.*0x0 - CTRL - Control register

31		2	1	0
RESERVED			IRQEN	EN
0			0	*
r			rw	rw

31 : 2	RESERVED
1	Interrupt enable (IRQEN) - When this bit is set to '1' the core will generate an interrupt each time the DMA field in the status register transitions from '0' to '1'.
0	Core enable (EN) - When this bit is set to '1' the core is enabled and will respond to I2C accesses. Otherwise the core will not react to I2C traffic.

Reset value: Implementation dependent

85.3.2 Status Register

*Table 1728.*0x04 - STAT - Status register

31		3	2	1	0
RESERVED			PROT	WR	DMA

31 : 3	RESERVED
2	Protection triggered (PROT) - Set to '1' if an access has triggered the memory protection. This bit will remain set until cleared by writing '1' to this position. Note that the other fields in this register will be updated on each AHB access while the PROT bit will remain at '1' once set.
1	Write access (WR) - Last AHB access performed was a write access. This bit is read only.
0	Direct Memory Access (DMA) - This bit gets set to '1' each time the core attempts to perform an AHB access. By setting the IRQEN field in the control register this condition can generate an interrupt. This bit can be cleared by software by writing '1' to this position.

85.3.3 Protection Address Register

*Table 1729.*0x08 - PADDR - Protection address register

31	0
PROTADDR	
*	
rw	

31 : 0	Protection address (PROTADDR) - Defines the base address for the memory area where the core is allowed to make accesses.

85.3.4 Protection Mask Register

*Table 1730.*0x0C - PMASK - Protection mask register

31	0
PROTMASK	
*	
rw	

31 : 0	Protection mask (PROTMASK) - Selects which bits in the Protection address register that are used to define the protected memory area.

85.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x00B. For a description of vendor and device identifiers see the GRLIB IP Library User's Manual.

85.5 Implementation

85.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

85.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

85.6 Configuration options

Table 1733 shows the configuration options of the core (VHDL generics). Two different top level entites for the core is available. One with the optional APB interface (i2c2ahb_apb) and one without the APB interface (i2c2ahb). The entity without the APB interface has fewer generics as indicated in the table below.

Table 1733. Configuration options

Generic name	Function	Allowed range	Default
hindex	AHB master index	0 - NAHBMST	0
ahbaddrh	Defines bits 31:16 of the address used for the memory protection area	0 - 16#FFFF#	0

GRIP

+46 31 7758650 | frontgrade.com/gaisler

*Table 1733.*Configuration options

Generic name	Function	Allowed range	Default
ahbaddrl	Defines bits 15:0 of the address used for the memory protection area	0 - 16#FFFF#	0
ahbmaskh	Defines bits 31:16 of the mask used for the memory protection area	0 - 16#FFFF#	0
ahbmaskl	Defines bits 15:0 of the mask used for the memory protection area	0 - 16#FFFF#	0
resen	Reset value for core enable bit (only available on the i2c2ahb_apb entity).	0 - 1	0
pindex	APB slave index (only available on the i2c2ahb_apb entity).	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR (only available on the i2c2ahb_apb entity).	0 - 16#FFF#	0
pmask	MASK field of the APB BAR (only available on the i2c2ahb_apb entity).	0 - 16#FFF#	16#FFF#
pirq	Interrupt line driven by APB interface (only available on the i2c2ahb_apb entity).	0 - NAHBIRQ-1	0
i2caddr	The slave's (initial) I^2C address. i2caddr specified the core's I2C memory address and (i2caddr+1) will be the cores I2C configuration address.	0 - 126	0
oepol	Output enable polarity	0 - 1	0
filter	Low-pass filter length. This generic should specify, in number of system clock cycles plus one, the time of the shortest pulse on the I2C bus to be registered as a valid value. For instance, to disregard any pulse that is 50 ns or shorter in a system with a system frequency of 54 MHz this generic should be set to: ((pulse time) / (clock period)) + 1 = (50 ns) / ((1/(54 MHz)) + 1 = 3.7 The value from this calculation should always be rounded up. In other words an appropriate filter length for a 54 MHz system is 4.	2 - 512	2

86   I2CMST - I^{2}C-master

86.1   Overview

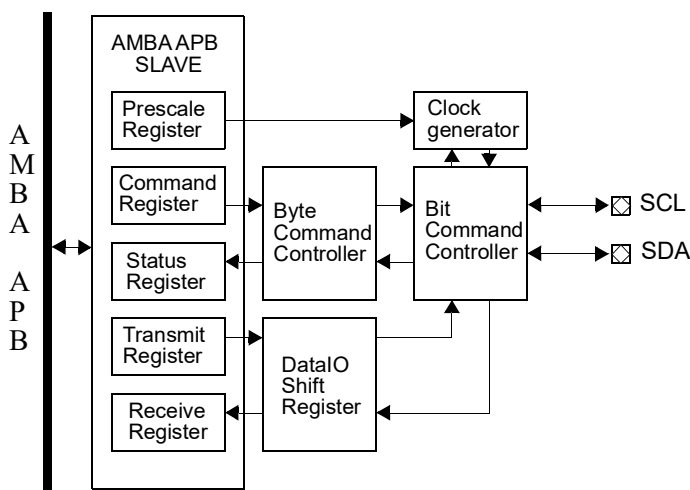
The I^{2}C-master core is a modified version of the OpenCores I^{2}C-Master with an AMBA APB interface. The core is compatible with Philips I^{2}C standard and supports 7- and 10-bit addressing. Standard-mode (100 kb/s) and Fast-mode (400 kb/s) operation are supported directly. External pull-up resistors must be supplied for both bus lines.


Figure 231. Block diagram

86.2   Operation

86.2.1   Transmission protocol

The I^{2}C-bus is a simple 2-wire serial multi-master bus with collision detection and arbitration. The bus consists of a serial data line (SDA) and a serial clock line (SCL). The I^{2}C standard defines three transmission speeds; Standard (100 kb/s), Fast (400 kb/s) and High speed (3.4 Mb/s).

A transfer on the I^{2}C-bus begins with a START condition. A START condition is defined as a high to low transition of the SDA line while SCL is high. Transfers end with a STOP condition, defined as a low to high transition of the SDA line while SCL is high. These conditions are always generated by a master. The bus is considered to be busy after the START condition and is free after a certain amount of time following a STOP condition. The bus free time required between a STOP and a START condition is defined in the I^{2}C-bus specification and is dependent on the bus bit rate.

Figure 232 shows a data transfer taking place over the I^{2}C-bus. The master first generates a START condition and then transmits the 7-bit slave address. The bit following the slave address is the R/$\overline{W}$ bit which determines the direction of the data transfer. In this case the R/$\overline{W}$ bit is zero indicating a write operation. After the master has transmitted the address and the R/$\overline{W}$ bit it releases the SDA line. The receiver pulls the SDA line low to acknowledge the transfer. If the receiver does not acknowledge the transfer, the master may generate a STOP condition to abort the transfer or start a new transfer by generating a repeated START condition.

After the first byte has been acknowledged the master transmits the data byte. If the R/$\overline{W}$ bit had been set to '1' the master would have acted as a receiver during this phase of the transfer. After the data byte has been transferred the receiver acknowledges the byte and the master generates a STOP condition to complete the transfer. Section 86.2.3 contains three more example transfers from the perspective of a software driver.
Figure 232. Complete I^{2}C data transfer

If the data bitrate is too high for a slave device, it may stretch the clock period by keeping SCL low after the master has driven SCL low.

86.2.2 Clock generation

The core uses the prescale register to determine the frequency of the SCL clock line and of the 5*SCL clock that the core uses internally. To calculate the prescale value use the formula:

$$Prescale = \frac{AMBAclockfrequency}{5 \cdot SCLfrequency} - 1$$

The *SCLfrequency* is 100 kHz for Standard-mode operation (100 kb/s) and 400 kHz for Fast mode operation. To use the core in Standard-mode in a system with a 60 MHz clock driving the AMBA bus the required prescale value is:

$$Prescale = \frac{60Mhz}{5 \cdot 100kHz} - 1 = 119 = 0x77$$

Note that the prescale register should only be changed when the core is disabled. The minimum recommended prescale value is 3 due to synchronization issues. This limits the minimum system frequency to 2 MHz for operation in Standard-mode (to be able to generate a 100 kHz SCL clock). However, a system frequency of 2 MHz will not allow the implementation fulfill the 100 ns minimum requirement for data setup time (required for Fast-mode operation). For compatibility with the I^{2}C Specification, in terms of minimum required data setup time, the minimum allowed system frequency is 20 MHz due to synchronization issues. If the core is run at lower system frequencies, care should be taken so that data from devices is stable on the bus one system clock period before the rising edge of SCL.

86.2.3 Software operational model

The core is initialized by writing an appropriate value to the clock prescale register and then setting the enable (EN) bit in the control register. Interrupts are enabled via the interrupt enable (IEN) bit in the control register.

To write a byte to a slave the I^{2}C-master must generate a START condition and send the slave address with the R/$\overline{W}$ bit set to '0'. After the slave has acknowledged the address, the master transmits the

data, waits for an acknowledge and generates a STOP condition. The sequence below instructs the core to perform a write:

1. Left-shift the I^{2}C-device address one position and write the result to the transmit register. The least significant bit of the transmit register (R/$\overline{\text{W}}$) is set to '0'.

2. Generate START condition and send contents of transmit register by setting the STA and WR bits in the command register.

3. Wait for interrupt, or for TIP bit in the status register to go low.

4. Read RxACK bit in status register. If RxACK is low the slave has acknowledged the transfer, proceed to step 5. If RxACK is set the device did not acknowledge the transfer, go to step 1.

5. Write the slave-data to the transmit register.

6. Send the data to the slave and generate a stop condition by setting STO and WR in the command register.

7. Wait for interrupt, or for TIP bit in the status register to go low.

8. Verify that the slave has acknowledged the data by reading the RxACK bit in the status register. RxACK should not be set.

To read a byte from an I^{2}C-connected memory much of the sequence above is repeated. The data written in this case is the memory location on the I^{2}C slave. After the address has been written the master generates a repeated START condition and reads the data from the slave. The sequence that software should perform to read from a memory device:

1. Left-shift the I^{2}C-device address one position and write the result to the transmit register. The least significant bit of the transmit register (R/W) is set to '0'.

2. Generate START condition and send contents of transmit register by setting the STA and WR bits in the command register.

3. Wait for interrupt or for TIP bit in the status register to go low.

4. Read RxACK bit in status register. If RxACK is low the slave has acknowledged the transfer, proceed to step 5. If RxACK is set the device did not acknowledge the transfer, go to step 1.

5. Write the memory location to be read from the slave to the transmit register.

6. Set the WR bit in the command register. Note that a STOP condition is not generated here.

7. Wait for interrupt, or for TIP bit in the status register to go low.

8. Read RxACK bit in the status register. RxACK should be low.

9. Address the I^{2}C-slave again by writing its left-shifted address into the transmit register. Set the least significant bit of the transmit register (R/W) to '1' to read from the slave.

10. Set the STA and WR bits in the command register to generate a repeated START condition.

11. Wait for interrupt, or for TIP bit in the status register to go low.

12. Read RxACK bit in the status register. The slave should acknowledge the transfer.

13. Prepare to receive the data read from the I^{2}C-connected memory. Set bits RD, ACK and STO on the command register. Setting the ACK bit NAKs the received data and signifies the end of the transfer.

14. Wait for interrupt, or for TIP in the status register to go low.

15. The received data can now be read from the receive register.

To perform sequential reads the master can iterate over steps 13 - 15 by not setting the ACK and STO bits in step 13. To end the sequential reads the ACK and STO bits are set. Consult the documentation of the I^{2}C-slave to see if sequential reads are supported.

The final sequence illustrates how to write one byte to an I^{2}C-slave which requires addressing. First the slave is addressed and the memory location on the slave is transmitted. After the slave has acknowledged the memory location the data to be written is transmitted without a generating a new START condition:

1. Left-shift the I^{2}C-device address one position and write the result to the transmit register. The least significant bit of the transmit register (R/W) is set to '0'.

2. Generate START condition and send contents of transmit register by setting the STA and WR bits in the command register.

3. Wait for interrupt or for TIP bit in the status register to go low.

4. Read RxACK bit in status register. If RxACK is low the slave has acknowledged the transfer, proceed to step 5. If RxACK is set the device did not acknowledge the transfer, go to step 1.

5. Write the memory location to be written from the slave to the transmit register.

6. Set the WR bit in the command register.

7. Wait for interrupt, or for TIP bit in the status register to go low.

8. Read RxACK bit in the status register. RxACK should be low.

9. Write the data byte to the transmit register.

10. Set WR and STO in the command register to send the data byte and then generate a STOP condition.

11. Wait for interrupt, or for TIP bit in the status register to go low.

12. Check RxACK bit in the status register. If the write succeeded the slave should acknowledge the data byte transfer.

The example sequences presented here can be generally applied to I^{2}C-slaves. However, some devices may deviate from the protocol above, please consult the documentation of the I^{2}C-slave in question. Note that a software driver should also monitor the arbitration lost (AL) bit in the status register.

86.2.4 Signal filters

The core is configured at implementation to use one of two possible filter strategies: a static filter or a dynamic filter, the selection between the two options is made with the *dynfilt* VHDL generic.

With a static filter (*dynfilt* = 0) the core will implement low-pass filters using simple shift registers. The number of shift registers is determined by the VHDL generic *filter*. When all bits in a shift register are equal, the core will consider the state of the input signal (SCL or SDA) to have changed. An appropriate value for the filter generic is calculated via:

$$filter = \frac{\overline{pulsetime}}{systemclockperiod} + 1$$

To disregard any pulse that is 50 ns or shorter in a system with a system frequency of 54 MHz the *filter* generic should be set to: (50 ns) / ((1/(54 MHz)) + 1 = 3.7. The value from this calculation should always be rounded up. In other words an appropriate filter length for a 54 MHz system is 4.

With a dynamic filter (*dynfilt* = 1) the VHDL generic *filter* determines the number of bits implemented in a counter that controls the sample window. The reload value for the counter can then be specified by software by writing to the core's dynamic filter register available via the APB interface. The number of bits required for the dynamic counter is calculated using (where system clock period is the shortest system clock period that the design will use):

$$filter = \log 2 \left(\frac{\overline{pulsetime}}{systemclockperiod} + 1 \right)$$

86.3.7 I²C-Master Dynamic Filter Register

*Table 1744.*0x10 - FILT - I²C-master dynamic filter register

31	x	x-1	0
RESERVED		FILT	
0		all 1	
r		rw*	

31 : x	RESERVED
x-1 : 0	Dynamic filter reload value (FILT) - This field sets the reload value for the dynamic filter counter. The core will ignore all pulses on the bus shorter than FILT * (system clock period) and may also ignore pulses shorter than 2 * FILT * (system clock period) - 1. The reset value of this register is all '1'.
	This register is not available in all implementations, and only for core revisions higher than two (the core's version number can be read from the plug'n'play area). When implemented, the number of bits in the FILT field is implementation dependent. Software can probe the precense of this register by writing 0x1 to the register location and reading back the value. If the read value is non-zero then the core has been implemented with a dynamic filter.

86.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x028. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

86.5 Implementation

86.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

86.6 Configuration options

Table 1745 shows the configuration options of the core (VHDL generics).

Table 1745. Configuration options

Generic name	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by I^2C-master	0 - NAHBIRQ-1	0
oepol	Output enable polarity	0 - 1	0
filter	Low-pass filter length. This generic should specify, in number of system clock cycles plus one, the time of the shortest pulse on the I2C bus to be registered as a valid value. For instance, to disregard any pulse that is 50 ns or shorter in a system with a system frequency of 54 MHz this generic should be set to: ((pulse time) / (clock period)) + 1 = (50 ns) / ((1/(54 MHz)) + 1 = 3.7 The value from this calculation should always be rounded up. In other words an appropriate filter length for a 54 MHz system is 4. Note that the value of this generic changes meaning if the dynfilt generic described below is non-zero. See description below.	2 - 512	2
dynfilt	Dynamic low-pass filter length. If this generic is non-zero the core will be implemented with a configurable filter. If dynfilt is non-zero the filter generic, described above, specifies how many bits that will be implemented for the dynamic filter counter.	0 - 1	0

86.7 Signal descriptions

Table 1746 shows the interface signals of the core (VHDL ports).

Table 1746. Signal descriptions

Signal name	Field	Type	Function	Active

87 I2CSLV - I^{2}C slave

87.1 Overview

The I^{2}C slave core is a simple I^{2}C slave that provides a link between the I^{2}C bus and the AMBA APB. The core is compatible with Philips I^{2}C standard and supports 7- and 10-bit addressing with an optionally software programmable address. Standard-mode (100 kb/s) and Fast-mode (400 kb/s) operation are supported directly. External pull-up resistors must be supplied for both bus lines.

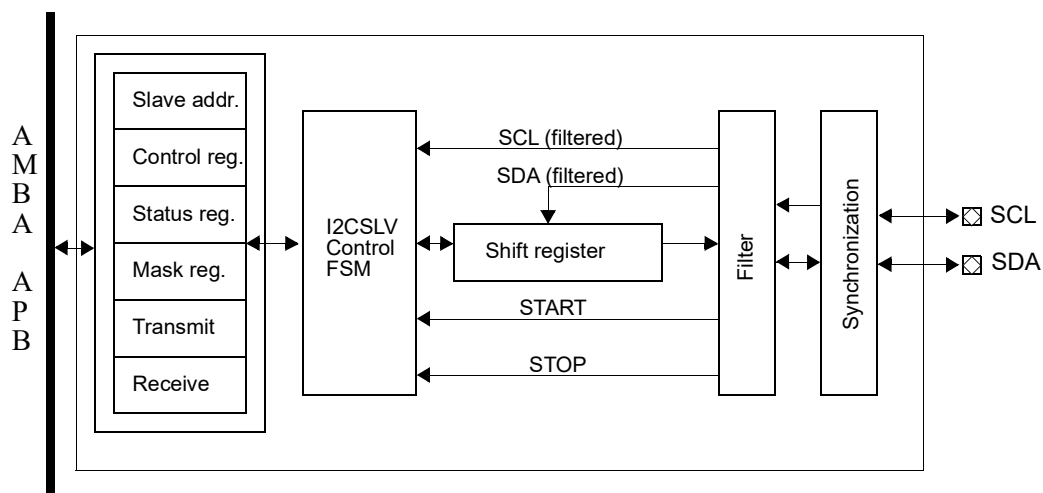
GRLIB also contains another I^{2}C slave core that has DMA capabilities, see the I2C2AHB core documentation for details.


Figure 234. Block diagram

87.2 Operation

87.2.1 Transmission protocol

The I^{2}C-bus is a simple 2-wire serial multi-master bus with collision detection and arbitration. The bus consists of a serial data line (SDA) and a serial clock line (SCL). The I^{2}C standard defines three transmission speeds; Standard (100 kb/s), Fast (400 kb/s) and High speed (3.4 Mb/s).

A transfer on the I^{2}C-bus begins with a START condition. A START condition is defined as a high to low transition of the SDA line while SCL is high. Transfers end with a STOP condition, defined as a low to high transition of the SDA line while SCL is high. These conditions are always generated by a master. The bus is considered to be busy after the START condition and is free after a certain amount of time following a STOP condition. The bus free time required between a STOP and a START condition is defined in the I^{2}C-bus specification and is dependent on the bus bit rate.

Figure 235 shows a data transfer taking place over the I^{2}C-bus. The master first generates a START condition and then transmits the 7-bit slave address. I^{2}C also supports 10-bit addresses, which are discussed briefly below. The bit following the slave address is the R/$\overline{W}$ bit which determines the direction of the data transfer. In this case the R/$\overline{W}$ bit is zero indicating a write operation. After the master has transmitted the address and the R/$\overline{W}$ bit it releases the SDA line. The receiver pulls the SDA line low to acknowledge the transfer. If the receiver does not acknowledge the transfer, the master may generate a STOP condition to abort the transfer or start a new transfer by generating a repeated START condition.

After the address has been acknowledged the master transmits the data byte. If the R/$\overline{W}$ bit had been set to '1' the master would have acted as a receiver during this phase of the transfer. After the data

GRIP
Apr 2024, Version 2024.1

1441

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

byte has been transferred the receiver acknowledges the byte and the master generates a STOP condition to complete the transfer.

Figure 235. Complete I^{2}C data transfer

An I^{2}C slave may also support 10-bit addressing. In this case the master first transmits a pattern of five reserved bits followed by the two first bits of the 10-bit address and the R/$\overline{W}$ bit set to '0'. The next byte contains the remaining bits of the 10-bit address. If the transfer is a write operation the master then transmits data to the slave. To perform a read operation the master generates a repeated START condition and repeats the first part of the 10-bit address phase with the R/$\overline{W}$ bit set to '1'.

If the data bitrate is too high for a slave device or if the slave needs time to process data, it may stretch the clock period by keeping SCL low after the master has driven SCL low.

87.2.2 Slave addressing

The core's addressing support is implementation dependent. The core may have a programmable address and may support 10-bit addresses. If the core has support for 10-bit addressing, the TBA bit of the Slave address register will be set to '1' after reset. If the core's address is programmable this bit is writable and is used by the core to determine if it should listen to a 7- or 10-bit address.

Software can determine the addressing characteristics of the core by writing and reading the Slave address register. The core supports 10-bit addresses if the TBA bit is, or can be set, to '1'. The core has a software programmable address if the SLVADDR field in the same register can be changed.

87.2.3 System clock requirements and sampling

The core samples the incoming I^{2}C SCL clock and does not introduce any additional clock domains into the system. Both the SCL and SDA lines first pass through two stage synchronizers and are then filtered with a low pass filter consisting of four registers.

START and STOP conditions are detected if the SDA line, while SCL is high, is at one value for two system clock cycles, toggles and keeps the new level for two system clock cycles.

The synchronizers and filters constrain the minimum system frequency. The core requires the SCL signal to be stable for at least four system clock cycles before the core accepts the SCL value as the new clock value. The core's reaction to transitions will be additionally delayed since both lines are taken through two-stage synchronizers before they are filtered. Therefore it takes the core over eight system clock cycles to discover a transition on SCL. To use the slave in Standard-mode operation at 100 kHz the recommended minimum system frequency is 2 MHz. For Fast-mode operation at 400 kHz the recommended minimum system frequency is 6 MHz.

1442
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

87.2.4 Operational model

The core has four main modes of operation and is configured to use one of these modes via the Control register bits Receive Mode (RMOD) and Transmit Mode (TMOD). The mode setting controls the core's behavior after a byte has been received or transmitted.

The core will always NAK a received byte if the receive register is full when the whole byte is received. If the receive register is free the value of RMOD determines if the core should continue to listen to the bus for the master's next action or if the core should drive SCL low to force the master into a wait state. If the value of the RMOD field is '0' the core will listen for the master's next action. If the value of the RMOD field is '1' the core will drive SCL low until the Receive register has been read and the Status register bit Byte Received (REC) has been cleared. Note that the core has not accepted a byte if it does not acknowledge the byte.

When the core receives a read request it evaluates the Transmit Valid (TV) bit in the Control register. If the Transmit Valid bit is set the core will acknowledge the address and proceed to transmit the data held in the Transmit register. After a byte has been transmitted the core assigns the value of the Control register bit Transmit Always Valid (TAV) to the Transmit Valid (TV) bit. This mechanism allows the same byte to be sent on all read requests without software intervention. The value of the Transmit Mode (TMOD) bit determines how the core acts after a byte has been transmitted and the master has acknowledged the byte, if the master NAKs the transmitted byte the transfer has ended and the core goes into an idle state. If TMOD is set to '0' when the master acknowledges a byte the core will continue to listen to the bus and wait for the master's next action. If the master continues with a sequential read operation the core will respond to all subsequent requests with the byte located in the Transmit Register. If TMOD is '1' the core will drive SCL low after a master has acknowledged the transmitted byte. SCL will be driven low until the Transmit Valid bit in the control register is set to '1'. Note that if the Transmit Always Valid (TAV) bit is set to '1' the Transmit Valid bit will immediately be set and the core will have show the same behavior for both Transmit modes.

When operating in Receive or Transmit Mode '1', the bus will be blocked by the core until software has acknowledged the transmitted or received byte. This may have a negative impact on bus performance and it also affects single byte transfers since the master is prevented to generate STOP or repeated START conditions when SCL is driven low by the core.

The core reports three types of events via the Status register. When the core NAKs a received byte, or its address in a read transfer, the NAK bit in the Status register will be set. When a byte is successfully received the core asserts the Byte Received (REC) bit. After transmission of a byte, the Byte Transmitted (TRA) bit is asserted. These three bits can be used as interrupt sources by setting the corresponding bits in the Mask register.

87.3 Registers

The core is programmed through registers mapped into APB address space.

*Table 1750.*I^{2}C slave registers

*Table 1751.*0x00 - SLVADDR - Slave address register

31	30	ALEN	ALEN-1	0
TBA	RESERVED		SLVADDR	
*	0		*	
rw	r		rw*	

31	Ten-bit Address (TBA) - When this bit is set the core will interpret the value in the SLVADDR field as a 10-bit address. If the core has 10-bit address support this bit will have the reset value '1'.
30 : ALEN	RESERVED
(ALEN-1):0	Slave address (SLVADDR) - Contains the slave I2C address. The width of the slave address field, ALEN, is 7 bits (6:0) if the core only has support for 7-bit addresses. If the core has support for 10-bit addressing the width of SLVADDR is 10 bits. Depending on the hardware configuration this register may be read only. The core checks the length of the programmed address and will function with 7-bit addresses even if it has support for 10-bit addresses.

I^2C addresses can be allocated by NXP, please see the link in the core's overview section.

87.3.2 Control Register

*Table 1752.*0x04 - CTRL - Control register

31	5	4	3	2	1	0
RESERVED		RMOD	TMOD	TV	TAV	EN
0		NR	NR	NR	NR	NR
r		rw	rw	rw	rw	rw

31 : 5	RESERVED
4	Receive Mode (RMOD) - Selects how the core handles writes:
	'0': The slave accepts one byte and NAKs all other transfers until software has acknowledged the received byte by reading the Receive register.
	'1': The slave accepts one byte and keeps SCL low until software has acknowledged the received byte by reading the Receive register.
3	Transmit Mode (TMOD) - Selects how the core handles reads:
	'0': The slave transmits the same byte to all if the master requests more than one byte in the transfer. The slave then NAKs all read requests as long as the Transmit Valid (TV) bit is unset.
	'1': The slave transmits one byte and then keeps SCL low until software has acknowledged that the byte has been transmitted by setting the Transmit Valid (TV) bit.
2	Transmit Valid (TV) - Software sets this bit to indicate that the data in the transmit register is valid. The core automatically resets this bit when the byte has been transmitted. When this bit is '0' the core will either NAK or insert wait states on incoming read requests, depending on the Transmit Mode (TMOD).
1	Transmit Always Valid (TAV) - When this bit is set, the core will not clear the Transmit Valid (TV) bit when a byte has been transmitted.
0	Enable core (EN) - Enables core. When this bit is set to '1' the core will react to requests to the address set in the Slave address register. If this bit is '0' the core will keep both SCL and SDA inputs in Hi-Z state.

87.3.3 Status Register

*Table 1753.*0x08 - STAT - Status register

31			3	2	1	0
RESERVED				REC	TRA	NAK
0				0	0	0
r				*	wc	wc

31 : 3	RESERVED	
2	Byte Received (REC) - This bit is set to '1' when the core accepts a byte and is automatically cleared when the Receive register has been read.	
1	Byte Transmitted (TRA) - This bit is set to '1' when the core has transmitted a byte and is cleared by writing '1' to this position. Writes of '0' have no effect.	
0	NAK Response (NAK) - This bit is set to '1' when the core has responded with NAK to a read or write request. This bit does not get set to '1' when the core responds with a NAK to an address that does not match the cores address. This bit is cleared by writing '1' to this position, writes of '0' have no effect.	

87.3.4 Mask Register

*Table 1754.*0x0C - MASK - Mask register

31			3	2	1	0
RESERVED				RECE	TRAE	NAKE
0				0	0	0
r				rw	rw	rw

31 : 3	RESERVED	
2	Byte Received Enable (RECE) - When this bit is set the core will generate an interrupt when bit 2 in the Status register gets set.	
1	Byte Transmitted Enable (TRAE) - When this bit is set the core will generate an interrupt when bit 1 in the Status register gets set.	
0	NAK Response Enable (NAKE) - When this bit is set the core will generate an interrupt when bit 0 in the Status register gets set.	

87.3.5 Receive Register

RESERVED		RECBYTE	
0		NR	
r		r	

31 : 8	RESERVED	
7:0	Received Byte (RECBYTE) - Last byte received from master. This field only contains valid data if the Byte received (REC) bit in the status register has been set.	

87.3.6 Transmit Register

*Table 1756.*0x14 - TX - Transmit register

31	8	8	7	0
RESERVED			TRABYTE	
0			NR	
r			rw	

31 : 8	RESERVED
7:0	Transmit Byte (TRABYTE) - Byte to transmit on the next master read request.

Reset value: Undefined

87.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x03E. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

87.5 Implementation

87.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

87.6 Configuration options

Table 1757 shows the configuration options of the core (VHDL generics).

*Table 1757.*Configuration options

Generic name	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by I^{2}C slave	0 - NAHBIRQ-1	0
hardaddr	If this generic is set to 1 the core uses the value of generic i2caddr as the hard coded address. If hardaddr is set to 0 the core's address can be changed via the Slave address register.	0 - 1	0
tenbit	If this generic is set to 1 the core will support 10-bit addresses. Note that the core can still be configured to use a 7-bit address.	0 - 1	0
i2caddr	The slave's (initial) I^{2}C address.	0 - 1023	0
oepol	Output enable polarity	0 - 1	0
filter	Low-pass filter length. This generic should specify, in number of system clock cycles plus one, the time of the shortest pulse on the I2C bus to be registered as a valid value. For instance, to disregard any pulse that is 50 ns or shorter in a system with a system frequency of 54 MHz this generic should be set to: ((pulse time) / (clock period)) + 1 = (50 ns) / ((1/(54 MHz)) + 1 = 3.7 The value from this calculation should always be rounded up. In other words an appropriate filter length for a 54 MHz system is 4.	2 - 512	2

88 IRQMP - Multiprocessor Interrupt Controller

88.1 Overview

The AMBA system in GRLIB provides an interrupt scheme where interrupt lines are routed together with the remaining AHB/APB bus signals, forming an interrupt bus. Interrupts from AHB and APB units are routed through the bus, combined together, and propagated back to all units. The multiprocessor interrupt controller core is attached to the AMBA bus as an APB slave, and monitors the combined interrupt signals.

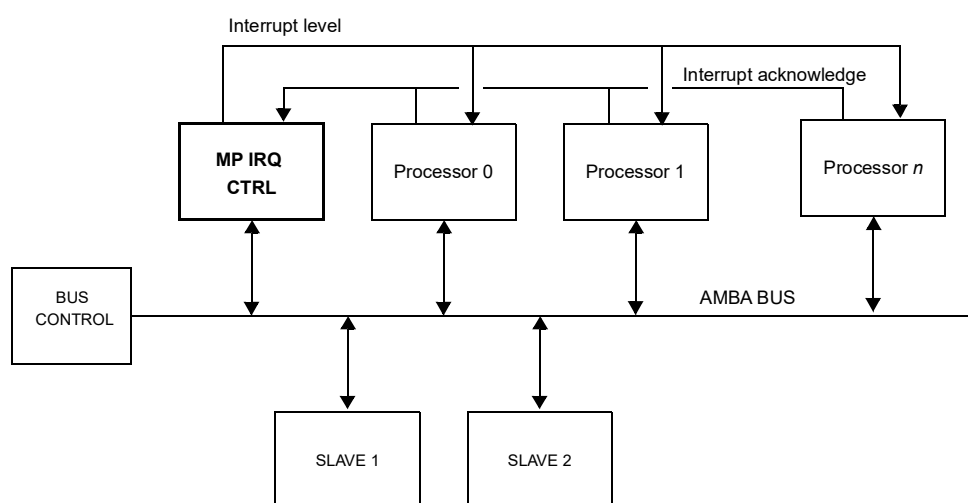
The interrupts generated on the interrupt bus are all forwarded to the interrupt controller. The interrupt controller prioritizes, masks and propagates the interrupt with the highest priority to the processor. In multiprocessor systems, the interrupts are propagated to all processors.


Figure 236. LEON multiprocessor system with Multiprocessor Interrupt controller

88.2 Operation

88.2.1 Interrupt prioritization

The interrupt controller monitors interrupt 1 - 15 of the interrupt bus (APBI.PIRQ[15:1]). When any of these lines are asserted high, the corresponding bit in the interrupt pending register is set. The pending bits will stay set even if the PIRQ line is de-asserted, until cleared by software or by an interrupt acknowledge from the processor. The default behaviour for peripherals is to use pulsed interrupts (an interrupt line is asserted for one clock cycle to signal an interrupt).

Each interrupt can be assigned to one of two priority levels (0 or 1) as programmed in the interrupt level register. Level 1 has higher priority than level 0. The interrupts are prioritized within each level, with interrupt 15 having the highest priority and interrupt 1 the lowest. The highest interrupt from level 1 will be forwarded to the processor. If no unmasked pending interrupt exists on level 1, then the highest unmasked interrupt from level 0 will be forwarded. PIRQ[31:16] are not used by the IRQMP core unless extended interrupts are enabled (see section 88.2.2). PIRQ[0] is not used by the IRQMP core unless interrupt remapping is enabled (see section 88.2.6).

Interrupts are prioritized at system level, while masking and forwarding of interrupts in done for each processor separately. Each processor in a multiprocessor system has separate interrupt mask and force registers. When an interrupt is signaled on the interrupt bus, the interrupt controller will prioritize

GRIP

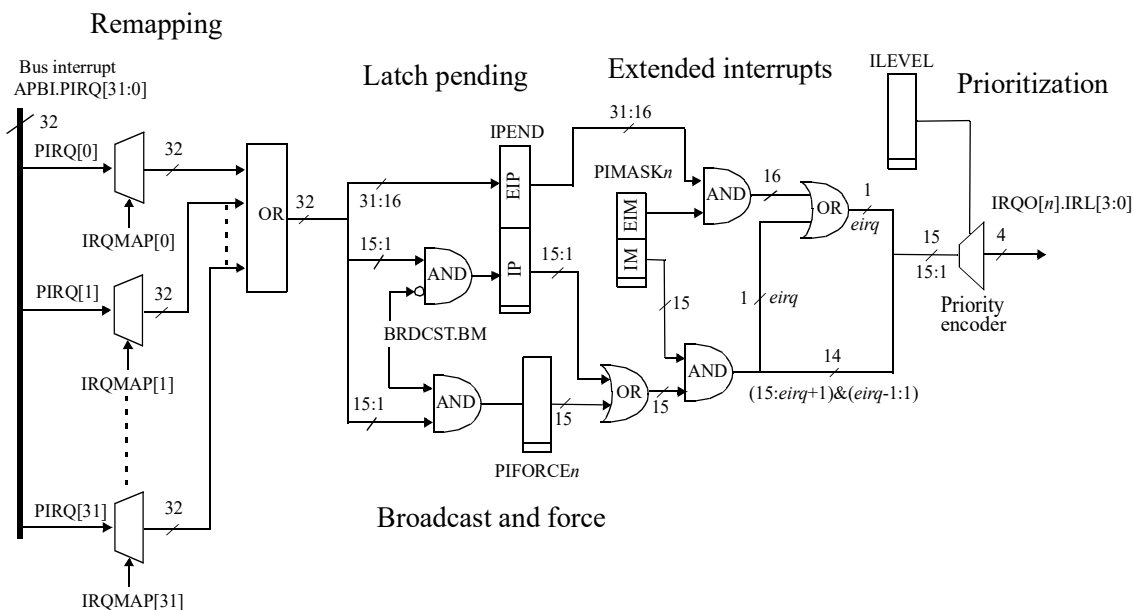
interrupts, perform interrupt masking for each processor according to the mask in the corresponding mask register and forward the interrupts to the processors.


Figure 237. Interrupt controller block diagram. Interrupt acknowledgement is not shown. Logic is only shown for one processor. When multiple processors are implemented (*ncpu*>1), the interrupt forcing, masking, and priority encoding is performed separately for each processor. Each processor has its own PIFORCE*n* and PIMASK*n* register. The registers IRQMAP, IPEND, BRDCST, and ILEVEL are common to all processors. Interrupt remapping and extended interrupts are optional features that can be disabled at implementation time to reduce complexity.

When a processor acknowledges the interrupt (which happens automatically in the process of taking an interrupt trap), the corresponding pending bit will automatically be cleared. Note that in a multi-processor system, the bit in the pending register will be cleared as soon as one of the processors acknowledges the interrupt and interrupt broadcast functionality should be used for interrupts that need to be propagated to all processors.

Interrupts can also be forced by setting a bit in the interrupt force register. In this case, the processor acknowledgment will clear the force bit rather than the pending bit. After reset, the interrupt mask register is set to all zeros while the remaining control registers are undefined. Note that interrupt 15 cannot be masked by the LEON processor and should be used with care - most operating systems do not safely handle this interrupt.

Most GRLIB peripherals use pulsed interrupts, but some (notably GRGPIO and APBUART) can also generate level interrupts. A level interrupt line remains set until the condition that triggered the interrupt has cleared. Hence the interrupt line will typically remain asserted when the processor acknowledges the interrupt (as this occurs immediately when the interrupt trap is taken) and therefore the same interrupt will be latched into the pending interrupt register again on the next clock cycle. Therefore, the interrupt trap will usually be taken a second time as soon as software returns from the interrupt handler. It is possible to prevent such duplicate interrupts by explicitly clearing the pending interrupt from the interrupt handler, but if the interrupt line is shared with pulsed interrupts then care must be taken to prevent interrupts from being missed.

88.2.2 Extended interrupts

The AHB/APB interrupt bus consist of 32 signals ([31:0]), while the IRQMP only uses lines 1 - 15 in the nominal mode. To use the additional 16 interrupt lines (16-31), extended interrupt handling can be enabled by setting the VHDL generic *eirq* to a value between 1 - 15. The interrupt lines 16 - 31 will then also be handled by the interrupt controller, and the interrupt pending and mask registers will be

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

extended to 31 bits. Since the processor only has 15 interrupt levels (1 - 15), the extended interrupts will generate one of the regular interrupts, indicated by the value of the *eirq* generic. When the interrupt is taken and acknowledged by the processor, the regular interrupt (*eirq*) and the extended interrupt pending bits are automatically cleared. The extended interrupt acknowledge register will identify which extended interrupt that was most recently acknowledged. This register can be used by software to invoke the appropriate interrupt handler for the extended interrupts.

88.2.3   Processor status monitoring

The processor status can be monitored through the Multiprocessor Status Register. The STATUS field in this register indicates if a processor is in power-down ('1') or running ('0'). A processor can be made running by writing a '1' to its status field. After reset, all processors except processor 0 are halted (can be changed using the functionality associated with the *extrun* VHDL generic). When the system is properly initialized, processor 0 can start the remaining processors by writing to their STATUS bits. See also the extended boot support in section 88.2.4.

88.2.4   Extended boot support

When the bootreg generic is set, registers are added to allow starting a halted CPU from an arbitrary 8 byte aligned entry point. The CPU can be started with the same register write as when the entry point is written, or the CPU can be started later using the regular multiprocessor status register bit.

An error register is also added to allow monitoring CPUs for error mode, and to allow forcing a specific CPU into error mode. This can be used to monitor and re-boot CPUs without resetting the system.

A read-only bit in the multiprocessor status register can be read to see if the bootreg functionality has been implemented.

88.2.5   Interrupt broadcasting

The Broadcast Register is activated when the generic *ncpu* is > 1. An incoming irq that has its bit set in the Broadcast Register is propagated to the force register of *all* CPUs instead of to the Pending Register. This can be used to implement a timer that fires to all CPUs with that same irq.

88.2.6   Interrupt (re)map functionality

The interrupt controller can optionally be implemented (as an alternative to the two-level interrupt scheme) with functionality to allow dynamic remapping between bus interrupt lines and interrupt controller interrupt lines. If the design includes this functionality then switch-logic will be placed on the incoming interrupt vector from the AMBA bus before the IRQ pending register. The Interrupt map registers will be available starting at offset 0x300 from the interrupt controller's base address.

The interrupt map registers contain one field for each bus interrupt line in the system. The value within this field determines to which interrupt controller line the bus interrupt line is connected. In case several bus interrupt lines are mapped to the same controller interrupt line (several fields in the Interrupt map registers have the same value) then the bus interrupt lines will be OR:ed together.

Note that if bus interrupt line X is remapped to controller interrupt line Y then bit Y of the pending register will be set when a peripheral asserts interrupt X. Remapping interrupt lines via the Interrupt map registers has the same effect as changing the interrupt assignments in the RTL code.

88.3 Registers

The core is controlled through registers mapped into APB address space. The number of implemented registers depends on the number of processor in the multiprocessor system.

To make the boot registers available in the lower 256-byte space (the default APB bar size, with *pmask*=16#fff#), the registers are mapped into space that becomes unused when the number of processors (*ncpu*) is 8 or lower. If the number of CPUs is higher than 8, then the registers are only available in the higher space and a larger APB address mapping must be used to make them available. For example by setting *pmask*=16#ffc# to set the APB bar size to 1024 bytes.

*Table 1761.*Interrupt Controller registers

88.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x00D. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

88.5 Implementation

88.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

88.6 Configuration options

Table 1774 shows the configuration options of the core (VHDL generics).

*Table 1774.*Configuration options

Generic	Function	Allowed range	Defau1lt
pindex	Selects which APB select signal (PSEL) that will be used to access the interrupt controller	0 to NAPBMAX-1	0
paddr	The 12-bit MSB APB address	16#000# to 16#fff#	0
pmask	The APB address mask	16#000# to 16#fff#	16#fff#
ncpu	Number of processors in multiprocessor system	1 to 16	1
eirq	Enable extended interrupts	0 - 15	0
irqmap	Enable interrupt (re-)map registers. If irqmap is set to 0 then interrupt map functionality is disabled. If irqmap is nonzero then (irqmap + eirq) = 1 includes map registers for bus interrupt lines 0 - 15. If (irqmap + eirq) > 1 then interrupt map registers are available for bus interrupt lines 0 - 31.	0 - 2	0
bootreg	Enable boot address register and error mode register.	0 - 1	1
extrun	Use external run vector. If this generic is set to 1 the start of processors after reset will be controlled via the input signal cpurun. If this generic is set to 0, CPU 0 will be started after reset and the other CPUs will be put in power-down mode. This requires that the *smp* VHDL generic on the LEON entity is nonzero.	0 - 1	0

89   IRQ(A)MP - Multiprocessor Interrupt Controller with extended ASMP support

89.1   Overview

The AMBA system in GRLIB provides an interrupt scheme where interrupt lines are routed together with the remaining AHB/APB bus signals, forming an interrupt bus. Interrupts from AHB and APB units are routed through the bus, combined together, and propagated back to all units. The multiprocessor interrupt controller core is attached to the AMBA bus as an APB slave, and monitors the combined interrupt signals.

The interrupts generated on the interrupt bus are all forwarded to the interrupt controller. The interrupt controller prioritizes, masks and propagates the interrupt with the highest priority. The interrupt controller is configured at instantiation to implement one or several internal interrupt controllers. Each processor in a system can then be dynamically routed to one of the internal controllers. This allows safe Asymmetric Multiprocessing (ASMP) operation. For Symmetric Multiprocessor (SMP) operation, several processors can be routed to the same internal interrupt controller.

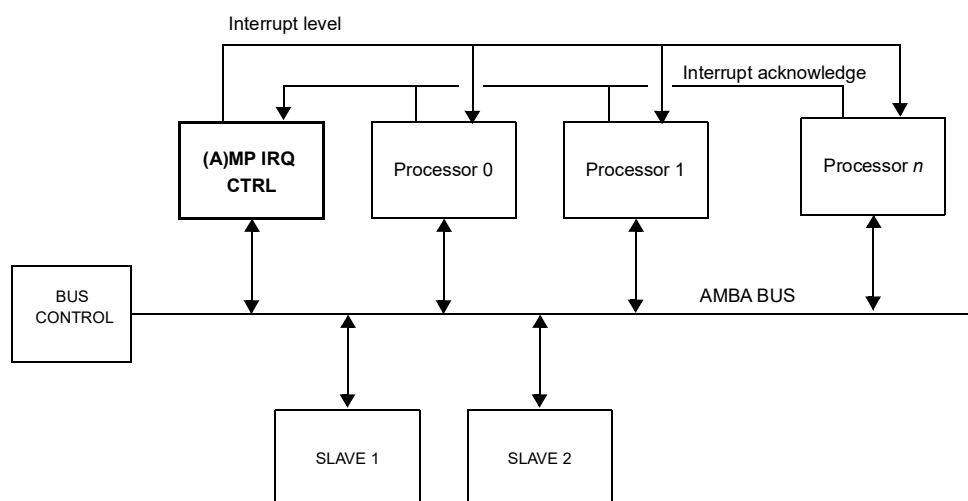
The IRQ(A)MP core is an extended version of the traditional multiprocessor interrupt controller. If a design does not need to have extended support for Asymmetric Multiprocessing, nor support for interrupt timestamping, it is recommended to use the IRQMP core instead.


Figure 238. LEON multiprocessor system with Multiprocessor Interrupt controller

89.2   Operation

89.2.1   Support for Asymmetric Multiprocessing

Extended support for Asymmetric Multiprocessing (ASMP) is activated when the VHDL generic *nctrl* is > 1. Asymmetric Multiprocessing support means that parts of the interrupt controller are duplicated in order to provide safe ASMP operation. If the VHDL generic nctrl = 1 the core will have the same behavior as the normal IRQMP Multiprocessor interrupt controller core. If nctrl > 1, the core's register set will be duplicated on 4 KiB address boundaries. The core's register interface will also enable the use of three new registers, one Asymmetric Multiprocessing Control Register and two Interrupt Controller Select Registers.

Software can detect if the controller has been implemented with support for ASMP by reading the Asymmetric Multiprocessing Control register. If the field NCTRL is 0, the core was not implemented

with ASMP extensions. If the value of NCTRL is non-zero, the core has NCTRL+1 sets of registers with additional underlying functionality. From a software view this is equivalent to having NCTRL+1 interrupt controllers available and software can configure to which interrupt controller a processor should connect.

After system reset, all processors are connected to the first interrupt controller accessible at the core's base address. Software can then use the Interrupt Controller Select Registers to assign processors to other (internal) interrupt controllers. After assignments have been made, it is recommended to freeze the contents of the select registers by writing '1' to the lock bit in the Asymmetric Multiprocessing Control Register. The lock bit can be cleared by software by writing '0' to the bit.

When a software driver for the interrupt controller is loaded, the driver should check the Asymmetric Multiprocessing Control Register and Interrupt Controller Select Registers to determine to which controller the current processor is connected. After software has determined that it has been assigned to controller n, software should only access the controller with registers at offset 0x1000 * n. Note that the controllers are enumerated with the first controller being n = 0.

The processor specific registers (mask, force, interrupt acknowledge) can be read from all interrupt controllers. However the processor specific mask and interrupt acknowledge registers can only be written from the interrupt controller to which the processor is assigned. This also applies to individual bits in the Multiprocessor Status Register. Interrupt Force bits in a processor's Interrupt Force Register can only be cleared through the controller to which the processor is assigned. If the ICF field in the Asymmetric Multiprocessing Control Register is set to '1', all bits in all Interrupt Force Registers can be set, but not cleared, from all controllers. If the ICF field is '0' the bits in a processor's Interrupt Force register can only be set from the controller to which the processor is assigned.

89.2.2 Interrupt prioritization

The interrupt controller monitors interrupt 1 - 15 of the interrupt bus (APBI.PIRQ[15:1]). When any of these lines are asserted high, the corresponding bit in the interrupt pending register is set. The pending bits will stay set even if the PIRQ line is de-asserted, until cleared by software or by an interrupt acknowledge from the processor. The default behaviour for peripherals is to use pulsed interrupts (an interrupt line is asserted for one clock cycle to signal an interrupt).

Each interrupt can be assigned to one of two levels (0 or 1) as programmed in the interrupt level register. Level 1 has higher priority than level 0. The interrupts are prioritised within each level, with interrupt 15 having the highest priority and interrupt 1 the lowest. The highest interrupt from level 1 will be forwarded to the processor. If no unmasked pending interrupt exists on level 1, then the highest unmasked interrupt from level 0 will be forwarded. PIRQ[31:16] are not used by the IRQMP core.

Interrupts are prioritised at system level, while masking and forwarding of interrupts in done for each processor separately. Each processor in an multiprocessor system has separate interrupt mask and force registers. When an interrupt is signalled on the interrupt bus, the interrupt controller will prioritize interrupts, perform interrupt masking for each processor according to the mask in the corresponding mask register and forward the interrupts to the processors.

Apr 2024, Version 2024.1

1460

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler
Figure 239. Interrupt controller block diagram

When a processor acknowledges the interrupt, the corresponding pending bit will automatically be cleared. Note that in a multiprocessor system, the bit in the pending register will be cleared as soon as one of the processors acknowledges the interrupt and interrupt broadcast functionality should be used for interrupts that need to be propagated to all processors. Interrupt can also be forced by setting a bit in the interrupt force register. In this case, the processor acknowledgement will clear the force bit rather than the pending bit. After reset, the interrupt mask register is set to all zeros while the remaining control registers are undefined. Note that interrupt 15 cannot be maskable by the LEON processor and should be used with care - most operating systems do not safely handle this interrupt.

89.2.3 Extended interrupts

The AHB/APB interrupt consist of 32 signals ([31:0]), while the IRQMP only uses lines 1 - 15 in the nominal mode. To use the additional 16 interrupt lines (16-31), extended interrupt handling can be enabled by setting the VHDL generic *eirq* to a value between 1 - 15. The interrupt lines 16 - 31 will then also be handled by the interrupt controller, and the interrupt pending and mask registers will be extended to 32 bits. Since the processor only has 15 interrupt levels (1 - 15), the extended interrupts will generate one of the regular interrupts, indicated by the value of the *eirq* generic. When the interrupt is taken and acknowledged by the processor, the regular interrupt (*eirq*) and the extended interrupt pending bits are automatically cleared. The extended interrupt acknowledge register will identify which extended interrupt that was most recently acknowledged. This register can be used by software to invoke the appropriate interrupt handler for the extended interrupts. When VHDL generic *irqmap* has a value of 3, support for 64 AHB/APB interrupts lines are enabled. Interrupt 32 - 63 are not handled by the interrupt controller and therefor needs to be remapped to one of the interrupt 1 - 31.

89.2.4 Processor status monitoring

The processor status can be monitored through the Multiprocessor Status Register. The STATUS field in this register indicates if a processor is in power-down ('1') or running ('0'). A processor can be made running by writing a '1' to its status field. After reset, all processors except processor 0 are in power-down (can be changed using the functionality associated with the *extrun* VHDL generic).

GRIP
Apr 2024, Version 2024.1

1461

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

When the system is properly initialized, processor 0 can start the remaining processors by writing to their STATUS bits.

The core can be implemented with support for specifying the processor reset start address dynamically. Please see section 89.2.10 for further information.

89.2.5 Interrupt broadcasting

The Broadcast Register is activated when the generic *ncpu* is > 1. An incoming irq that has its bit set in the Broadcast Register is propagated to the force register of *all* CPUs instead of to the Pending Register. This can be used to implement a timer that fires to all CPUs with that same irq.

89.2.6 Interrupt timestamping description

Support for interrupt timestamping is implemented when the VHDL generic *tstamp* is > 0.

Interrupt timestamping is controlled via the Interrupt Timestamp Control register(s). Each Interrupt Timestamp Control register contains a field (TSTAMP) that contains the number of timestamp registers sets that the core implements. A timestamp register sets consist of one Interrupt Timestamp Counter register, one Interrupt Timestamp Control register, one Interrupt Assertion Timestamp register and one Interrupt Acknowledge Timestamp register.

Software enables timestamping for a specific interrupt via a Interrupt Timestamp Control Register. When the selected interrupt line is asserted, software will save the current value of the interrupt timestamp counter into the Interrupt Assertion Timestamp register and set the S1 field in the Interrupt Timestamp Control Register. When the processor acknowledges the interrupt, the S2 field of the Interrupt Timestamp Control register will be set and the current value of the timestamp counter will be saved in the Interrupt Acknowledge Timestamp Register. The difference between the Interrupt Assertion timestamp and the Interrupt Acknowledge timestamp is the number of system clock cycles that was required for the processor to react to the interrupt and divert execution to the trap handler.

The core can be configured to stamp only the first occurrence of an interrupt or to continuously stamp interrupts. The behavior is controlled via the Keep Stamp (KS) field in the Interrupt Timestamp Control Register. If KS is set, only the first assertion and acknowledge of an interrupt is stamped. Software must then clear the S1 and S2 fields for a new timestamp to be taken. If Keep Stamp is disabled (KS field not set), the controller will update the Interrupt Assertion Timestamp Register every time the selected interrupt line is asserted. In this case the controller will also automatically clear the S2 field and also update the Interrupt Acknowledge Timestamp register with the current value when the interrupt is acknowledged.

For controllers with extended ASMP support, each internal controller has a dedicated set of Interrupt timestamp registers. This means that the Interrupt Acknowledge Timestamp Register(s) on a specific controller will only be updated if and when the processor connected to the controller acknowledges the selected interrupt. The Interrupt Timestamp Counter is shared by all controllers and will be incremented when an Interrupt Timestamp Control register has the ITSEL field set to a non-zero value.

89.2.7 Interrupt timestamping usage guidelines

Note that KS = '0' and a high interrupt rate may cause the Interrupt Assertion Timestamp register to be updated (and the S2 field reset) before the processor has acknowledged the first occurrence of the interrupt. When the processor then acknowledges the first occurrence, the Interrupt Acknowledge Timestamp register will be updated and the difference between the two Timestamp registers will not show how long it took the processor to react to the first interrupt request. If the interrupt frequency is expected to be high it is recommended to keep the first stamp (KS field set to '1') in order to get reliable measurements. KS = '0' should not be used in systems that include cores that use level interrupts, the timestamp logic will register each cycle that the interrupt line is asserted as an interrupt.

In order to measure the full interrupt handling latency in a system, software should also read the current value of the Interrupt Timestamp Counter when entering the interrupt handler. In the typical case,

GRIP
Apr 2024, Version 2024.1

1462

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

a software driver's interrupt handler reads a status register and then determines the action to take. Adding a read of the timestamp counter before this status register read can give an accurate view of the latency during interrupt handling.

The core listens to the system interrupt vector when reacting to interrupt line assertions. This means that the Interrupt Assertion Timestamp Register(s) will not be updated if software writes directly to the pending or force registers. To measure the time required to serve a forced interrupt, read the value of the Interrupt Timestamp counter before forcing the interrupt and then read the Interrupt Acknowledge Timestamp and Interrupt Timestamp counter when the processor has reacted to the interrupt.

89.2.8 Watchdog

Support for watchdog inputs is implemented when the VHDL generic *wdogen* > 0, the number of watchdog input is determined by the VHDL generic *nwdog*.

The core can be implemented with support for asserting a bit in the controller's Interrupt Pending Register when an external watchdog signal is asserted. This functionality can be used to implement a sort of soft watchdog for one or several processor cores. The controller's Watchdog Control Register contains a field that shows the number of external watchdog inputs supported and fields for configuring which watchdog inputs that should be able to assert a bit in the Interrupt Pending Register. The pending register will be assigned in each cycle that a selected watchdog input is high. Therefore it is recommended that the watchdog inputs are connected to sources which send a one clock cycle long pulse when a watchdog expires. Otherwise software should make sure that the watchdog signal is deasserted before re-enabling interrupts during interrupt handling.

For controllers with extended ASMP support, each internal controller has a dedicated Watchdog Control register. Assertion of a watchdog input will only affect the pending register on the internal interrupt controllers that have enabled the watchdog input in their Watchdog Control Register.

89.2.9 Interrupt (re)map functionality

The interrupt controller can optionally be implemented (as an alternative to the two-interrupt levels scheme) with functionality to allow dynamic remapping between bus interrupt lines and interrupt controller interrupt lines. If the design includes this functionality then switch-logic will be placed on the incoming interrupt vector from the AMBA bus before the IRQ pending register. The Interrupt map registers will be available starting at offset 0x300 from the interrupt controller's base address.

The interrupt map registers contain one field for each bus interrupt line in the system. The value within this field determines to which interrupt controller line the bus interrupt line is connected. In case several bus interrupt lines are mapped to the same controller interrupt line (several fields in the Interrupt map registers have the same value) then the bus interrupt lines will be OR:ed together.

Note that if bus interrupt line X is remapped to controller interrupt line Y then bit Y of the pending register will be set when a peripheral asserts interrupt X. Remapping interrupt lines via the Interrupt map registers has the same effect as changing the interrupt assignments in the RTL code.

89.2.10 Dynamic processor reset start address

When the bootreg generic is set, registers are added to allow starting a halted CPU from an arbitrary 8 byte aligned entry point. The CPU can be started with the same register write as when the entry point is written, or the CPU can be started later using the regular multiprocessor status register bit.

An error register is also added to allow monitoring CPUs for error mode, and to allow forcing a specific CPU into error mode. This can be used to monitor and re-boot CPUs without resetting the system.

A read-only bit in the multiprocessor status register can be read to see if the bootreg functionality has been configured in.

89.3   Registers

The core is controlled through registers mapped into APB address space. The number of implemented registers depends on the number of processors in the multiprocessor system. The number of accessible register sets depend on the value of the NCTRL field in the Asymmetric Multiprocessing Control Register. The register set for controller n is accessed at offset 0x1000*n.

In order to make the boot registers available in the lower 256-byte space that is in legacy mappings, the registers are mapped into space that becomes unused when the number of processors is 8 or lower. If the number of CPUs is higher than 8, then the registers are only available in the higher space and a larger APB address mapping must be used to make them available.

Table 1777. Interrupt Controller registers

31:27	Number of watchdog inputs (NWDOG) - Number of watchdog inputs that the core supports.
26:20	Reserved
19:16	Watchdog interrupt (WDOGIRQ) - Selects the bit in the pending register to set when any line watchdog line selected by the WDOGMSK field is asserted.
15:0	Watchdog Mask n (WDOGMSK[n]) - If WDOGMSK[n] = '1' then the assertion of watchdog input n will lead to the bit selected by the WDOGIRQ field being set in the controller's Interrupt Pending Register.

89.3.9 Asymmetric Multiprocessing Control Register

*Table 1786.*0x020 - ASMPCTRL - Asymmetric Multiprocessing Control Register

31 28	27 2	1	0
NCTRL	RESERVED	ICF	L
*	0	0	0
r	r	rw	rw

31:28	Number of internal controllers (NCTRL) - NCTRL + 1 is the number of internal interrupt controllers available.
27:2	Reserved
1	Inter-controller Force (ICF) - If this bit is set to '1' all Interrupt Force Registers can be set from any internal controller. If this bit is '0', a processor's Interrupt Force Register can only be set from the controller to which the processor is connected. Bits in an Interrupt Force Register can only be cleared by the controller or by writing the Interrupt Force Clear field on the controller to which the processor is connected.
0	Lock (L) - If this bit is written to '1', the contents of the Interrupt Controller Select registers is frozen. This bit can only be set if NCTRL > 0.

89.3.10 Interrupt Controller Select Register for Processors 0 - 7 (NCTRL > 0)

*Table 1787.*0x024 - ICLSELR0 - Interrupt Controller Select Register for Processors 0 -7 (NCTRL > 0)

TSTAMP		S1	S2	RESERVED		KS	TSISEL	
*		0	0	0		0	0	
r		wc	wc	r		rw	rw	

31:27	Number of timestamp register sets (TSTAMP) - The number of available timestamp register sets.
26	Assertion Stamped (S1) - Set to '1' when the assertion of the selected line has received a timestamp. This bit is cleared by writing '1' to its position. Writes of '0' have no effect.
25	Acknowledge Stamped (S2) - Set to '1' when the processor acknowledge of the selected interrupt has received a timestamp. This bit can be cleared by writing '1' to this position, writes of '0' have no effect. This bit can also be cleared automatically by the core, see description of the KS field below.
24:6	RESERVED
5	Keep Stamp (KS) - If this bit is set to '1' the core will keep the first stamp value for the first interrupt until the S1 and S2 fields are cleared by software. If this bit is set to '0' the core will time stamp the most recent interrupt. This also has the effect that the core will automatically clear the S2 field whenever the selected interrupt line is asserted and thereby also stamp the next acknowledge of the interrupt.
4:0	Timestamp Interrupt Select (TSISEL) - This field selects the interrupt line (0 - 31) to timestamp.

89.5 Implementation

89.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

89.6 Configuration options

Table 1798 shows the configuration options of the core (VHDL generics).

Table 1798. Configuration options

Generic	Function	Allowed range	Default
pindex	Selects which APB select signal (PSEL) that will be used to access the interrupt controller	0 to NAPBSLV-1	0
paddr	The 12-bit MSB APB address	0 - 16#FFF#	0
pmask	The APB address mask. The mask determines the size of the memory area occupied by the core. The minimum required memory area based on the *nctrl* VHDL generic gives (nctrl : pmask) = 1 : 16#FFF#, 2: 16#FE0#, 3-4 : 16#FC0#, 5-8 : 16#F80#, 9-16 : 16#F00#. Note that even with nctrl = 1 the core may require a larger area than 256 bytes if the core has been implemented with support for timestamping and/or dynamic reset addresses.	0 - 16#FFF#	16#FFF#
ncpu	Number of processors in multiprocessor system	1 to 16	1
eirq	Enable extended interrupts	0 - 15	0
nctrl	Asymmetric multiprocessing system extension. This generic defines the number of internal interrupt controllers that will be implemented in the core.	1 - 16	1
tstamp	Interrupt timestamping. If this generic is non-zero the core will include a timestamp counter and *tstamp* set(s) of interrupt timestamp register(s).	0 - 16	0
wdogen	Enable watchdog inputs. If this generic is set to 1 the core will include logic to assert a selected interrupt when a watchdog input is asserted.	0 - 1	0
nwdog	Number of watchdog inputs	1 - 16	1
dynrstaddr	Deprecated feature, must be set to 0	0 - 0	0
rstaddr	Deprecated feature, must be set to 0	$0 - (2^{20}-1)$	0
extrun	Use external run vector. If this generic is set to 1 the start of processors after reset will be controlled via the input signal cpurun. If this generic is set to 0, CPU 0 will be started after reset and the other CPUs will be put in power-down mode. This requires that the SMP VHDL generic on the LEON entity is nonzero.	0 - 1	0
irqmap	Enable interrupt (re-)map registers. If irqmap is set to 0 then interrupt map functionality is disabled. If irqmap is nonzero then (irqmap + eirq) = 1 includes map registers for bus interrupt lines 0 - 15. If (irqmap + eirq) > 1 then interrupt map registers are available for bus interrupt lines 0 - 31. When irqmap = 3 then support for 64 interrupt sources is enabled and interrupt map registers are available for bus interrupt lines 0 - 63.	0 - 3	0

90   L2C - Level 2 Cache controller

90.1   Overview

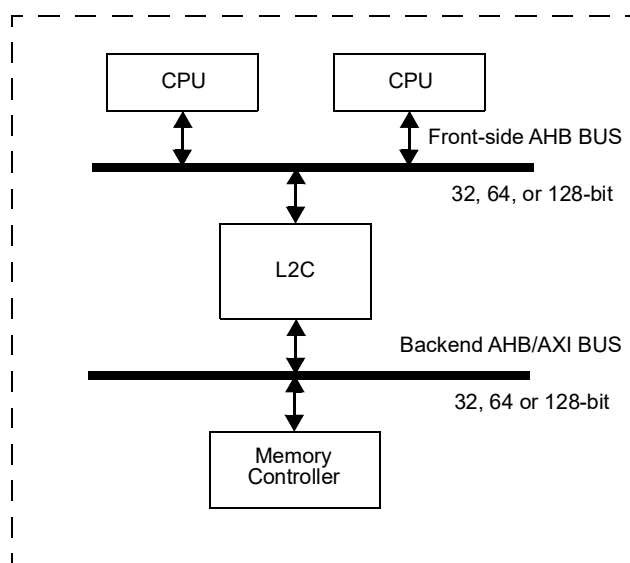
The L2C implements a Level-2 cache for processors with AHB interfaces. The L2C works as an AHB to AHB/AXI bridge, caching data that is read or written via the bridge. The cache is a unified cache and in a system with LEON processors, data may exist in the Level-1 and Level-2 cache, or only in the Level-1 or Level-2 cache. A front-side AHB interface is connected to the processor bus, while a backend AHB/AXI interface is connected to the memory bus. Both front-side and backend buses can be individually configured to 32, 64 or 128 bits data width. The front-side bus and the backend bus must be clocked with the same clock. Figure 240 shows a system block diagram for the cache controller.


Figure 240. Block diagram

90.2   Configuration

The Level-2 cache can be configured as direct-mapped or multi-way with associativity 2, 3 or 4. The replacement policy for a multi-way configuration can be configured as: LRU (least-recently-used), pseudo-random or master-index (where the way to replace is determined by the master index). The way size is configurable between 1 - 512 KiB with a line size of 32/64 bytes.

90.2.1   Replacement policy

The core can implements three different replacement policies: LRU (least-recently-used), (pseudo-) random and master-index. The LRU replacement policy is configured as default. With master-index replacement policy, master 0 would replace way 1, master 1 would replace way 2, and so on. For master indexes corresponding to a way number larger than the number of implemented ways, there are two options to determine which way to replace. One option is to map all these master indexes to a specific way. This is done by specifying this way in the index-replace field in the control register and selecting this option in the replacement policy field, also located in the control register. It is not allowed to select a locked way in the index-replace field. The second option is to replace way = ((master index) modulus (number of ways)). This option can be selected in the replacement policy field, but is only allowed with multi-way associativity 2 or 4.

90.2.2 Write policy

The cache can be configured to operate as write-through or copy-back cache. Before changing the write policy to write-through, the cache has to be disabled and flushed (to write back dirty cache lines to memory). This can be done by setting the Cache disable bit when issuing a flush all command. The write policy is controlled via the cache control register. More fine-grained control can also be obtained by enabling the MTRR registers (see text below).

90.2.3 Memory type range registers

The memory type range registers (MTRR) are used to control the cache operation with respect to the address. Each MTRR can define an area in memory to be uncached, write-through or write-protected. The MTRR consist of a 14-bit address field, a 14-bit mask and two 2-bit control fields. The address field is compared to the 14 most significant bits of the cache address, masked by the mask field. If the unmasked bits are equal to the address, an MTRR hit is declared. The cache operation is then performed according to the control fields (see register descriptions). If no hit is declared or if the MTRR is disabled, cache operation takes place according to the cache control register. The number of MTRRs is configurable through the *mtrr* VHDL generic. When changing the value of any MTRR register, cache must be disabled and flushed (This can be done by setting the Cache disable bit when issue a flush all command).

Note that the write-protection provided via the MTRR registers is enforced even if the cache is disabled.

90.2.4 Cachability

The core uses a VHDL generic CACHED to determine which address range is cachable. Each bit in this 16-bit value defines the cachability of a 256 Mbyte address block on the AMBA AHB bus. A value of 16#00F3# will thus define cachable areas in 0 - 0x20000000 and 0x40000000 - 0x80000000. When the VHDL generic CACHED is 0, the cachable areas is defined by the plug&play information on the backend bus. When implemented with a AXI backend bus the cachability needs to be defined with the VHDL generic CACHED. The core can also be configured to use the HPROT signal to override the cachable area defined by VHDL generic CACHED. A access can only be redefined as non-cachable by the HPROT signal. See table 1801 for information on how HPROT can change the access cachability within a cachable address area. The AMBA AHB signal HPROT[3] defines the access cacheable when active high and the AMBA AHB signal HPROT[2] defines the access bufferable when active high.

Table 1801. Access cachability using HPROT.

HPROT:	non-cachable, non-bufferable	non-cachable, bufferable	cacheable
Read hit	Cache access*	Cache access	Cache access
Read miss	Memory access	Memory access	Cache allocation and Memory access
Write hit	Cache and Memory access	Cache access	Cache access
Write miss	Memory access	Memory access	Cache allocation

* When the HPROT-Read-Hit-Bypass bit is set in the cache control register this will generate a Memory access.

+46 31 7758650 | frontgrade.com/gaisler

90.2.5 Cache tag entry

Table 1802 show the different fields of the cache tag entry for a cache with set size equal to 1 kbyte. The number of bits implemented is depending on the cache configuration.

Table 1802. L2C Cache tag entry

31	10	9	8	7	6	5	4	0
TAG		Valid		Dirty		RES	LRU	

31 : 10	Address Tag (TAG) - Contains the address of the data held in the cache line.
9 : 8	Valid bits. When set, the corresponding sub-block of the cache line contains valid data. Valid bit 0 corresponds to the lower 16 bytes sub-block (with offset 1) in the cache line and valid bit 1 corresponds to the upper 16 bytes sub-block (with offset 0) in the cache line.
7 : 6	Dirty bits When set, this sub-block contains modified data.
5	RESERVED
4 : 0	LRU bits

90.2.6 AHB address mapping

The AHB slave interface occupies three AHB address ranges. The first AHB memory bar is used for memory/cache data access. The address and size of this bar is configured via VHDL generics. The second AHB memory bar is used for access to configuration registers and the diagnostic interface. This bar has a configurable address via VHDL generic but always occupies 4 MiB in the AHB address space. The third AHB memory bar is used to map the ioarea of the backend AHB bus (to access the plug&play information on that bus, not supported when AXI backend is selected). The address and size of the this bar is configured via VHDL generics. The address is available in the user-defined register 1 of the configuration record.

90.2.7 Memory protection and Error handling

The ft VHDL generic enables the implementation of the Error Detection And Correction (EDAC) protection for the data and tag memory. One error can be corrected and two error can be detected with the use of a (39, 32, 7) BCH code. When implemented, the EDAC functionality can dynamically be enabled or disabled. Before being enabled the cache should be flushed. The dirty and valid bits fore each cache line is implemented with TMR. When EDAC error or backend AHB/AXI error or write-protection hit in a MTRR register is detected the error status register is updated to store the error type. The address which cause the error is also saved in the error address register. The error types is priori-tised in the way that a uncorrected EDAC error will overwrite any other previously stored error in the error status register. In all other cases, the error status register has to be cleared before a new error can be stored. Each error type (correctable-, uncorrectable EDAC error, write-protection hit, backend AHB/AXI error) has a pending register bit. When set and this error is unmasked, a interrupt is gener-ated. When uncorrectable error is detected in the read data the core will respond with a AHB error. AHB error response can also be enabled for a access that match a stored error in the error status regis-ter. Error detection is done per cache line. The core also provide a correctable error counter accessible via the error status register.

GRIP
Apr 2024, Version 2024.1

1476

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 1803.*Cache action on detected EDAC error

Access/Error type	Cache-line not dirty	Cache-line dirty
Read, Correctable Tag error	Tag is corrected before read is handled, Error status is updated with a correctable error.	Tag is corrected before read is handled, Error status is updated with a correctable error.
Read, Uncorrectable Tag error	Cache-line invalidated before read is handled, Error status is updated with a correctable error.	Cache-line invalidated before read is handled, Error status is updated with a uncorrectable error. Cache data is lost.
Write, Correctable Tag error	Tag is corrected before write is handed, Error status is updated with a correctable error.	Tag is corrected before write is handled, Error status is updated with a correctable error.
Write, Uncorrectable Tag error	Cache-line invalidated before write is handled, Error status is updated with a correctable error.	Cache-line invalidated before write is handled, Error status is updated with a uncorrectable error. Cache data is lost.
Read, Correctable Data error	Cache-data is corrected and updated, Error status is updated with a correctable error. AHB access is not affected.	Cache-data is corrected and updated, Error status is updated with a correctable error. AHB access is not affected.
Read, Uncorrectable Data error	Cache-line is invalidated, Error status is updated with a correctable error. AHB access is terminated with retry.	By default the cache-line is NOT invalidated (this can be configured by bit[10] EDI in the Error Handling / Injection configuration register), Error status is updated with a uncorrectable error. AHB access is terminated with error.
Write (<32-bit), Correctable Data error	Cache-data is corrected and updated, Error status is updated with a correctable error. AHB access is not affected.	Cache-data is corrected and updated, Error status is updated with a correctable error. AHB access is not affected.
Write (<32-bit), Uncorrectable Data error	Cache-line is re-fetched from memory, Error status is updated with a correctable error. AHB access is not affected.	Cache-line is invalidated, Error status is updated with a uncorrectable error. AHB access write data and cache data is lost.

90.2.8 Scrubber

When EDAC protection is implemented a cache scrubber is enabled. The scrubber is controlled via two register in the cache configuration interface. To scrub one specific cache line the index and way of the line is set in the scrub control register. To issue the scrub operation, the pending bit is set to 1. The scrubber can also be configured to continuously loop through and scrub each cache line by setting the enabled bit to 1. In this mode, the delay between the scrub operation on each cache line is determine by the scrub delay register (in clock cycles).

90.2.9 Locked way

One or more ways can be configured to be locked (not replaced). The number of way that should be locked is configured by the locked-way field in the control register. The way to be locked is starting with the uppermost way (for a 4-way associative cache way 4 is the first locked way, way 3 the second, and so on). After a way is locked, this way has to be flushed with the "way flush" function to update the tag match the desired locked address. During this "way flush" operation, the data can also be fetched from memory.

90.2.10 Data priming

Data can be loaded from one or two address ranges. Before triggering the priming operation, the start and stop address need to be configured. To specify if one or both address ranges should be loaded the respective enable bit (PSTART0/1.EN) need to be set. To trigger the operation, the pending bit (PSTART0.P) needs to be set to '1'. If only one address range should be loaded, the first set of priming register (PSTART0, PSTOP0) should be used. The cache lines are loaded from the start address to the

GRIP
Apr 2024, Version 2024.1

+46 31 7758650 | frontgrade.com/gaisler

stop address. When two address ranges should be loaded, one cache line from each area is loaded before moving to the next line in the address range. If the cache already contains the cache line specified to be loaded, the priming operation moves to the next line in the priming address range without fetching any data from memory but the LRU replacement information is updated.

90.3 Operation

90.3.1 Read

A cachable read access to the core results in a tag lookup to determine if the requested data is located in the cache memory. For a hit (requested data is in the cache) the data is read from the cache and no read access is issued to the memory. If the requested data is not in the cache (cache miss), the cache controller issue a read access to the memory controller to fetch the cache line including the requested data. The replacement policy determine which cache line in a multi-way configuration that should be replaced and its tag is updated. If the replaced cache line is modified (dirty) this data is stored in a write buffer and after the requested data is fetched from memory the replaced cache line is written to memory.

For a non-cachable read access to the cache, the cache controller can issue a single read access or a burst read access to fetch the data from memory. The access type is determine by how the cache is configured regarding hprot support and bypass line fetch in the access control register. The data is stored in a read buffer and the state of the cache is not modified in any way.

The cache will insert wait-states until the read access is determined to be a cache hit or miss. For a cache hit the data is then delivered. For a miss the cache can insert wait-states during the memory fetch or issue a AMBA SPLIT (depending on how the cache is configured). AMBA SPLIT response is only implemented in version 3 of the core.

90.3.2 Write

A cachable write access to the core results in a tag lookup to determine if the cache line is located in the cache. For a hit the cache line is updated. No access is issued to the memory for a copy-back configuration. When the core is configured as a write-through cache, each write access is also issued towards the memory. For a miss, the replacement policy determines which cache line in a multi-way configuration that should be replaced and updates its tag. If the replaced cache line is dirty, this is stored in a write buffer to be written back to the memory. The new cache line is updated with the data from the write access and for a non 128-bit access the rest of the cache line is fetched from memory. Last (when copy-back policy is used and the replaced cache line was marked dirty) the replaced cache line is written to memory. When the core is configured as a write-through cache, no cache lines are marked as dirty and no cache line needs to be written back to memory. Instead the write access is issued towards the memory as well. A new cache line is allocated on a miss for a cacheable write access independent of write policy (copy-back or write-through).

For a non-cachable write access to the core, the data is stored in a write buffer and the cache controller issue single write accesses to write the data to memory. The state of the cache is unmodified during this access.

The cache can accept a non sub-word write hit access every clock cycle. When the cache is unable to accept a new write access the cache inserts wait-states or issue a AMBA SPLIT response depending on how the cache is configured. AMBA SPLIT response is only implemented in version 3 of the core.

90.3.3 Cache flushing

The cache can be flushed by accessing a cache flush register. There is three flushing modes: invalidate (reset valid bits), write back (write back dirty cache lines to memory, but no invalidation of the cache content) and flush (write back dirty cache lines to memory and invalidate the cache line). The flush command can be applied to the entire cache, one way or to only one cache line. The cache line to be flushed can be addresses in two ways: direct address (specify way and line address) and memory

address (specify which memory address that should be flushed in the cache. The controller will make a cache lookup for the specified address and on a hit, flush that cache line). When the entire cache is flushed the Memory Address field should be set to zero. Invalidate a cache line takes 5 clock cycles. If the cache line needs to be written back to memory one additional clock cycle is needed plus the memory write latency. When the whole cache is flushed the invalidation of the first cache line takes 5 clock cycles, after this one line can be invalidate each clock cycle. When a cache line needs to be written back to memory this memory access will be stored in a access buffer. If the buffer is full the invalidation of the next cache line is stall until a slot in the buffer has opened up. If the cache also should be disabled after the flush is complete, it is recommended to set the cache disable bit together with the flush command instead of writing '0' to the cache enable bit in the cache control register.

Note that after a processor (or any other AHB master) has initiated a flush the processor is not blocked by the flush unless it writes or requests data from the Level-2 cache. The cache blocks all accesses (responds with AMBA SPLIT or wait-states depending on cache configuration) until the flush is complete. AMBA SPLIT response is only implemented in version 3 of the core.

90.3.4 Disabling Cache

To be able to safely disable the cache when it is being accessed, the cache need to be disabled and flushed at the same time. This is accomplished by setting the cache disable bit when issue the flush command.

90.3.5 Diagnostic cache access

The diagnostic interface can be used for RAM block testing and direct access to the cache tag, cache data content and EDAC check bits. The read-check-bits field in the error control register selects if data content or the EDAC check bits should be read out. On writes, the EDAC check bits can be selected from the data-check-bit or tag-check-bit register. These register can also be XOR:ed with the correct check bits on a write. See the error control register for how this is done.

90.3.6 Error injection

Except using the diagnostic interface, the EDAC check bits can also be manipulated on a regular cache access. By setting the xor-check-bit field in the error control register the data EDAC check bits will be XOR:ed with the data-check-bit register on the next write or the tag EDAC check bits will be XOR:ed with the tag-check-bit register on the next tag replacement. The tag check bit manipulation is only done if the tag-check-bit register is not zero. The xor-check-bit is reset on the next tag replacement or data write. Error can also be injected by writing a address (or way, index, offset) together with the inject bit to the "Error injection" register. This will XOR the check-bits (or tag/data) for the specified address (or cache-line) with the tag-/data-check-bit register depending on the Error injection configuration register. If the specified address in not cached, the cache content will be unchanged.

90.3.7 AHB slave interface

The slave interface is the core's connection to the CPU and the level 1 cache. The core can accept 8-bit(byte), 16-bit(half word), 32-bit(word), 64-bit, and 128-bit single accesses and also 32-bit, 64-bit, and 128-bit burst accesses. For an access during a flush operation, the core will respond with a AHB SPLIT response or with wait-states. For a uncorrectable error or a backend AHB error on a read access, the core will respond with a AMBA ERROR response. AMBA SPLIT response is only implemented in version 3 of the core.

90.3.8 AHB master interface

The master interface is the core's connection to the memory controller. During cache line fetch, the controller can issue either a 32-bit, 64-bit or 128-bit burst access. For a non cachable access and in write-through mode the core can also issue a 8-bit(byte), 16-bit(half word), 32-bit(word), 64-bit, or 128-bit single write access. The bbuswidth VHDL generic controls the maximum bus access size on

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

the master interface in the "wide-bus" address range. If set to 128 (default), the largest access will be 128-bit. If set to 64, the largest access will be 64-bit. If set to 32, the largest access will be 32-bit. The "wide-bus address range is defined by the wbmask VHDL generic. Each bit in this 16-bit value represents a 256 Mbyte address block on the AMBA AHB bus. The cache will only generate wide accesses (> 32-bit) to address ranges which wbmask bit is '1'. For address ranges which wbmask bit is '0', wide accesses will be translated to 32-bit bursts.

The HBURST value during burst accesses will correspond to SINGLE, INCR, INCR4, INCR8 or INCR16, depending on burst type and AHB data bus width.

90.3.9   AXI master interface

AXI master interface supports data width of 32, 64, or 128-bit, configured with the GRLIB configuration option AXIDW. The interface supports both AXI3/AXI4 bus interfaces (no AXI4 specific operation is performed by the master interface). The value of the AXI AxCACHE can be configured via a configuration register (L2CACCC). When the cache need to fetch a cache line from memory and write a cache line to memory, both the read and write operation are started at the same time. The AXI master interface supports only one outstanding read and one outstanding write access. The burst length depends on the bus width and cache line size. Minimum burst size is 16 Bytes (one half 32 Bytes cache line) and the maximum burst size is 64 Bytes (one 64 Bytes cache line).

90.3.10 Cache status

The cache controller has a status register which provide information on the cache configuration (multi-way configuration and set size). The core also provides an access counter and a hit counter via AHB mapped registers. These register can be used to calculate hit rate. The counters increments for each data access to core (i.e. a burst access is only counted as one access). When writing 0 to the access counter, the internal access/hit counters is cleared and its value is loaded to the registers accessible via the AHB interface. In wrapping mode both counters will be cleared when the access counter is wrapping at 0xFFFFFFFF. In shifting mode both counters will be shifted down 16 bits when the access counter reach 0xFFFFFFFF. In this mode the accessible counter registers is updated automatically when the access counter's 16 LSB reach the value of 0xFFFF.

The core can also implement a front-side bus usage counter. This counter records every clock cycle the bus is not in idle state. The registers accessible via the AHB interface is updated in the same way as for the hit counter registers. Writing 0 to the bus cycle counter register resets the bus usage counters. This counter also has a wrapping and shifting mode similar to the hit counter.

In addition to the counter registers, the core also provide output signals for: cache hit, cache miss, and cache access. These signals can be connected to external statistic counters.

90.3.11 Endianness

The core is designed for big-endian systems.

90.4.10 Error Address Register

*Table 1814.*0x24 - L2CERRA - L2C Error address register

31	0
Error address (EADDR)	
NR	
r	

31 : 0   Error address (EADDR). Depending on which type of access (AHB access or scrubber access) that triggered the error, the address has different formats.
- When an AHB access triggers the error this register contains the address of the access. Bit[3:0] may be cleared.
- When the scrubber triggers the error this register contains the index and way of the cache line where the error was detected. The format is: [0..0 & index & 0..0 & way]. The bit rage of the index depends on the cache line size (lower limit of index) and cache way size (upper limit of index). The way field is defined as: 0001 for way 1, 0010 for way 2, 0100 for way 3, and 1000 for way 4.

90.5 Core versions

The L2 cache controller exists in several different versions. The latest version is v3 and this is the default version used in GRLIB. For existing users of version 2 that want to continue with this version, the GRLIB design Makefile can be modified to add:

```
DIRSKIP=l2cache/v3
DIRADD=l2cache/v2
```

Performing the modification above will mean that the scripts will be generated to use version 2 of the Level-2 cache.

90.6 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x04B. For description of vendor and device identifier see GRLIB IP Library User's Manual

90.7 Implementation

90.7.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

GRIP
Apr 2024, Version 2024.1

1494

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers if the GRLIB config package setting *grlib_async_reset_enable* is set.

90.7.2 RAM usage

The L2C uses single-port RAM to implement both cache tags and data memory. The tags are implemented using the SYNCRAM core, with the width and depth depending on the cache size configuration. The data memory is implemented using the SYNCRAM_128BW or SYNCRAM_156BW core, which is a 128-bit or 156-bit wide RAM wrapper with byte enables. The SYNCRAM_156BW is used when memory protection (EDAC) is implemented. For multi-way caches, each way's tag is implemented with a separate SYNCRAM block. The data memory can be implemented with separate SYNCRAM_128BW/156BW cores, or merged into the same SYNCRAM_128BW/156BW if the ARCH generic is set to 1. This will reduce the number of SYNCRAM_128BW/156BW core in multi-ways cache to one. The valid/dirty bits are stored in a SYNCRAM_2PFT core.

90.7.3 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

90.8 Configuration options

Table 1830 shows the configuration options of the core (VHDL generics).

Table 1830. Configuration options

Generic name	Function	Allowed range	Default
AHB slave interface			
hmstndx	AHB master index.	0 - NAHBMST-1	0
hslvndx	AHB slave index.	0 - NAHBSLV-1	0
haddr	ADDR field of the AHB BAR (for data access).	0 - 16#FFF#	16#F00#
hmask	MASK field of the AHB BAR.	0 - 16#FFF#	16#F00#
ioaddr	ADDR field of the AHB BAR (for register and diagnostic access).	0 - 16#FFF#	16#F00#
AHB master interface			
hmstndx	AHB master index.	0 - NAHBMST-1	0
bbuswidth	Maximum bus width on master AHB interface	32, 64, 128	128
bioaddr	ADDR field of the AHB BAR (for backend ioarea). Appears in the bridge's slave interface user-defined register 1.	0 - 16#FFF#	0
biomask	MASK field of the AHB BAR.	0 - 16#FFF#	0
wbmask	Wide-bus mask. Each bit in this value represent a 256Mbyte address range. To enabled wide accesses (>32-bit) to an address range, set the corresponding bit to '1'.	0 - 16#FFFF#	16#FFFF#
AXI master interface			
axiid	AXI ID	0 - 15	0
Cache configuration			
memtech	The memory technology used for the internal FIFOs.	0 - NTECH	0
cached	Fixed cachability mask.	0 - 16#FFFF#	16#0000#

```

91 L2C-Lite - Level 2 Cache controller

91.1 Overview

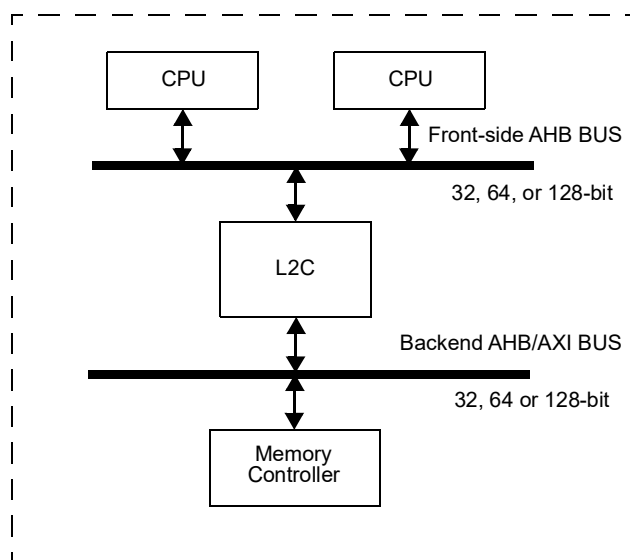
L2C-L implements a level-2 cache for processors with an AHB interface. It uses the GRLIB core "Generic Bus Master" as a bridge between AHB-AHB or AHB-AXI. The cache supports both big and little endian, making it suitable for NOEL-V and LEON designs. The frontend and backend support bus widths between 32-128 bits.


Figure 241. Block diagram

91.2 Configuration

L2C-L can be configured as a direct-mapped or multi-way associative cache. The cache supports 1, 2, 4, 8, 16, or 32 ways, with a cache line size of 32 or 64 Bytes. The way size is configurable between 1 KiB and 2 MiB, but can be limited by the techmap.

91.2.1 Replacement policy

L2C-L implements Pseudo LRU and Random replacement policies. Pseudo LRU mimics LRU with less memory overhead, this is especially beneficial when using many ways. The random replacement selects cache lines to evict based on a counter that is incremented each clock cycle.

91.2.2 Write policy

The cache uses a copy-back write policy. A write access fetches the associated cache line from memory (unless a cache hit), updates the cache line, and sets the valid and dirty bits. Evicted cache lines are written back to memory.

91.2.3 Cachability

The core uses the VHDL generic, "cached", to determine which address range is cachable. Each bit in the 16-bit value defines the cachability of a 256 Mbyte address block on the AMBA AHB bus. A value of 16#00F3# will thus define cachable areas in 0 - 0x20000000 and 0x40000000 - 0x80000000

GRIP

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

91.2.4 AHB address mapping

The AHB slave interface occupies two AHB address ranges. The first AHB memory bar is used for the cache data range and is set up using VHDL generics "haddr" and "hmask". The second range is used for accessing I/O registers and its address is set up using VHDL generic "ioaddr". The size of the I/O area is statically set to 1 kB.

91.3 Operation

91.3.1 Read

A read access starts with a tag lookup. If the tag is found and valid, the cache delivers the requested data. Burst reads within a cacheline have no wait states after the initial tag matching. If a burst crosses a cacheline, wait states are inserted and a new tag lookup is performed. If the tag is not found, the replacement policy selects the cache line to be replaced. Evicted cache lines are buffered and written back to main memory once the new line is fetched. Wait states are inserted during the fetch. Non-cacheable read accesses issue single read accesses to the backend, affecting performance.

91.3.2 Write

A write access begins with a tag lookup. If the tag is found, writes are buffered and combined, then written back to memory. For write burst accesses, the tag lookup is repeated for each cacheline. Writing to a cacheline sets the dirty bit, triggering eviction during replacement. Write misses allocate new cache lines.

91.3.3 AHB slave interface

AHB Slave Interface: The slave interface connects the core to the CPU and level 1 cache. It supports 8-bit (byte), 16-bit (half word), 32-bit (word), 64-bit, and 128-bit single and burst accesses. Fixed increment and WRAP accesses are not supported.

91.3.4 AXI/AHB Master interface

The master interface connects the core to the memory controller using the Generic Bus Master IP core. It supports AXI and AHB and can be configured as 32, 64, or 128 bits.

91.3.5 Endianness

The core is compatible with big and little-endian systems.

91.3.6 Performance counters

Two 31-bit performance counters are available for access and misses. The overflow indicator is set in the last bit, which can only be cleared through the register interface. The counters can be read and reset. The hit counter can be calculated by subtracting the miss counter from the access counter.

91.3.7 Flush

L2C-L supports 5 flush modes: Flushing, Flush+Invalidate, Invalidate, Flush Address, and Flush Address + Invalidate.

91.3.8 Diagnostics

Diagnostic access to the tag and data RAM is available through the register interface. Internal RAMs can be read and written to.

1	Valid
0	Dirty

91.5   Vendor and device identifiers

The core has vendor identifier 0x01 (Cobham Gaisler) and device identifier 0x0D0. For description of vendor and device identifier see GRLIB IP Library User's Manual.

91.6   Implementation

91.6.1   RAM usage

The L2C-Lite uses dual-port RAM to implement both cache tags and data memory. The tags are implemented using the SYNCRAM_2P core, with the width and depth depending on the cache size configuration. The data memory is implemented using the SYNCRAM_2P which means that it can limit the line size and way size depending on which technology is used. See SYNCRAM_2P for technology specific limitations.

91.7   Configuration options

Table 1841 shows the configuration options of the core (VHDL generics).

*Table 1841.*Configuration options

Generic name	Function	Allowed range	Default
tech	The memory technology used for the internal Syncram.	0 - NTECH	0
hmindex	Master index	0 - NAHBMST-1	0
hsindex	Slave index.	0 - NAHBSLV-1	0
ways	Number of cache ways	1, 2, 4, 8, 16, 32	2
waysize	Size of ways (KiB)	1,2,4,8,16,32,64, 128 ...	64
linesize	MASK field of the AHB BAR.	32/64	32
repl	Replacement policy: 0 = pseudo-random, 1 = pseudo-LRU/pseudo-random	0-1	0
haddr	ADDR field of the AHB BAR	0 - 16#FFF#	0
hmask	MASK field of the AHB BAR.	0 - 16#FFF#	0
ioaddr	ADDR field of the AHB I/O BAR	0 - 16#FFF#	16#000#
cached	Cacheable memory ranges	0 - 16#FFFF#	16#FFFF#
be_dw	Backend bus width	32, 64, 128	32

```

92   L3STAT - LEON3 Statistics Unit

92.1   Overview

The LEON3 Statistics Unit (L3STAT) is used to count events in the LEON3 processor and on the AHB bus, in order to create performance statistics for various software applications.

L3STAT consists of a configurable number of 32-bit counters, which increment on a certain event. The counters roll over to zero when reaching their maximum value, but can also be automatically cleared on reading to facilitate statistics building over longer periods. Each counter has a control register where the event type is selected. In multi-processor systems, the control registers also indicates which particular processor core is monitored. The table 1844 below shows the event types that can be monitored.

NOTE: L3STAT does currently not support double-clocked processor configurations. The processors and statistics unit must be run on the same frequency as the AMBA buses for L3STAT to function correctly.

Table 1844. Event types and IDs

ID	Event description
Processor events:	
0x00	Instruction cache miss
0x01	Instruction MMU TLB miss
0x02	Instruction cache hold
0x03	Instruction MMU hold
0x08	Data cache (read) miss
0x09	Data MMU TLB miss
0x0A	Data cache hold
0x0B	Data MMU hold
0x10	Data write buffer hold
0x11	Total instruction count
0x12	Integer instructions
0x13	Floating-point unit instruction count
0x14	Branch prediction miss
0x15	Execution time, excluding debug mode
0x17	AHB utilization (per AHB master) (implementation depedent)
0x18	AHB utilization (total, master/CPU selection is ignored) (implementation dependent)
0x22	Integer branches
0x28	CALL instructions
0x30	Regular type 2 instructions
0x38	LOAD and STORE instructions
0x39	LOAD instructions
0x3A	STORE instructions
AHB events (only available if core is connected to a LEON3 Debug Support Unit):	
0x40	AHB IDLE cycles.
0x41	AHB BUSY cycles.
0x42	AHB NON-SEQUENTIAL transfers. Filtered on CPU/AHBM if SU(1) = '1'
0x43	AHB SEQUENTIAL transfers. Filtered on CPU/AHBM if SU(1) = '1'
0x44	AHB read accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x45	AHB write accesses. Filtered on CPU/AHBM if SU(1) = '1'

0x47	AHB half-word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x48	AHB word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x49	AHB double word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x4A	AHB quad word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x4B	AHB eight word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x4C	AHB waitstates. Filtered on CPU/AHBM if SU(1) = '1'
0x4D	AHB RETRY responses. Filtered on CPU/AHBM if SU(1) = '1'
0x4E	AHB SPLIT responses. Filtered on CPU/AHBM if SU(1) = '1'
0x4F	AHB SPLIT delay. Filtered on CPU/AHBM if SU(1) = '1'
0x50	AHB bus locked. Filtered on CPU/AHBM if SU(1) = '1'
0x51-0x5F	Reserved
Implementation specific events:	
0x60 - 0x6F	External event 0 - 15. Filtered on CPU/AHBM if SU(1) = '1'.
AHB events (only available if core is connected to a standalone AHB trace buffer):	
0x70	AHB IDLE cycles.
0x71	AHB BUSY cycles. Filtered on CPU/AHBM if SU(1) = '1'
0x72	AHB NON-SEQUENTIAL transfers. Filtered on CPU/AHBM if SU(1) = '1'
0x73	AHB SEQUENTIAL transfers. Filtered on CPU/AHBM if SU(1) = '1'
0x74	AHB read accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x75	AHB write accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x76	AHB byte accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x77	AHB half-word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x78	AHB word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x79	AHB double word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x7A	AHB quad word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x7B	AHB eight word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x7C	AHB waitstates. Filtered on CPU/AHBM if SU(1) = '1'
0x7D	AHB RETRY responses. Filtered on CPU/AHBM if SU(1) = '1'
0x7E	AHB SPLIT responses. Filtered on CPU/AHBM if SU(1) = '1'
0x7F	AHB SPLIT delay. Filtered on CPU/AHBM if SU(1) = '1'
Events generated from REQ/GNT signals (only available if core has been implemented with VHDL generic reqsel /=0)	
0x80 - 0x8F	Active when master selected by CPU/AHBM field has request asserted while grant is asserted for the master correspoding to the least significant nibble of the event ID. 0x80 is master 0 grant, 0x81 is master 1 grant, .., and so on.
0x90 - 0x9F	Active when master selected by CPU/AHBM field has request asserted while grant is deasserted for the master correspoding to the least significant nibble of the event ID. 0x90 is master 0 grant, 0x91 is master 1 grant, .., and so on.

Note that IDs 0x39 (LOAD instructions) and 0x3A (STORE instructions) will both count all LDST and SWAP instructions. The sum of events counted for 0x39 and 0x3A may therefore be larger than the number of events counted with ID 0x38 (LOAD and STORE instructions).

Event 0x00 - 0x3A can be counted of the core has been connected to one or several LEON3 processor cores. Counting of events 0x40 - 0x5F requires that the core is connected to a LEON3 Debug Support Unit (DSU). The core's Counter control registers have a field that shows if the core has been imple-

GRIP
Apr 2024, Version 2024.1
1508
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

mented with this connection. The documentation for the Debug Support Unit contains more information on events 0x40 - 0x5F. Please note that the statistical outputs from the DSU may be subject to AHB trace buffer filters. The same applies to events 0x70 - 0x7F that can come from an AHBTRACE core.

The core can also be implemented with support for counting up to 15 external events. These events can come from any source, but should be clocked by a clock which is synchronous with the AMBA clock used for the L3STAT core.

92.2   Multiple APB interfaces

The core can be implemented with two AMBA APB interfaces. The first APB interface always has precedence when both interfaces handle write operations to the same address.

92.3   Registers

The L3STAT core is programmed through registers mapped into APB address space.

Table 1845. L3STAT counter control register

APB address offset	Register
0x00	Counter 0 value register
0x04	Counter 1 value register
4 * n	Counter n value register
0x100	Counter 0 control register
0x104	Counter 1 control register
0x100 + (4 * n)	Counter n control register
0x200	Counter 0 max/latch register
0x204	Counter 1 max/latch register
0x200 + (4 * n)	Counter n max/latch register
0x300	Timestamp register

Note: Revision 0 of this IP core had control registers starting at 0x80, max/latch registers starting at 0x100 and the timestamp register at 0x180. This IP core documentation is valid for revision 1 of the IP core.

92.3.1 Counter Value Register

Table 1846.0x000+n.4 - CVALn - Counter value register

31	0
CVAL	
NR	
rw	

31: 0   Counter value (CVAL) - This register holds the current value of the counter. If the core has been implemented with support for keeping the maximum count (MC field of Counter control register is '1') and the Counter control register field CD is '1', then the value displayed by this register will be the maximum counter value reached with the settings in the counter's control register. Writing to this register will write both to the counter and, if implemented, the hold register for the maximum counter value.

92.3.2 Counter Control Register

Table 1847.0x100+n.4 - CCTRLn - Counter control register

31 23	22	21	20	19	18	17	16	15 14	13	12	11 4	3 0
NCNT	MC	IA	DS	EE	AE	EL	CD	SU	CL	EN	EVENT ID	CPU/AHBM
*	*	*	*	*	*	NR	NR	NR	NR	0	NR	NR
r	r	r	r	r	r	rw	rw	rw	rw	rw	rw	rw

31: 23   Number of counters (NCNT) - Number of implemented counters - 1

           Note revision 0 of this core used bits 31:28 to indicate the number of CPUs. This manual applies to revision 1 of the core.

22   Maximum count (MC) - If this field is '1' then this counter has support for keeping the maximum count value

21   Internal AHB count (IA) - If this field is '1' the core supports events 0x17 and 0x18

20   DSU support (DS) - If this field is '1' the core supports events 0x40-0x5F

19   External events (EE) - If this field is '1' the core supports external events (events 0x60 - 0x6F)

18   AHBTRACE Events (AE) - If this field is '1' the core supports events 0x70 - 0x7F.

17   Event Level (EL) - The value of this field determines the level where the counter keeps running when the CD field below has been set to '1'. If this field is '0' the counter will count the time between event assertions. If this field is '1' the counter will count the cycles where the event is asserted. This field can only be set if the MC field of this register is '1'.

16   Count maximum duration (CD) - If this bit is set to '1' the core will save the maximum time the selected event has been at the level specified by the EL field. This also means that the counter will be reset when the event is activated or deactivated depending on the value of the EL field.

           When this bit is set to '1', the value shown in the counter value register will be the maximum current value which may be different from the current value of the counter.

           This field can only be set if the MC field of this register is '1'.

15: 14   Supervisor/User mode filter (SU) - "01" - Only count supervisor mode events, "10" - Only count user mode events, others values - Count events regardless of user or supervisor mode. This setting only applies to events 0x0 - 0x3A.

           When SU = "1x" only events generated by the CPU/AHB master specified in the CPU/AHBM field will be counted. This applies to events 0x40 - 0x7F.

: 13   Clear counter on read (CL) - If this bit is set the counter will be cleared when the counter's value is read. The register holding the maximum value will also be cleared, if implemented.

           If an event occurs in the same cycle as the counter is cleared by a read then the event will not be counted. The counter latch register can be used to guarantee that no events are lost

12   Enable counter (EN) - Enable counter

11: 4   Event ID to be counted

3: 0   CPU or AHB master to monitor.(CPU/AHBM) - The value of this field does not matter when selecting one of the events coming from the Debug Support Unit or one of the external events.

92.3.3 Counter max/latch Register

*Table 1848.*0x200+4n - CSVALn - Counter max/latch register

31	0
CSVAL	
NR	
rw*	

31: 0   Counter max/latch value (CSVAL) - This register holds the current value of the counter max/latch register. It is only available for a specific counter If the core has been implemented with support for keeping the maximum count (MC field of Counter control register is '1').

If the counter control register field CD is '1', then the value displayed by this register will be the maximum counter value reached with the settings in the counter's control register.

If the counter control register field CD is '0', then the value displayed by this register is the latched (saved) counter value. The counter value is saved whenever a write access is made to the core in address range 0x100 - 0x1FC (all counters are saved simultaneously). If the counter control register CL field is set, then the current counter value will be cleared when the counter value is saved into this register.

92.3.4 Timestamp Register

*Table 1849.*0x300 - TSTAMP - Timestamp register

31	0
TSTAMP	
NR	
rw*	

31: 0   Timestamp (TSTAMP) - Timestamp taken at latch of counters

92.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x098. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

92.5 Implementation

92.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

92.6 Configuration options

Table 1850 shows the configuration options of the core (VHDL generics).

Table 1850. Configuration options

Generic	Function	Allowed range	Default
pindex	Selects which APB select signal (PSEL) will be used to access the statistical unit	0 to NAPBMAX-1	0
paddr	The 12-bit MSB APB address	0 to 16#FFF#	0
pmask	The APB address mask. Needs to be set to 16#FFE# if max/latch registers are enabled (VHDL generic clatch).	0 to 16#FFF#	16#FFF#
ncnt	Defines the number of counters	1 to 32	4
ncpu	Defines the number of CPUs monitored	1 - 16	1
nmax	If this generic is > 0, the core will include functionality for tracking the longest consecutive time that an event is active or inactive. The functionality will be available for the *nmax* first counters.	0 - 32	0
lahben	If this generic is 1, the core makes use of the AHBSI input for events 0x17 and 0x18, otherwise the AHBSI input is unused and events 0x17 and 0x18 will never increment a counter.	0 - 1	0
dsuen	If this generic is 1, the core makes use of the DSUO input for events 0x40 - 0x5F, otherwise the DSUO input is unused and events 0x40 - 0x5F will never increment a counter.	0 - 1	0
nextev	Defines the number of external events monitored	0 - 16	0
apb2en	Enables the second APB port on the core.	0 - 1	0
pindex2	Selects which APB select signal (PSEL) will be used to access the second interface of the statistical unit	0 to NAPBMAX-1	0
paddr2	The 12-bit MSB APB address for second interface	0 to 16#FFF#	0
pmask2	The APB address mask for second interface	0 to 16#FFF#	16#FFF#
astaten	If this generic is 1, the core makes use of the ASTAT input for events 0x70 - 0x7F, otherwise the ASTAT input is unused and events 0x70 - 0x7F will never increment a counter.	0 - 1	0
selreq	Support STATI.REQ/SEL events. If selreq is nonzero then the value+1 defines the number of monitored sel/req signals.	0 - 15	0
clatch	Include support for counter max/latch registers and time-stamp.	0 - 1	0
forcer0	For core to revision 0. If this generic is set to 1 then the maximum number of supported counters is 32 and the register address offsets and layout of the control register changes to comply to revision 0 of the IP core.	0 - 1	0

93   L4STAT - LEON4 Statistics Unit

93.1   Overview

The LEON4 Statistics Unit (L4STAT) is used count events in the LEON4 processor and on the AHB bus, in order to create performance statistics for various software applications.

L4STAT consists of a configurable number of 32-bit counters, which increment on a certain event. The counters roll over to zero when reaching their maximum value, but can also be automatically cleared on reading to facilitate statistics building over longer periods. Each counter has a control register where the event type is selected. In multi-processor systems, the control registers also indicates which particular processor core is monitored. The table 1853 below shows the event types that can be monitored.

NOTE: L4STAT does currently not support double-clocked processor configurations. The processors and statistics unit must be run on the same frequency as the AMBA buses for L4STAT to function correctly.

*Table 1853.*Event types and IDs

ID	Event description
Processor events:	
0x00	Instruction cache miss
0x01	Instruction MMU TLB miss
0x02	Instruction cache hold
0x03	Instruction MMU hold
0x08	Data cache (read) miss
0x09	Data MMU TLB miss
0x0A	Data cache hold
0x0B	Data MMU hold
0x10	Data write buffer hold
0x11	Total instruction count
0x12	Integer instructions
0x13	Floating-point unit instruction count
0x14	Branch prediction miss
0x15	Execution time, excluding debug mode
0x17	AHB utilization (per AHB master) (implementation depedent)
0x18	AHB utilization (total, master/CPU selection is ignored) (implementation dependent)
0x22	Integer branches
0x28	CALL instructions
0x30	Regular type 2 instructions
0x38	LOAD and STORE instructions
0x39	LOAD instructions
0x3A	STORE instructions
AHB events (only available if core is connected to a LEON4 Debug Support Unit):	
0x40	AHB IDLE cycles. Filtered on CPU/AHBM if SU(1) = '1'
0x41	AHB BUSY cycles. Filtered on CPU/AHBM if SU(1) = '1'
0x42	AHB NON-SEQUENTIAL transfers. Filtered on CPU/AHBM if SU(1) = '1'
0x43	AHB SEQUENTIAL transfers. Filtered on CPU/AHBM if SU(1) = '1'
0x44	AHB read accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x45	AHB write accesses. Filtered on CPU/AHBM if SU(1) = '1'

Table 1853. Event types and IDs

ID	Event description
0x46	AHB byte accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x47	AHB half-word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x48	AHB word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x49	AHB double word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x4A	AHB quad word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x4B	AHB eight word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x4C	AHB waitstates. Filtered on CPU/AHBM if SU(1) = '1'
0x4D	AHB RETRY responses. Filtered on CPU/AHBM if SU(1) = '1'
0x4E	AHB SPLIT responses. Filtered on CPU/AHBM if SU(1) = '1'
0x4F	AHB SPLIT delay. Filtered on CPU/AHBM if SU(1) = '1'
0x50	AHB bus locked. Filtered on CPU/AHBM if SU(1) = '1'
0x51-0x5F	Reserved
Implementation specific events:	
0x60 - 0x6F	External event 0 - 15. Filtered on CPU/AHBM if SU(1) = '1'.
AHB events (only available if core is connected to a standalone AHB trace buffer):	
0x70	AHB IDLE cycles. Filtered on CPU/AHBM if SU(1) = '1'
0x71	AHB BUSY cycles. Filtered on CPU/AHBM if SU(1) = '1'
0x72	AHB NON-SEQUENTIAL transfers. Filtered on CPU/AHBM if SU(1) = '1'
0x73	AHB SEQUENTIAL transfers. Filtered on CPU/AHBM if SU(1) = '1'
0x74	AHB read accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x75	AHB write accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x76	AHB byte accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x77	AHB half-word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x78	AHB word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x79	AHB double word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x7A	AHB quad word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x7B	AHB eight word accesses. Filtered on CPU/AHBM if SU(1) = '1'
0x7C	AHB waitstates. Filtered on CPU/AHBM if SU(1) = '1'
0x7D	AHB RETRY responses. Filtered on CPU/AHBM if SU(1) = '1'
0x7E	AHB SPLIT responses. Filtered on CPU/AHBM if SU(1) = '1'
0x7F	AHB SPLIT delay. Filtered on CPU/AHBM if SU(1) = '1'
Events generated from REQ/GNT signals (only available if core has been implemented with VHDL generic reqsel /=0)	
0x80 - 0x8F	Active when master selected by CPU/AHBM field has request asserted while grant is asserted for the master correspoding to the least significant nibble of the event ID. 0x80 is master 0 grant, 0x81 is master 1 grant, .., and so on.
0x90 - 0x9F	Active when master selected by CPU/AHBM field has request asserted while grant is deasserted for the master correspoding to the least significant nibble of the event ID. 0x90 is master 0 grant, 0x91 is master 1 grant, .., and so on.

Note that IDs 0x39 (LOAD instructions) and 0x3A (STORE instructions) will both count all LDST and SWAP instructions. The sum of events counted for 0x39 and 0x3A may therefore be larger than the number of events counted with ID 0x38 (LOAD and STORE instructions).

Event 0x00 - 0x3A can be counted of the core has been connected to one or several LEON4 processor cores. Counting of events 0x40 - 0x5F requires that the core is connected to a LEON4 Debug Support Unit (DSU). The core's Counter control registers have a field that shows if the core has been imple-

mented with this connection. The documentation for the Debug Support Unit contains more information on events 0x40 - 0x5F. Please note that the statistical outputs from the DSU may be subject to AHB trace buffer filters. The same applies to events 0x70 - 0x7F that can come from an AHBTRACE core.

The core can also be implemented with support for counting up to 15 external events. These events can come from any source, but should be clocked by a clock which is synchronous with the AMBA clock used for the L4STAT core.

93.2 Multiple APB interfaces

The core can be implemented with two AMBA APB interfaces. The first APB interface always has precedence when both interfaces handle write operations to the same address.

93.3 Registers

The L4STAT core is programmed through registers mapped into APB address space.

Table 1854. L4STAT counter control register

APB address offset	Register
0x00	Counter 0 value register
0x04	Counter 1 value register
4 * n	Counter n value register
0x100	Counter 0 control register
0x104	Counter 1 control register
0x100 + (4 * n)	Counter n control register
0x200	Counter 0 max/latch register
0x204	Counter 1 max/latch register
0x200 + (4 * n)	Counter n max/latch register
0x300	Timestamp register

Note: Revision 0 of this IP core had control registers starting at 0x80, max/latch registers starting at 0x100 and the timestamp register at 0x180. This IP core documentation is valid for revision 1 of the IP core.

93.3.1 Counter Value Register

*Table 1855.*0x000+n.4 - CVALn - Counter value register

31	0
CVAL	
NR	
rw	

31: 0   Counter value (CVAL) - This register holds the current value of the counter. If the core has been implemented with support for keeping the maximum count (MC field of Counter control register is '1') and the Counter control register field CD is '1', then the value displayed by this register will be the maximum counter value reached with the settings in the counter's control register. Writing to this register will write both to the counter and, if implemented, the hold register for the maximum counter value.

93.3.2 Counter Control Register

*Table 1856.*0x100+n.4 - CCTRLn - Counter control register

31 23	22	21	20	19	18	17	16	15 14	13	12	11 4	3 0
NCNT	MC	IA	DS	EE	AE	EL	CD	SU	CL	EN	EVENT ID	CPU/AHBM
*	*	*	*	*	*	NR	NR	NR	NR	0	NR	NR
r	r	r	r	r	r	rw	rw	rw	rw	rw	rw	rw

31: 23   Number of counters (NCNT) - Number of implemented counters - 1

Note revision 0 of this core used bits 31:28 to indicate the number of CPUs. This manual applies to revision 1 of the core.

22   Maximum count (MC) - If this field is '1' then this counter has support for keeping the maximum count value

21   Internal AHB count (IA) - If this field is '1' the core supports events 0x17 and 0x18

20   DSU support (DS) - If this field is '1' the core supports events 0x40-0x5F

19   External events (EE) - If this field is '1' the core supports external events (events 0x60 - 0x6F)

18   AHBTRACE Events (AE) - If this field is '1' the core supports events 0x70 - 0x7F.

17   Event Level (EL) - The value of this field determines the level where the counter keeps running when the CD field below has been set to '1'. If this field is '0' the counter will count the time between event assertions. If this field is '1' the counter will count the cycles where the event is asserted. This field can only be set if the MC field of this register is '1'.

16   Count maximum duration (CD) - If this bit is set to '1' the core will save the maximum time the selected event has been at the level specified by the EL field. This also means that the counter will be reset when the event is activated or deactivated depending on the value of the EL field.

When this bit is set to '1', the value shown in the counter value register will be the maximum current value which may be different from the current value of the counter.

This field can only be set if the MC field of this register is '1'.

15: 14   Supervisor/User mode filter (SU) - "01" - Only count supervisor mode events, "10" - Only count user mode events, others values - Count events regardless of user or supervisor mode. This setting only applies to events 0x0 - 0x3A.

When SU = "1x" only events generated by the CPU/AHB master specified in the CPU/AHBM field will be counted. This applies to events 0x40 - 0x7F

:   13   Clear counter on read (CL) - If this bit is set the counter will be cleared when the counter's value is read. The register holding the maximum value will also be cleared, if implemented.

If an event occurs in the same cycle as the counter is cleared by a read then the event will not be counted. The counter latch register can be used to guarantee that no events are lost.

12   Enable counter (EN) - Enable counter

11: 4   Event ID to be counted

3: 0   CPU or AHB master to monitor.(CPU/AHBM) - The value of this field does not matter when selecting one of the events coming from the Debug Support Unit or one of the external events.

93.3.3 Counter Max/Latch Register

*Table 1857.*0x200+4n - CSVALn - Counter max/latch register

31	0
CSVAL	
NR	
rw*	

31: 0   Counter max/latch value (CSVAL) - This register holds the current value of the counter max/latch register. It is only available for a specific counter If the core has been implemented with support for keeping the maximum count (MC field of Counter control register is '1').

If the counter control register field CD is '1', then the value displayed by this register will be the maximum counter value reached with the settings in the counter's control register.

If the counter control register field CDis '0', then the value displayed by this register is the latched (saved) counter value. The counter value is saved whenever a write access is made to the core in address range 0x100 - 0x1FC (all counters are saved simultaneously). If the counter control register CL field is set, then the current counter value will be cleared when the counter value is saved into this register.

93.3.4 Timestamp Register

*Table 1858.*0x300 - TSTAMP - Timestamp register

31	0
TSTAMP	
NR	
rw*	

31: 0   Timestamp (TSTAMP) - Timestamp taken at latch of counters

93.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x047. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

93.5 Implementation

93.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

93.6   Configuration options

Table 1859 shows the configuration options of the core (VHDL generics).

Table 1859. Configuration options

Generic	Function	Allowed range	Default
pindex	Selects which APB select signal (PSEL) will be used to access the statistical unit	0 to NAPBMAX-1	0
paddr	The 12-bit MSB APB address	0 to 16#FFF#	0
pmask	The APB address mask. Needs to be set to 16#FFE# if max/latch registers are enabled (VHDL generic clatch).	0 to 16#FFF#	16#FFF#
ncnt	Defines the number of counters	1 to 32	4
ncpu	Defines the number of CPUs monitored	1 - 16	1
nmax	If this generic is > 0, the core will include functionality for tracking the longest consecutive time that an event is active or inactive. The functionality will be available for the *nmax* first counters.	0 - 32	0
lahben	If this generic is 1, the core makes use of the AHBSI input for events 0x17 and 0x18, otherwise the AHBSI input is unused and events 0x17 and 0x18 will never increment a counter.	0 - 1	0
dsuen	If this generic is 1, the core makes use of the DSUO input for events 0x40 - 0x5F, otherwise the DSUO input is unused and events 0x40 - 0x5F will never increment a counter.	0 - 1	0
nextev	Defines the number of external events monitored	0 - 16	0
apb2en	Enables the second APB port on the core.	0 - 1	0
pindex2	Selects which APB select signal (PSEL) will be used to access the second interface of the statistical unit	0 to NAPBMAX-1	0
paddr2	The 12-bit MSB APB address for second interface	0 to 16#FFF#	0
pmask2	The APB address mask for second interface	0 to 16#FFF#	16#FFF#
astaten	If this generic is 1, the core makes use of the ASTAT input for events 0x70 - 0x7F, otherwise the ASTAT input is unused and events 0x70 - 0x7F will never increment a counter.	0 - 1	0
selreq	Support STATI.REQ/SEL events. If selreq is nonzero then the value+1 defines the number of monitored sel/req signals.	0 - 15	0
clatch	Include support for counter max/latch registers and time-stamp.	0 - 1	0
forcer0	For core to revision 0. If this generic is set to 1 then the maximum number of supported counters is 32 and the register address offsets and layout of the control register changes to comply to revision 0 of the IP core.	0 - 1	0

94   LEON_DSU_STAT_BASE - LEON3/4 SUBSYSTEM

94.1   Overview

LEON_DSU_STAT_BASE is a subsystem component that can be used to instantiate LEON3 or LEON4 processors together with their respective debug support unit (DSU) and a statistics unit (performance counters).

LEON_DSU_STAT_BASE allows to select between LEON3 and LEON4, with FT options optionally enabled for both variants. The subsystem also supports sharing one FPU between several processors.

The subsystem makes use of the following interfaces:

- Clock and reset input

- One AHB master output per processor, shared AHB master input and AHB slave inputs for all processors

- One interrupt controller interface per processor

- One AMBA APB port for, optional, performance counters

- Performance counter inputs

- DSU AHB slave interface and trace buffer inputs

- DSU enable, break, active and timer stop signals

The subsystem does not provide any additional functionality to the LEON, DSU and statistics IP cores. The subsystem is provided as a convenient way to include the three separate IP cores and to decrease the amount of top-level code required in designs that can be configured to select between LEON3 and LEON4.

The subsystem is primarily targeted to FPGA designs and for designs without a clock gate unit. The design does not propagate scan test settings and memory BIST signals.

94.2   Operation

94.2.1   Operational model

For a subsystem with LEON3, please refer to the documentation for:

- LEON3, section 95

- DSU3, section 27

- L3STAT, section 92

For a subsystem with LEON4, please refer to the documentation for:

- LEON4, section 96

- DSU4, section 28

- L4STAT, section 93

94.2.2   Bus widths

LEON_DSU_STAT_BASE allows to select between LEON3 and LEON4. If LEON4 is selected then the GRLIB AMBA bus width needs to be set to 64 or 128 bits. This is accomplished by changing the GRLIB configuration (GRLIB_CONFIG) package. The configuration package is described in GRLIB IP Library User's Manual (grlib.pdf). See also section 94.7 for references to example usage of LEON_DSU_STAT_BASE where the designs select the bus width depending on the selection between LEON3 and LEON4.

94.3 Implementation

Please refer to the IP core documentation listed in section 94.2.1.

94.4 Configuration options

Table 1862 shows the configuration options of the core (VHDL generics).

*Table 1862.*Configuration options

Generic name	Function	Allowed range	Default
leon	Selects between LEON3 (3) and LEON4 (4)	0, 3, 4	0
ncpu	Number of processors. Propagated to generic with the same name on LEON and DSU instances.	1 - 16	1

95 LEON3/FT - High-performance SPARC V8 32-bit Processor

95.1 Overview

LEON3 is a 32-bit processor core conforming to the IEEE-1754 (SPARC V8) architecture. It is designed for embedded applications, combining high performance with low complexity and low power consumption.

The LEON3 core has the following main features: 7-stage pipeline with Harvard architecture, separate instruction and data caches, memory management unit, hardware multiplier and divider, on-chip debug support and multi-processor extensions.

The LEON3 processor can be enhanced with fault-tolerance against SEU errors (referred to as LEON3FT). The fault-tolerance is focused on the protection of on-chip RAM blocks, which are used to implement IU/FPU register files and the cache memory. Configuring the processor to implement fault-tolerance enables additional internal registers, register fields and changes the processor's plug&play device ID. This documentation describes both the LEON3 and LEON3FT versions of the processor.
Figure 242. LEON3 processor core block diagram

Note: This manual describes the full functionality of the LEON3 core. Through the use of VHDL generics, parts of the described functionality can be suppressed or modified to generate a smaller or faster implementation. A comparison with earlier revisions can be found in section 95.13.

Please also refer to the *LEON/GRLIB Configuration and Development Guide* for recommendations on system design and LEON3 configuration.

95.1.1 Integer unit

The LEON3 integer unit implements the full SPARC V8 manual, including hardware multiply and divide instructions. The number of register windows is configurable within the limit of the SPARC manual (2 - 32), with a default setting of 8. The pipeline consists of 7 stages with a separate instruction and data cache interface (Harvard architecture).

95.1.2 Cache sub-system

LEON3 has a highly configurable cache system, consisting of a separate instruction and data cache. Both caches can be configured with 1 - 4 ways, 1 - 256 KiB/way, 16 or 32 bytes per line. The instruc-

GRIP

Apr 2024, Version 2024.1

1529

Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

tion cache maintains one valid bit per 32-bit word and uses streaming during line-refill to minimize refill latency. The data cache has one valid bit per cache line, uses write-through policy and implements a double-word write-buffer. Bus-snooping on the AHB bus can be used to maintain cache coherency for the data cache. Local scratch pad ram can be added to either of the instruction and data caches to allow 0-waitstates access instruction or data memory without any AHB bus access.

95.1.3 Floating-point unit and co-processor

The LEON3 integer unit provides interfaces for a floating-point unit (FPU), and a custom co-processor. Two FPU controllers are available, one for the high-performance GRFPU and one for the GRFPU-Lite core. The floating-point processors and co-processor execute in parallel with the integer unit, and does not block the operation unless a data or resource dependency exists. Note that the FPUs are provided separately.

95.1.4 Memory management unit

A SPARC V8 Reference Memory Management Unit (SRMMU) can optionally be enabled. The SRMMU implements the full SPARC V8 MMU specification, and provides mapping between multiple 32-bit virtual address spaces and physical memory. A three-level hardware table-walk is implemented, and the MMU can be configured to up to 64 fully associative TLB entries per implemented TLB.

95.1.5 On-chip debug support

The LEON3 pipeline includes functionality to allow non-intrusive debugging on target hardware. To aid software debugging, up to four watchpoint registers can be enabled. Each register can cause a breakpoint trap on an arbitrary instruction or data address range. When the (optional) debug support unit is attached, the watchpoints can be used to enter debug mode. Through a debug support interface, full access to all processor registers and caches is provided. The debug interfaces also allows single stepping, instruction tracing and hardware breakpoint/watchpoint control. An internal trace buffer can monitor and store executed instructions, which can later be read out via the debug interface.

95.1.6 Interrupt interface

LEON3 supports the SPARC V8 interrupt model with a total of 15 asynchronous interrupts. The interrupt interface provides functionality to both generate and acknowledge interrupts.

95.1.7 AMBA interface

The cache system implements an AMBA AHB master to load and store data to/from the caches. The interface is compliant with the AMBA-2.0 standard. During line refill, incremental bursts are generated to optimise the data transfer. The processor also has a snoop AHB slave input port which is used to monitor the accesses made by other masters, if snooping has been enabled.

95.1.8 Power-down mode

The LEON3 processor core implements a power-down mode, which halts the pipeline and caches until the next interrupt. The processor supports optional clock gating during the power down period by providing a clock-enable signal that can be tied to an external clock gate cell, and by providing a separate clock input for the small part of the CPU that needs to run during power-down to check for wake-up conditions and maintain cache coherency.

95.1.9 Multi-processor support

LEON3 is designed to be used in multi-processor systems. Each processor has a unique index to allow processor enumeration. The write-through caches and snooping mechanism guarantees cache coherency in shared-memory systems.

95.2 LEON3 integer unit

95.2.1 Overview

The LEON3 integer unit implements the integer part of the SPARC V8 instruction set. The implementation is focused on high performance and low complexity. The LEON3 integer unit has the following main features:

- 7-stage instruction pipeline

- Separate instruction and data cache interface

- Support for 2 - 32 register windows

- Hardware multiplier with optional 16x16 bit MAC and 40-bit accumulator

- Radix-2 divider (non-restoring)

- Static branch prediction

- Single-vector trapping for reduced code size

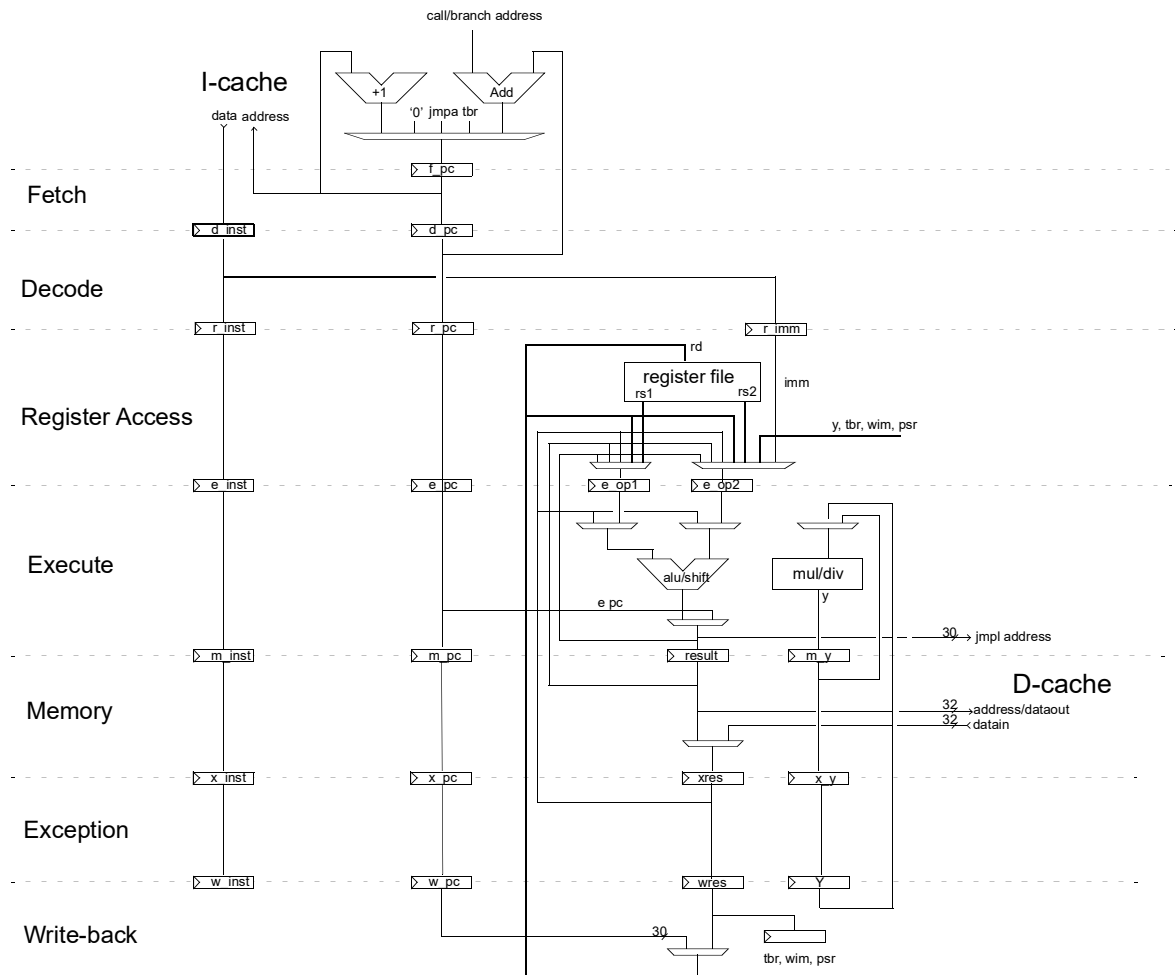
Figure 243 shows a block diagram of the integer unit.


Figure 243. LEON3 integer unit datapath diagram

+46 31 7758650 | frontgrade.com/gaisler

95.2.2 Instruction pipeline

The LEON3 integer unit uses a single instruction issue pipeline with 7 stages:

1. FE (Instruction Fetch): If the instruction cache is enabled, the instruction is fetched from the instruction cache. Otherwise, the fetch is forwarded to the AHB bus. The instruction is valid at the end of this stage and is latched inside the IU.
2. DE (Decode): The instruction is decoded and the CALL and Branch target addresses are generated.
3. RA (Register access): Operands are read from the register file or from internal data bypasses.
4. EX (Execute): ALU, logical, and shift operations are performed. For memory operations (e.g., LD) and for JMPL/RETT, the address is generated.
5. ME (Memory): Data cache is read or written at this time.
6. XC (Exception) Traps and interrupts are resolved. For cache reads, the data is aligned as appropriate.
7. WR (Write): The result of any ALU, logical, shift, or cache operations are written back to the register file.

Table 1865 lists the cycles per instruction (assuming cache hit and no icc or load interlock):

*Table 1865.*Instruction timing

Instruction	Cycles (MMU disabled)	Cycles (MMU fast-write)	Cycles (MMU slow-write)
JMPL	3^1	3^1	3^1
JMPL,RETT pair	4	4	4
Double load	2	2	2
Single store	2	2	4
Double store	3	3	5
SMUL/UMUL	$1/4^2$	$1/4^2$	$1/4^2$
SDIV/UDIV	35	35	35
Taken Trap	5	5	5
Atomic load/store	3	3	5
All other instructions	**1**	**1**	**1**

[1] Assuming instruction in JMPL delay slot takes one cycle. Additional cycles spent in the delay slot will reduce the effective time of the JMPL to 2 or 1.

[2] Multiplication cycle count is 1 clock (1 clock issue rate, 2 clock data latency), for the 32x32 multiplier and 4 clocks (issue rate, 4/5 clocks data latency for standard/pipelined version) for the 16x16 version.

A number of conditions can extend an instruction's duration in the pipeline:

Branch interlock: When a conditional branch or trap is performed 1-2 cycles after an instruction which modifies the condition codes, 1-2 cycles of delay is added to allow the condition to be computed. If static branch prediction is enabled, this extra delay is incurred only if the branch is not taken.

Load delay: When using data resulting on a load shortly after the load, the instruction will be delayed to satisfy the pipeline's load delay. The processor pipeline can be configured for one or two cycles load delay. One cycle load delay will improve performance at a fixed speed but may degrade maximum clock frequency due to added forwarding paths in the pipeline.

Mul latency: For pipelined multiplier implementations there is 1 cycle extra data latency, accessing the result immediately after a MUL or MAC will then add one cycle pipeline delay.

Hold cycles: During cache miss processing or when blocking on the store buffer, the pipeline will be held still until the data is ready, effectively extending the execution time of the instruction causing the miss by the corresponding number of cycles. Note that since the whole pipeline is held still, hold cycles will not mask load delay or interlock delays. For instance on a load cache miss followed by a data-dependent instruction, both hold cycles and load delay will be incurred.

FPU/Coprocessor: The floating-point unit or coprocessor may need to hold the pipeline or extend a specific instruction. When this is done is specific to the FP/CP unit.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

95.2.3 SPARC Implementor's ID

Frontgrade Gaisler is assigned number 15 (0xF) as SPARC implementor's identification. This value is hard-coded into bits 31:28 in the %psr register. The version number for LEON3 is 3, which is hard-coded in to bits 27:24 of the %psr.

95.2.4 Divide instructions

Full support for SPARC V8 divide instructions is provided (SDIV, UDIV, SDIVCC & UDIVCC). The divide instructions perform a 64-by-32 bit divide and produce a 32-bit result. Rounding and overflow detection is performed as defined in the SPARC V8 manual.

The divide instruction is required for full SPARC V8 compliance but can be configured out to save area using the *v8* VHDL generic.

95.2.5 Multiply instructions

The LEON processor supports the SPARC integer multiply instructions UMUL, SMUL UMULCC and SMULCC. These instructions perform a 32x32-bit integer multiply, producing a 64-bit result. SMUL and SMULCC performs signed multiply while UMUL and UMULCC performs unsigned multiply. UMULCC and SMULCC also set the condition codes to reflect the result. The multiply instructions are performed using a 32x32 pipelined hardware multiplier, or a 16x16 hardware multiplier which is iterated four times. To improve the maximum frequency on slow technologies, the 16x16 multiplier can optionally be provided with a pipeline stage.

The multiply instruction is required for full SPARC V8 compliance, but can be configured out to save area using the *v8* VHDL generic.

95.2.6 Multiply and accumulate instructions

To accelerate DSP algorithms, two multiply&accumulate instructions are implemented: UMAC and SMAC. The UMAC performs an unsigned 16-bit multiply, producing a 32-bit result, and adds the result to a 40-bit accumulator made up by the 8 lsb bits from the %y register and the %asr18 register. The least significant 32 bits are also written to the destination register. SMAC works similarly but performs signed multiply and accumulate. The MAC instructions execute in one clock but have two clocks latency, meaning that one pipeline stall cycle will be inserted if the following instruction uses the destination register of the MAC as a source operand.

The UMAC and SMAC instructions occupy the unused opcodes op=10,op3=1111110 for UMAC and op=10,op3=1111111 for SMAC.

Assembler syntax:

```
umac rs1, reg_imm, rd
smac rs1, reg_imm, rd
```

Operation:

```
prod[31:0] = rs1[15:0] * reg_imm[15:0]
result[39:0] = (Y[7:0] & %asr18[31:0]) + prod[31:0]
(Y[7:0] & %asr18[31:0]) = result[39:0]
rd = result[31:0]
```

%asr18 can be read and written using the RDASR and WRASR instructions.

The MAC instructions are an optional extension to SPARC V8, and enabled using the *mac* VHDL generic. The multiply and accumulate support also requires MUL/DIV support enabled by the *v8* VHDL generic and can only be used together with a 16x16 multiplier.

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

95.2.7 Compare and Swap instruction (CASA)

LEON3 implements the SPARC V9 Compare and Swap Alternative (CASA) instruction. The CASA instruction operates as described in the SPARC V9 manual. The instruction is privileged but setting ASI = 0xA (user data) will allow it to be used in user mode.

Software can determine if the processor supports CASA by checking the NOTAG field of the %asr17 register described in section 95.11.2.

95.2.8 Branch prediction

Static branch prediction can be optionally be enabled, and reduces the penalty for branches preceded by an instruction that modifies the integer condition codes (see section 95.2.2). The predictor uses a branch-always strategy, and starts fetching instruction from the branch address. On a prediction hit, 1 or 2 clock cycles are saved, and there is no extra penalty incurred for misprediction as long as the branch target can be fetched from cache. Branch prediction improves the performance with 10 - 20% on most control-type applications.

95.2.9 Register file data protection

Register file data protection is available for the fault-tolerant version of the LEON3 and is enabled via a VHDL generic. Register file data protection is described in section 95.9.2.

95.2.10 Hardware breakpoints

The integer unit can be configured to include up to four hardware breakpoints. Each breakpoint consists of a pair of ancillary state registers (see section 95.11.3). Any binary aligned address range can be watched for instruction or data access, and on a breakpoint hit, trap 0x0B is generated.

95.2.11 Instruction trace buffer

The (optional) instruction trace buffer consists of a circular buffer that stores executed instructions. This is enabled and accessed only through the processor's debug port via the Debug Support Unit. When enabled, the following information is stored in real time, without affecting performance:

• Instruction address and opcode

• Instruction result

• Load/store data and address

• Trap information

• 30-bit time tag

The operation and control of the trace buffer is further described in section 27.4. Note that in multi-processor systems, each processor has its own trace buffer allowing simultaneous tracing of all instruction streams.

The size of the trace buffer is configurable from 1 to 64 KiB through the *tbuf* VHDL generic. If the value of tbuf is in the 65-128 range, a two-port instruction trace buffer of size *tbuf*-64 KiB will be used, allowing contextual reading of instructions while tracing is ongoing.

95.2.12 Processor configuration register

The ancillary state register 17 (%asr17) provides information on how various configuration options were set during synthesis. This can be used to enhance the performance of software, or to support enumeration in multi-processor systems. See section 95.11.2 for layout.

95.2.13 Exceptions

LEON3 adheres to the general SPARC trap model. The table below shows the implemented traps and their individual priority. When PSR (processor status register) bit ET=0, an exception trap causes the processor to halt execution and enter error mode, and the external error signal will then be asserted.

Table 1866. Trap allocation and priority

Trap	TT	Pri	Description	Class
reset	0x00	1	Power-on reset	Interrupting
data_store_error	0x2b	2	write buffer error during data store	Interrupting
instruction_access_exception	0x01	3	Error or MMU page fault during instruction fetch	Precise
privileged_instruction	0x03	4	Execution of privileged instruction in user mode	Precise
illegal_instruction	0x02	5	UNIMP or other un-implemented instruction	Precise
fp_disabled	0x04	6	FP instruction while FPU disabled	Precise

interrupt_level_6	0x16	26	Asynchronous interrupt 6	Interrupting
interrupt_level_5	0x15	27	Asynchronous interrupt 5	Interrupting
interrupt_level_4	0x14	28	Asynchronous interrupt 4	Interrupting
interrupt_level_3	0x13	29	Asynchronous interrupt 3	Interrupting
interrupt_level_2	0x12	30	Asynchronous interrupt 2	Interrupting
interrupt_level_1	0x11	31	Asynchronous interrupt 1	Interrupting

The prioritization follows the SPARC V8 manual in the regular non-FT case. In the FT case there is a minor difference for r_register_access_error, which has lower priority than window_over/underflow because the window condition is detected before the register file is accessed on the LEON3FT.

The fp/cp_exception traps may be either deferred or precise depending on implementation, for the GRFPU and GRFPU-Lite implementations they are deferred.

GRIP
Apr 2024, Version 2024.1

1535

Frontgrade Gaisler AB

+46 31 7758650 | frontgrade.com/gaisler

The data_store_error is delivered as a deferred exception but is non-resumable and therefore classed as interrupting. Likewise, r_register_access_error is delivered as a precise trap but since it is non-resumable it is classed as an interrupting trap.

95.2.14 Single vector trapping (SVT)

Single-vector trapping (SVT) is an SPARC V8e option to reduce code size for embedded applications. When enabled, any taken trap will always jump to the reset trap handler (%tbr.tba + 0). The trap type will be indicated in %tbr.tt, and must be decoded by the shared trap handler. SVT is enabled by setting bit 13 in %asr17. The model must also be configured with the VHDL generic *svt* = 1

95.2.15 Address space identifiers (ASI)

In addition to the address, a SPARC processor also generates an 8-bit address space identifier (ASI), providing up to 256 separate, 32-bit address spaces. During normal operation, the LEON3 processor accesses instructions and data using ASI 0x8 - 0xB as defined in the SPARC manual. Using the LDA/STA instructions, alternative address spaces can be accessed. The different available ASIs are described in section 95.10.

95.2.16 Partial WRPSR

Partial write %PSR (WRPSR) is a SPARC V8e option that allows WRPSR instructions to only affect the %PSR.ET field. If the processor has been implemented with support for partial WRPSR and the WRPSR instruction's rd field is non-zero, then the WRPSR write will only update ET.

The model must be configured with the VHDL generic pwrpsr = 1 for partial WRPSR to be supported. Implementations that do not support partial WRPSR will write the full %PSR register regardless of the value of the WRPSR instruction's rd field.

95.2.17 Alternative window pointer

Alternative window pointer (AWP) is a SPARC V8e option intended to reduce interrupt latency by allowing code that manipulates the current window pointer, mainly window over and underflow handlers and context switching code, to run with traps enabled.

Two bits are added to the PSR register, AW (alternative window) and PAW (previous alternative window). Also an AWP (alternative window pointer) field is added in an ASR register.

When the AW bit is set, the current register window used for reading/writing non-global registers is taken from the AWP register field instead of the normal CWP register field, and SAVE and RESTORE operations modify the AWP field instead of the CWP. SAVE and RESTORE can do not trigger the window over/underflow traps while AW is set.

When both AW and PAW are zero, the AWP field is kept equal to the CWP field.

When a trap occurs, the value of AW is copied into the PAW field, and AW is cleared. When returning from a trap using the RETT instruction, the PAW field is copied back into AW. The RETT will not trigger the window underflow trap if PAW is set regardless of if CWP or AWP point to an invalid window.

95.2.18 Register file partitioning

Register file partitioning is an optional extension (enabled through the altwin generic) to allow a subrange of the register windows to be used as if it was the whole register file. The selected subset is connected in a ring so that the outs of the lowest register window is aliased to the ins of the highest register window in the range. Other register windows outside this range are not accessible and will be kept at their old values while the partitioning is enabled.

The partitioning is activated by setting the STWIN and CWPMAX fields of the %asr20 register. This selects the subset of windows between STWIN and STWIN+CWPMAX so that they map to CWP

GRIP
Apr 2024, Version 2024.1

1536

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

values 0 to CWPMAX. STWIN and CWPMAX must be set so they map to a valid range, CWP-MAX+STWIN must not exceed the highest possible CWP value supported in the normal case. Also, for correct operation, CWP must be set to a value between 0 and CWPMAX before accessing any non-global register.

Writing CWPMAX to (otherwise illegal value) 0 in %asr20 will result in writing only AWP and keeping the values of STWIN and CWPMAX.

A special write-only bit in the %asr20 register can be used to write CWP in the PSR at the same time as writing the STWIN,CWPMAX,AWP fields, this is intended to allow switching between two register file partitions without disabling interrupts.

The WIM register is not managed by the partitioning logic, therefore the lowest bits of the WIM will map to the partitioned windows. The highest bits of the WIM will be masked to 0 on read to simulate a smaller register file, however these bits are still writable.

95.2.19 Power-down

The processor can be configured to include a power-down feature to minimize power consumption during idle periods. The power-down mode is entered by performing a WRASR instruction to %asr19:

```
wr %g0, %asr19
```

During power-down, the pipeline is halted until the next interrupt occurs. Signals inside the processor pipeline and caches are then static, reducing power consumption from dynamic switching.

Note: %asr19 must always be written with the data value zero to ensure compatiblity with future extensions.

Note: This instruction must be performed in supervisor mode with interrupts enabled.

When resuming from power-down, the pipeline will be re-filled from the point of power-down and the first instruction following the WRASR instruction will be executed prior to taking the interrupt trap. Up to six instructions after the WRASR instruction will be fetched (possibly with cache miss if they are not in cache) prior to fetching the trap handler.

95.2.20 Processor reset operation

The processor is reset by asserting the RESET input for at least 4 clock cycles. The following table indicates the reset values of a subset of the registers which are affected by the reset..

*Table 1867.*Processor reset values

Register	Reset value
Trap Base Register	Trap Base Address field reset (value given by *rstaddr* VHDL generic)
PC (program counter)	0x0 (*rstaddr* VHDL generic)
nPC (next program counter)	0x4 (*rstaddr* VHDL genericc + 4)
PSR (processor status register)	ET=0, S=1

By default, the execution will start from address 0. This can be overridden by setting the *rstaddr* VHDL generic in the model to a non-zero value. The reset address is always aligned on a 4 KiB boundary. If *rstaddr* is set to 16#FFFFF#, then the reset address is taken from the signal IRQI.RST-VEC. This allows the reset address to be changed dynamically.

95.2.21 Multi-processor systems

In multiprocessor systems, the ID of the processor on which the code is executing can be read out by reading the index field of the LEON3 configuration register. Only processor 0 starts executing after reset, the others are in power-down mode and are activated by a signal from the interrupt controller.

95.2.22 LEON-REX extension

The processor can be built with support for the LEON-REX addition to the SPARC instruction set, allowing a more compact code representation than the regular SPARC machine code. The details of the extension are given in a separate document. The extension is implemented when the *rex* VHDL generic is set.

Detection of whether support is present can be done by checking the REXV field in the asr17 register (see section 95.11.2). The REX support can be set to enabled, illegal or transparent mode via the REXEN/REXILL bits in the asr17 register, after reset the default setting is illegal so any LEON-REX code will cause an illegal instruction trap.

The extension is implemented as a decompressor internally inside the pipeline and does not affect the behavior of the caches, MMU or AHB bus interfaces.

When the *rex* generic is set, the instruction trace buffer entries are changed so the two most significant bits of the time tag are instead used to represent REX mode enabled status, and bit 1 of the program counter. The instructions opcodes logged into the trace buffer are the regular SPARC opcodes that are generated internally in the pipeline, not the LEON-REX opcodes that are in memory and cache.

95.3 Cache system

95.3.1 Overview

The LEON3 processor pipeline implements a Harvard architecture with separate instruction and data buses, connected to two separate cache controllers. As long as the execution does not cause a cache miss, the cache controllers can serve one 32-bit instruction fetch and one 32-bit data load/store per cycle, keeping the pipeline running at full speed. Each cache controller can be configured with different sizes and replacement policy, and it is also possible to attach local RAM to each cache controller.

On cache miss, the cache controller will assert a hold signal freezing the IU pipeline, and after delivering the data the hold signal is again lifted so execution continues. For accessing the bus, the cache controllers share the same AHB connection to the on-chip bus. Certain parts of the MMU (table walk logic, and depending on configuration also TLB buffer) are also shared between the two caches.

Another important component included in the data cache is the write buffer, allowing stores to proceed in parallel to executing instructions.

Cachability (memory areas that are cachable) for both caches is controlled either through the AHB plug&play address information or using a VHDL generic, see section 95.7.2.

95.3.2 Cache operation

Each cache controller has two main memory blocks, the tag memory and the data memory. At each address in the tag memory, a number of cache entries, ways, are stored for a certain set of possible memory addresses. The data memory stores the data for the corresponding ways.

For each way, the tag memory contains the following information:

- Valid bits saying if the entry contains valid data or is free. The I-cache has one valid bit per word (instruction) while the D-cache has a single valid bit for the whole cache line.

- The tag, all bits of the cached memory address that are not implied by the set

- If MMU is enabled, the context ID of the cache entry

- If MMU is enabled with *mmuen* generic set to 2, SO bit (supervisor only access)

- If locking support is enabled, a lock bit for that entry

- If LRR is used, a bit specifying the replacement order

- If FT is enabled, check bits for detecting errors

GRIP
Apr 2024, Version 2024.1
1538
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

When a read from cache is performed, the tags and data for all cache ways of the corresponding set are read out in parallel, the tags and valid bits are compared to the desired address and the matching way is selected. In the hit case, this is all done in the same cycle to support the full execution rate of the processor.

In the miss case, the cache will at first deliver incorrect data. However on the following cycle, a hold signal will be asserted to prevent the processor from proceeding with that data. After the miss has been processed, the correct data is injected into the pipeline using a memory data strobe (mds) signal, and afterwards the hold signal can be released. If the missed address is cacheable, then the data read in from the cache miss will be stored into the cache, possibly replacing one of the existing ways.

The miss case is handled slightly differently for the I and D caches. Depending on the instruction burst fetch configuration bit, the instruction cache will either read the single missed instruction, or stream in data from the missed address until to the end of that cache line. The valid bits in the cache will reflect which words in the line were actually read in. The D-cache will always fetch a whole cache line on miss and therefore only has one valid bit.

In the instruction streaming case, the processor pipeline is stepped one step for every received instruction. If the processor needs extra pipeline cycles to stretch a multi-cycle instruction, or due to an interlock condition (see section 95.2), or if the processor jumps/branches away, then the instruction cache will hold the pipe, fetch the remainder of the cache line, and the pipeline will then proceed normally.

95.3.3 Cache configuration options

Each cache controller can be configured to implement a single-way (direct-mapped) cache or a multiway cache with set associativity of 2 - 4. The way size is configurable to 1 - 256 KiB, divided into cache lines with 16 or 32 bytes of data.

In multi-way configurations, one of three replacement policies can be selected:

- Least-recently-used (LRU) - This maintains the order of usage for each set in the cache and replaces the one that has was used last. The LRU information needs to be updated on every cache hit and is therefore not stored with the tags but in separate flip flops.

- Least-recently-replaced (LRR) - This stores the index of the oldest replaced way along with the tags and uses this to select which way to replace. This policy can only be implemented when the number of ways is set to 2.

- Pseudo-random - This method samples a free-running counter to select which way to replace. System jitter (AMBA bus delay variations) will help to randomize the selected value.

Locking support can also be added to each cache if desired. This option adds a lock bit to each tag that allows you to lock a number of ways in each set, preventing those cache entries from being replaced. Note that when using locking together with LRU and more than two ways, this will add extra lookup tables to determine which way to replace and this might become a critical path in the core.

95.3.4 Address mapping

The addresses seen by the CPU are divided into tag, index and offset bits. The index is used to select the set in the cache, therefore only a limited number of cache lines with the same index part can be stored at one time in the cache. The tag is stored in the cache and compared upon read.

Figure 244. Cache address mapping examples

95.3.5 Data cache policy

The data cache employs a write-through policy, meaning that every store made on the CPU will propagate, via the write buffer, to the bus and there are no "dirty" lines in the cache that has not yet been written out apart from what is in the buffer. The store will also update the cache if the address is present, however a new line will not be allocated in that case

.

*Table 1868.*LEON3 Data caching behavior

Operation	In cache	Cacheable	Bus action	Cache action	Load data
Data load	No	No	Read	No change	Bus
	No	Yes	Read	Line allocated/replaced	Bus
	Yes	-	None	No change	Cache
Data load with forced cache miss (ASI 1)	No	No	Read	No change	Bus
	No	Yes	Read	Line allocated/replaced[1]	Bus
	Yes	-	Read	Data updated[1]	Bus
Data load with MMU bypass (ASI 0x1C)	-	-	Read (phys addr)	No change	Bus
Data store	No	No	Write (via buffer)	No change	(N/A)
	No	Yes	Write (via buffer)	No change	(N/A)
	Yes	-	Write (via buffer)	Data updated	(N/A)
Data store with MMU bypass (ASI 0x1C)	-	-	Write (via buffer, phys addr)	No change	(N/A)

[1] This behavior varies slightly between LEON3 versions, see section 95.13.3

95.3.6 Write buffer

The data cache contains a write buffer able to hold a single 8,16,32, or 64-bit write. For half-word or byte stores, the stored data replicated into proper byte alignment for writing to a word-addressed device. The write is processed in the background so the processor pipeline can keep executing while the write is being processed. However, any following instruction that requires bus access will block until the write buffer has been emptied. Loads served from cache will however not block, due to the cache policy used there can not be a mismatch between cache data and store buffer (the effect of this behavior on SMP systems is discussed in section 95.8).

Since the processor executes in parallel with the write buffer, a write error will not cause an exception to the store instruction. Depending on memory and cache activity, the write cycle may not occur until

several clock cycles after the store instructions has completed. If a write error occurs, the currently executing instruction will take trap 0x2b. This trap can be disabled using the DWT configuration (see section 95.11.2).

Note: a 0x2b trap handler should flush the data cache, since a write hit would update the cache while the memory would keep the old value due the write error.

95.3.7 Operating with MMU

When MMU is enabled, the virtual addresses seen by the running code no longer correspond directly to the physical addresses on the AHB bus. The cache uses tags based on the virtual addresses, as this avoids having to do any additional work to translate the address in the most timing-critical hit case. However, any time a bus access needs to be made, a translation request has to be sent to the MMU to convert the virtual address to a physical address. For the write buffer, this work is included in the background processing of the store. The translation request to the MMU may result in memory accesses from the MMU to perform table walk, depending on the state of the MMU.

The MMU context ID is included in the cache tags in order to allow switching between multiple MMU contexts mapping the same virtual address to different physical addresses. Note that the cache does not detect aliases to the same physical address so in that case the same physical address may be cached in multiple ways (also see snooping below).

95.3.8 Snooping

The data cache can be configured to support AHB bus snooping. The AHB bus the processor is connected to, is monitored for writes from other masters to an address that is in the cache. If a write is done to a cached address, that cache line is marked invalid and the processor will be forced to fetch the (new) data from memory the next time it is read.

For using snooping together with the MMU, an extra tag memory storing physical tags must be added to allow comparing with the physical address on the AHB bus (called separate snoop tags or physical tags).

The processor can snoop on itself and invalidate any other cache lines aliased to the same physical address in case there are multiple virtual mappings to the same physical address that is being written. However, note that this does not happen until the write occurs on the bus so the other virtual aliases will return the old data in the meantime. Note also that the behavior is not available in older LEON3 version.

Snooping requires the way size of the cache to be equal or smaller than the MMU page size, otherwise the index into the physical and virtual tag RAM:s may not match, resulting in aliasing problems.

95.3.9 Enabling and disabling cache

Both I and D caches are disabled after reset. They are enabled by writing to the cache control register (see 95.11.6). Before enabling the caches after a reset they must be flushed to ensure that all tags are marked invalid.

95.3.10 Cache freeze

Each cache can be in one of three modes: disabled, enabled and frozen. If disabled, no cache operation is performed and load and store requests are passed directly to the memory controller. If enabled, the cache operates as described above. In the frozen state, the cache is accessed and kept in sync with the main memory as if it was enabled, but no new lines are allocated on read misses.

If the DF or IF bit is set, the corresponding cache will be frozen when an asynchronous interrupt is taken. This can be beneficial in real-time system to allow a more accurate calculation of worst-case execution time for a code segment. The execution of the interrupt handler will not evict any cache lines and when control is returned to the interrupted task, the cache state is identical to what it was

before the interrupt. If a cache has been frozen by an interrupt, it can only be enabled again by enabling it in the CCR. This is typically done at the end of the interrupt handler before control is returned to the interrupted task.

95.3.11 Flushing

Both instruction and data cache are flushed either by executing the FLUSH instruction, setting the FI/FD bits in the cache control register, or by writing to certain ASI address spaces.

Cache flushing takes one clock cycle per cache set, during which the IU will not be halted, but during which the caches are disabled. When the flush operation is completed, the cache will resume the state (disabled, enabled or frozen) indicated in the cache control register. Diagnostic access to the cache is not possible during a flush operation and will cause a data exception (trap=0x09) if attempted.

Note that while the SPARC V8 specifies only that the instructions pointed to by the FLUSH argument will be flushed, the LEON3 will additionally flush the entire I and D cache (which is permitted by the manual as the additional flushing only affects performance and not operation). While the LEON3 currently ignores the address argument, it is recommended for future compatibility to only use the basic flush %g0 form if you want the full flush behavior.

95.3.12 Locking

In a multi-way configuration the instruction and data cache controllers can be configured with optional lock bit in the cache tag. Setting the lock bit prevents the cache line to be replaced by the replacement algorithm. A cache line is locked by performing a diagnostic write to the instruction tag (ASI 0xC, see 95.10.5) on the cache offset of the line to be locked, setting the Address Tag field to the address tag of the line to be locked, enabling the lock bit and clearing the valid bits. The locked cache line will be updated on a read-miss and will remain in the cache until the line is unlocked.

For correct operation, the ways must always be locked in ascending order, for example if two ways are locked it must always be way 0 and 1. Note also that you must always keep one way unlocked in each set for the cache to function correctly in case of miss to that set.

For run-time detection of this feature, setting the lock bit in a cache tag and reading the same tag will show if the cache line locking was enabled during the LEON3 configuration: the lock bit will be set if the cache line locking was enabled otherwise it will be 0.

Since the lock bit is not involved in the parity calculation, the locking option is not compatible with the fault tolerant configurations of the cache and therefore it should not be used if cmft > 0.

95.3.13 Diagnostic access

The cache tag and data contents can be directly accessed for diagnostics and for locking purposes via various ASI:s, see section 95.10.5.

95.3.14 Local scratch pad RAM

Local instruction and data ram can optionally be attached to the cache controllers. The ram can be between 1 - 256 KiB, and mapped on any 16 MiB block in the address space. Accesses performed to the local RAMs are not cached, and will not appear on the AHB bus or in the write buffer. The default address for the instruction ram is 0x8e000000, and for the data ram 0x8f000000, but these can be reconfigured using VHDL generics.

The local instruction RAM is intended for executing instructions and will serve instructions without any wait states. It can be accessed (with a few wait states) through 32-bit load and store instructions only, and is therefore not suitable for general application data. Initializing the instruction local RAM is done from software via stores as that is the only way to write into it.

The local data RAM will serve data accesses of any size without adding wait states. It can however not serve instructions.

The local instruction/data RAM implementation is not compatible with the MMU functionality, as it will "shadow" the virtual address space regardless of page table setup.

Since the local RAM implementation does not support error protection, it is not applicable for FT configurations of the LEON3.

95.3.15 Fault tolerance support

The cache memories (tags and data) can optionally be protected against soft errors using byte-parity-codes. Enabling of the data protection is done through the *cmft* VHDL generic and the functionality is only enabled for users that have licensed the fault-tolerant version of LEON3. Cache memory data protection is further described in section 95.9.6.

95.4 Memory management unit

95.4.1 Overview

A memory-management unit can optionally be enabled. This is compatible with the SPARC V8 reference MMU (SRMMU) architecture described inthe SPARC V8 manual, appendix H.

The MMU provides address translation of both instructions and data via page tables stored in memory.When needed, the MMU will automatically access the page tables to calculate the correct physical address. The latest translations are stored in a special cache called the translation lookaside buffer (TLB), also referred to as Page Descriptor Cache (PDC) in the SRMMU specification. The MMU also provides access control, making it possible to "sandbox" unpriviledged code from accessing the rest of the system.

95.4.2 MMU/Cache operation

When the MMU is disabled, the MMU is bypassed and the caches operate with physical address mapping. When the MMU is enabled, the cache tags store the virtual address and also include an 8-bit context field. Both the tag address and context field must match to generate a cache hit. When *mmuen* generic is set to 2 and MMU is enabled, the cache tags store a bit in addition to context called SO bit (supervisor only access). The SO bit is used to check the access permission of the data and instructions that resides in the level-1 caches when MMU is enabled. Without SO bit, access permissions of the load operations that hit in the data cache or the instruction accesses that hit in the instruction cache will not be checked properly.

If cache snooping is used, physical tags (separate snoop tags) must be enabled for it to work when address translation is used, see section 95.3.8.

Because the cache is virtually tagged, no extra clock cycles are needed in case of a cache load or instruction cache hit. In case of miss or write buffer processing, a translation is required that might add extra latency to the processing time, depending on TLB configuration and if there is a TLB miss.

The TLB can be configured in three different ways:

- Separate TLBs, slow access. TLB lookup adds 2 extra clock cycles.

- Shared TLB, slow access. TLB lookup adds 2 extra clock cycles, the TLB may be used by the other cache, leading to up to 4 extra cycles lookup time in the worst case.

- Separate TLBs, fast access. TLB lookup is done at the same time as tag lookup and therefore add no extra clock cycles.

If there is a TLB miss the page table must be traversed, resulting in up to four AMBA read accesses and one possible writeback operation. See the SRMMU specification for the exact format of the page table.

An MMU page fault will generate trap 0x09 for the D-cache and trap 0x01 for the I cache, and update the MMU status registers according to table 1869 and the SRMMU specification. In case of multiple

GRIP
Apr 2024, Version 2024.1
1543
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

errors, they fault type values are prioritized as the SRMMU specification requires. The cache and memory will not be modified on an MMU page fault.

*Table 1869.*LEON3 MMU Fault Status Register, fault type values

Fault type	SPARC V8 ref	Priority	Condition
6	Internal error	1	Never issued by LEON SRMMU
4	Translation error	2	AHB error response while performing table walk. Translations errors as defined in SPARC V8 manual. A translation error caused by an AMBA ERROR response will overwrite all other errors. Other translation errors do no overwrite existing translation errors when FAV = 1.
1	Invalid address error	3	Page table entry for address was marked invalid
3	Privlege violation error	4	Access denied based on page table and su status (see SRMMU spec for how privilege and protection error are prioritized)
2	Protection error	5	
0	None	-	No error (inside trap this means the trap occurred when fetching the actual data)

95.4.3 Translation look-aside buffer (TLB)

The MMU can be configured to use a shared TLB, or separate TLB for instructions and data. The number of TLB entries (for each implemented TLB) can be set to 2 - 64 via VHDL generics. The organisation of the TLB and number of entries is not visible to the software and does thus not require any modification to the operating system. The TLB can be flushed using an STA instruction to ASI 0x18, see section 95.10.7.

95.4.4 Variable minimum page sizes

The standard minimum page size for the SRMMU is 4 KiB. The minimum page size can also be configured to 8, 16 or 32 KiB in order to allow for large data cache ways. The page size can either be configured hard at implementation time or made software-configurable via the MMU control register. The page sizes for level 1, 2 and 3 is seen in the table below:

*Table 1870.*MMU page size

Scheme	Level-1	Level-2	Level-3
4 KiB (default)	16 MiB	256 KiB	4 KiB
8 KiB	32 MiB	512 KiB	8 KiB
16 KiB	64 MiB	1 MiB	16 KiB
32 KiB	256 MiB	2 MiB	32 KiB

The layouts of the indexes are chosen so that PTE page tables can be joined together inside one MMU page without leaving holes.

Note that most operating systems are hard-coded for a specific page size and using one other than 4 KiB usually requires reconfiguration/recompilation of the operating system kernel.

95.5 Floating-point unit

The SPARC V8 architecture defines two (optional) co-processors: one floating-point unit (FPU) and one user-defined co-processor. Two different FPU's can be interfaced the LEON3 pipeline: Frontgrade Gaisler's GRFPU and GRFPU-Lite. Selection of which FPU to use is done through the fpu generic. The characteristics of the FPU's are described in the next sections.

GRIP
Apr 2024, Version 2024.1
1544
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

95.5.1 Frontgrade Gaisler's floating-point unit (GRFPU)

The high-performance GRFPU operates on single- and double-precision operands, and implements all SPARC V8 FPU operations including square root and division. The FPU is interfaced to the LEON3 pipeline using a LEON3-specific FPU controller (GRFPC) that allows FPU instructions to be executed simultaneously with integer instructions. Only in case of a data or resource dependency is the integer pipeline held. The GRFPU is fully pipelined and allows the start of one instruction each clock cycle, with the exception is FDIV and FSQRT which can only be executed one at a time. The FDIV and FSQRT are however executed in a separate divide unit and do not block the FPU from performing all other operations in parallel.

All instructions except FDIV and FSQRT has a latency of three cycles, but to improve timing, the LEON3 FPU controller inserts an extra pipeline stage in the result forwarding path. This results in a latency of four clock cycles at instruction level. The table below shows the GRFPU instruction timing when used together with GRFPC:

*Table 1871.*GRFPU instruction timing with GRFPC

Instruction	Throughput	Latency
FADDS, FADDD, FSUBS, FSUBD,FMULS, FMULD, FSMULD, FITOS, FITOD, FSTOI, FDTOI, FSTOD, FDTOS, FCMPS, FCMPD, FCMPES. FCMPED	1	4
FDIVS	14	16
FDIVD	15	17
FSQRTS	22	24
FSQRTD	23	25

The GRFPC controller implements the SPARC deferred trap model, and the FPU trap queue (FQ) can contain up to 7 queued instructions when an FPU exception is taken. When the GRFPU is enabled in the model, the version field in %fsr has the value of 2.

The GRFPU does not handle denormalized numbers as inputs and will in that case cause an fp_exception with the FPU trap type set to unfinised_FPOP (tt=2). There is a non-standard mode in the FPU that will instead replace the denormalized inputs with zero and thus never create this condition.

95.5.2 GRFPU-Lite

GRFPU-Lite is a smaller version of GRFPU, suitable for FPGA implementations with limited logic resources. The GRFPU-Lite is not pipelined and executes thus only one instruction at a time. To improve performance, the FPU controller (GRLFPC) allows GRFPU-Lite to execute in parallel with the processor pipeline as long as no new FPU instructions are pending. Below is a table of worst-case throughput of the GRFPU-Lite:

*Table 1872.*GRFPU-Lite worst-case instruction timing with GRLFPC

Instruction	Throughput	Latency
FADDS, FADDD, FSUBS, FSUBD,FMULS, FMULD, FSMULD, FITOS, FITOD, FSTOI, FDTOI, FSTOD, FDTOS, FCMPS, FCMPD, FCMPES. FCMPED	8	8
FDIVS	31	31
FDIVD	57	57
FSQRTS	46	46
FSQRTD	65	65

The GRLFPC controller implements the SPARC deferred trap model, but the FPU trap queue (FQ) can contain only one queued instructions when an FPU exception is taken.When the GRFPU-Lite is enabled in the model, the version field in %fsr has the value of 3.

95.6   Co-processor interface

No implementation for the user-defined co-processor is currently provided.

95.7   AMBA interface

95.7.1   Overview

The LEON3 processor uses one AHB master interface for all data, instruction and MMU table-walk accesses. Instructions are fetched with incremental bursts if the IB bit is set in the cache control register, otherwise single READ cycles are used. Read data is accessed using bursts for cachable data, and byte, half-word and word accesses for uncacheable data. Store data is performed using single accesses or a two-beat incremental burst in case of 64-bit store.

The HPROT signals of the AHB bus are driven to indicate if the accesses is instruction or data, and if it is a user or supervisor access.

*Table 1873.*HPROT values

Type of access	User/Super	HPROT
Instruction	User	1100
Instruction	Super	1110
Data	User	1101
Data	Super	1111
MMU	Any	1101

In case of atomic accesses, a locked access will be made on the AMBA bus to guarantee atomicity as seen from other masters on the bus.

95.7.2   Cachability control

Cachability for both caches can be controlled through the AHB plug&play address information or set manually via the *cached* VHDL generic.

For plug'n'play based cachability, the memory mapping for each AHB slave indicates whether the area is cachable, and this information is used to (statically) determine which access will be treated as cacheable. This approach means that the cachability mapping is always coherent with the current AHB configuration.

When the *cached* VHDL generic is not zero, it is treated as a 16-bit field, defining the cachability of each 256 MiB address block on the AMBA bus. For example, a value of 16#00F3# will define cachable areas in 0 - 0x20000000 and 0x40000000 - 0x80000000.

In order to access the plug'n'play information, the processor takes the ahbso vector as input. Only the static hconfig signals are used so the use of this input will be eliminated through constant propagation during synthesis.

95.7.3   Error handling

An AHB ERROR response received while fetching instructions will normally cause an instruction access exception (tt=0x1). However if this occurs during streaming on an address which is not needed, the I cache controller will just not set the corresponding valid bit in the cache tag. If the IU later fetches an instruction from the failed address, a cache miss will occur, triggering a new access to the failed address.

An AHB ERROR response while fetching data into the data cache will normally trigger a data_access_exception trap (tt=0x9). If the error was for a part of the cache line other than what was currently being requested by the pipeline, a trap is not generated and the valid bit for that line is not set.

An ERROR response during an MMU table walk will lead the MMU to set the fault type to Internal error (1) and generate an instruction or data access exception, depending on which type of access that caused the table walk.

Error responses to writes will result in the data_store_error trap as described in section 95.3.6.

95.7.4 Snoop port

For the snooping logic, the LEON3 has an ahbsi input. For correct function, this must be tied to the same AHB bus that the master interface. It is not possible to snoop on another bus or to add extra pipeline registers to the snoop port, because the snoop logic must be in sync with the master interface.

95.8 Multi-processor system support

This section gives an overview of issues when using the LEON3 in multi-processor configuration.

Using the features described in earlier sections together with a multiprocessor capable IRQ controller (IRQMP), the LEON3 processor can support symmetric multiprocessing (SMP) configurations with shared memory, with up to 16 processors attached to the same AHB bus.

Enabling SMP features (sleeping on reset for CPU 1-N) is done by setting the *smp* VHDL generic to 1 or higher. Cache snooping should always be enabled in SMP systems to maintain data cache coherency between the processors.

95.8.1 Start-up

In multiprocessor systems, only the first processor will start after reset and all other processors will remain halted in power-down mode. After the system has been initialized, the remaining processors can be started by writing to the 'multiprocessor status register', located in the multiprocessor interrupt controller. The halted processors start executing from the reset address (0 or *rstaddr* VHDL generic, see section 95.2.20).

An application in a multiprocessor system can determine which processor it is executing on by checking the processor index field in the LEON3 configuration register (%asr17). As all processors typically have the same reset start address value, boot software must check the processor index and perform processor specific setup (e.g. initialization of stack pointer) based on the value of the processor index.

In recent versions of the LEON3, and if the IRQ controller is configured with the extended boot register extension, it is possible for one processor to monitor and reboot another processor.via the interrupt controller. This requires careful software design.

For earlier versions of the LEON3, this is not supported and if software detects that one processor is unresponsive and needs to restart the processor then the full system should be reset, for example by triggering the system's watchdog, if implemented. In order for software to monitor that all processors in a system are up and running it is recommended to implement a heartbeat mechanism in software.

While it is possible to have more fine-grained control over processor behaviour via the Debug Support Unit (if implemented) this is not recommended as the debug support unit is typically disabled in production mode.

95.8.2 Shared memory model

Each processor core has it's own separate AHB master interface and the AHB controller will arbitrate between them to share access to the on-chip bus.

If caches are not used, the processors will form a sequentially consistent (SC) system, where every processor will execute it's loads, stores and atomics to memory in program order on the AHB bus and the different processors operations will be interleaved in some order through the AHB arbitration. The

GRIP
Apr 2024, Version 2024.1

1547

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

shared memory controller AHB slave is assumed to not reorder accesses so a read always returns the latest written value to that location on the bus.

When using caches with snooping (and with physical tags, also called separate snoop tags, if using the MMU), the shared memory will act according to the slightly weaker SPARC Total Store Order (TSO) model. The TSO model is close to SC, except that loads may be reordered before stores coming from the same CPU. The stores and atomics are conceptually placed in a FIFO (see the diagrams in the SPARC manual) and the loads are allowed to bypass the FIFO if they are not to the same address as the stores. Loaded data from other addresses may therefore be either older or newer, with respect to the global memory order, than the stores that have been performed by the same CPU.

In the LEON3 case this happens because cache hits are served without blocking even when there is data in the write buffer. The loaded data will always return the stored data in case of reading the same address, because if it is cached, the store updates the cache before being put in the write buffer, and if it was not in cache then the load will result in a miss which waits for the write buffer to complete. Loaded data from a different address can be older than the store if it is served by cache before the write has completed, or newer if it results in a cache miss or if there is a long enough delay for the store to propagate to memory before reading.

See relevant literature on shared memory systems for more information. These details are mainly of concern for complex applications using lock-free data structures such as the Linux kernel, the recommendation for applications is to instead avoid concurrent access to shared structures by using mutexes/semaphores based on atomic instructions, or to use message passing schemes with one-directional circular buffers.

95.8.3   Memory-mapped hardware

Hardware resources (IP cores) are normally memory mapped on uncacheable address spaces. They will be accessible from all the CPU:s in a sequentially consistent manner. Since software drivers usually expect to be "alone" accessing the IP core and the IP cores register interfaces are not designed for concurrent use by multiple masters, using a bare-C application designed for single-processor usage on multiple cores at the same time will generally not work. This can be solved by partitioning the applications so that each IP core is only accessed by one of the CPU:s. This partitioning also need to be done between the interrupts so the IP core's interrupts will be received by the correct processor.

95.9   Fault tolerance

95.9.1   Overview

The LEON3 processor can be enhanced with fault-tolerance against SEU errors (referred to as LEON3FT). The fault-tolerance is focused on the protection of on-chip RAM blocks, which are used to implement IU/FPU register files and the cache memory.

The LEON3FT is licensed separately, and in the commercial LEON3 releases setting the FT VHDL generics will not have any effect.

95.9.2   Integer register file protection

The SEU protection for the integer unit register file can be implemented in four different ways, depending on target technology and available RAM blocks. The SEU protection scheme is selected

GRIP

Apr 2024, Version 2024.1

1548

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

during synthesis, using the *iuft* VHDL generic. Table 1874 below shows the implementation characteristics of the four possible SEU protection schemes.

Table 1874. Integer unit SEU protection schemes

ID	Implementation	Description	Usage
0	No protection (hardening at lower level)	No error checking, equivalent to non-FT version. Register file hardness must be ensured separately, for example by mapping the register file memories to SEU hardened flip-flops.	IU, GRFPU, GRFPU-Lite
1	4-bit parity with restart	4-bit checksum per 32-bit word. Detects and corrects 1 bit per byte (4 bits per word). Pipeline restart on correction.	IU, GRFPU-Lite
2	8-bit parity without restart	8-bit checksum per 32-bit word. Detects and corrects 1 bit per byte (4 bits per word). Correction on-the-fly without pipeline restart.	IU, GRFPU
3	7-bit BCH with restart	7-bit BCH checksum per 32-bit word. Detects 2 bits and corrects 1 bit per word. Pipeline restart on correction.	IU
4	Memory triplication	Memory blocks triplicated and bit by bit voted on outputs. Correction on-the-fly without pipeline restart, no error injection interface or error counters. Note that care must be taken by the implementer to ensure that the TMR is not collapsed in optimization by synthesis tools.	IU, GRFPU, GRFPU-Lite
5	7-bit BCH without restart	7-bit BCH checksum per 32-bit word. Correction on the fly without pipeline restart. Error correction logic performed on same cycle as memory read.	IU
6	Technology specific	Implement register files using native ECC capability of the technology (via syncram_2pft in the techmap library). Only valid for subset of (FPGA) technologies. Correction on-the-fly without pipeline restart. Error injection and error counters may be supported depending on technology. Technology specific protection is further documented in the GRLIB-FT User's Manual (grlib-ft.pdf).	IU

The SEU error detection has no impact on behavior, but a correction cycle (scheme 1 and 3) will delay the current instruction with 6 clock cycles. An uncorrectable error in the IU register file will cause trap 0x20 (*r_register_access_error*). A dedicated counter exists in ASR16 to count the number of register file corrections.

The register file is implemented using scheme 0 if the regfile_3p_infer array is set for the selected memory technology in the techmap library, or if bits 16-17 of memtech are set, regardless of iuft/fpft setting.

95.9.3 Integer register file scrubber

A register file scrubber function can be activated via the SCREN bit in asr16. The scrubber reads each register in the integer register file in turn as a flat memory regardless of which register window is currently active in the running program.

The scrubber works by accessing the register file whenever a branch instruction is executed and runs in parallel with the branch instruction. Since branch instructions do not read or write any registers in the register file, the scrubbing can be done without any performance overhead of the scrubber in the uncorrected case.

If a register file protection scheme with restart is used (iuft=1 or iuft=3), the scrubber will use the same correction mechanism and perform a restart of the branch instruction that the scrub iteration was

GRIP
Apr 2024, Version 2024.1

1549

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

running in parallel with. For other protection schemes, the register value is simply written back wit-zero overhead also in the corrected case.

If the register file protection scheme used can detect uncorrectable errors and generate r_register_ac-cess_error traps (iuft=3, iuft=5 or iuft=6), such traps will be delivered on the associated branch instruction of the scrubber access in case of an uncorrectable error.

The scrubber also performs a data consistency check between the two read ports, if there is no error detected but the read data between the two read ports differ for the scrubbed address then the SCRDM bit in asr18 is set.

95.9.4   Floating-point register file protection

The FPU register file has similar SEU protection as the IU register file, but with less configuration options. The FPU register file protection scheme is enabled with the fpft generic and has the same encoding as iuft. The protection schemes that are supported for the GRFPU and the GRFPU-Lite are listed in table 1874. An uncorrectable error in the FPU register file will cause an (deferred) FPU exception with %fsr.ftt set to 5 (hardware_error).

Note that the restrictions on protection scheme is not enforced, so it is recommended to simulate the configuration with error injection to ensure that the scheme chosen is functioning correctly. It is also recommended to confirm in the netlist that the expected register file type (memory block or flip flops) was implemented.

95.9.5   Register file EDAC/parity bits diagnostic read-out and error injection

The register file parity bits can be read out via ASI 0xF as described in section 95.10.6.

For test purposes, the IU and FPU register file EDAC/parity checkbits can be modified by software. This is done by setting the ITE or FTE bits in asr16 to '1'. In this mode, the EDAC/parity bits are first XORed with the contents of %asr16.FTB before written to the register files. This is done for all writes into the register file while the feature is enabled, so diagnostic code must be carefully designed to avoid accidentally injecting errors in other registers than intended. Also note that due to result for-warding in the pipeline, an injected error will not affect the immediately following instructions, which might cause surprising behavior such as errors triggering only when single stepping through the code.

Bit 0 (RF EDAC disable) in %asr16 should be set to 1 during diagnostic accesses and fault injection to the register file, to avoid EDAC correction cycles or error traps.

95.9.6   Cache protection

Each word in the tag or data memories is normally protected by four check bits. Use of the SYN-CRAM protection allows the processor to use technology specific protection and this can lead to sav-ings in resource utilization on target technologies that have built-in protection of SRAM blocks. If separate physical tags for snooping are enabled, the physical tag memory is also protected. An error during cache access will cause an invalidation of that cache line, and a re-execution of the failing instruction. This will ensure that the complete cache line (tags and data) is refilled from external memory.

If snooping is enabled, an error detected in the tags while snooping a write to that set will lead to that cache data being invalidated (since the tag before the error might have matched the written address).

For every detected error, a counter in the cache control register is incremented. The counters saturate at their maximum value (3), and should be reset by software after read-out.

The cache memory check bits can be diagnostically read and modified by setting the PS bit in the cache control register and then perform a normal tag or data diagnostic access, see section 95.10.5 for details.

95.10 ASI assignments

95.10.1 Summary

The table shows the ASI usage for LEON.

Table 1875. ASI usage

ASI	Usage
0x01	Forced cache miss.
0x02	System control registers (cache control register)
0x08, 0x09	Not supported
0x0A	Access level is determined by 'S' bit in %psr when MMU is enabled and *mmuen* generic is set to 1
	User Access when MMU is enabled and *mmuen* generic is set to 2
	Sets HPROT to user data regardless of MMU
0x0B	Access level is determined by 'S' bit in %psr when MMU is enabled and *mmuen* generic is set to 1
	Supervisor Access when MMU is enabled and *mmuen* generic is set to 2, otherwise normal cache access
	Sets HPROT to supervisor data regardless of MMU
0x0C	Instruction cache tags
0x0D	Instruction cache data
0x0E	Data cache tags
0x0F	Data cache data
0x0F	Register file diagnostic parity read-out (FT only)
0x10	Flush instruction cache (and also data cache when system is implemented with MMU)
0x11	Flush data cache
0x13	MMU only: Flush instruction and data cache
0x14	MMU only: MMU diagnostic D context cache access (deprecated, do not use)
0x15	MMU only: MMU diagnostic I cache context access (deprecated, do not use)
0x18, 0x03	MMU only: Flush TLB and I/D cache
0x19, 0x04	MMU only: MMU registers
0x1C	MMU and cache bypass
0x1D	MMU only: MMU diagnostic access (deprecated, do not use)
0x1E	MMU only: MMU snoop tags diagnostic access

95.10.2 ASI 0x1, Forced cache miss

ASI 1 is used for systems without cache coherency, to load data that may have changed in the background, for example by DMA units. It can also be used for other reasons, for example diagnostic purposes, to force a AHB load from memory regardless of cache state.

The address mapping of this ASI is matched with the regular address space, and if MMU is enabled then the address will be translated normally. Stores to this ASI will perform the same way as ordinary data stores.

For situations where you want to guarantee that the cache is not modified by the access, the MMU and cache bypass ASI, 0x1C, can be used instead.

95.10.3 ASI 0x2, System control registers

ASI 2 contains a few control registers that have not been assigned as ancillary state registers. These should only be read and written using 32-bit LDA/STA instructions.

GRIP
Apr 2024, Version 2024.1

1551

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

All cache registers are accessed through load/store operations to the alternate address space (LDA/STA), using ASI = 2. The table below shows the register addresses:

Table 1876. ASI 2 (system registers) address map

Address	Register
0x00	Cache control register
0x04	Reserved
0x08	Instruction cache configuration register
0x0C	Data cache configuration register

95.10.4 ASI 0x8-0xB, Data/Instruction

These ASIs are assigned by the SPARC manual for normal data and instruction fetches.

Accessing the instruction ASIs (0x8,0x9) explicitly via LDA/STA instructions is not supported in the LEON3 implementation.

Using LDA/STA with the user/supervisor data ASI (0xA,0xB) will behave as the affect the HPROT signal emitted by the processor according to section 95.7.1. If *mmuen* generic is set to 2, MMU access control will be done according to the indicated user or supervisor ASI inline with reference MMU description in Sparc V8 manual. If *mmuen* generic is set to 1, MMU access control will be done depending on the SU bit in the %psr register.

95.10.5 ASI 0xC-0xF, ICache tags/data, DCache tags/data

Note that on LEON3FT, ASI 0xF is double mapped and the description in this section is valid only if the RFT bit is not set.

ASI 0xC-0xF provide diagnostic access to the instruction cache memories. These ASIs should only be accessed by 32-bit LDA/STA instructions. These ASIs can not be used while a cache flush is in progress.

The same address bits used normally as index are used to index the cache also in the diagnostic access. For a multi-way cache, the lowest bits above the index part, the lowest bits that would normally be used as tag, are used to select which way to read/write. The remaining address bits are don't cares, leading the address map to wrap around.

If fault tolerance is enabled, the tag parity, context and SO bits can also be read out through these ASIs by setting the PS bit in the cache configuration register. When this bit is set, the parity data is read instead of the ordinary data. When writing the tag bits, the context bits will always be written with the current context in the MMU control register. The SO bit in the tag will be written with the SO bit value in the MMU control register (SO bit in MMU control register only exists in the tag when *mmuen* generic is set to 2). The parity to be written is calculated based on the supply write-value, the context ID and optionally SO bit (if mmuen is set to 2) in the MMU control register. The parity bits can be modified via the TB field in the cache control register.

+46 31 7758650 | frontgrade.com/gaisler

Example for 1 KiB way, 32 bytes/line, 4 ways

Tag diagnostic ASIs (ASI 0xC,E):

31	12	11	10	9	5	4	0
Addr: | (don't care) | | Way | | Index | | (don't care) |

31	10	9	8	7	0
Data: | ATAG | | LRR | LOCK | VALID | |

31	23	16	15	14	4	3	0
Parity: | Reserved | CTXID | | SO | Reserved | | TPAR | |

Data diagnostic ASIs (ASI 0xD,F):

31	12	11	10	9	5	4	0
Addr: | (don't care) | | Way | | Index | | Offset |

31	0
Data: | Cached data word |

31	4	3	0
Parity: | Reserved | | DPAR | |

Figure 245. ASI 0xC-0xF address mapping and data layout

Field Definitions:

Address Tag (ATAG) - Contains the tag address of the cache line.

LRR - Used by LRR algorithm to store replacement history, otherwise 0.

LOCK - Locks a cache line when set. 0 if cache locking not implemented.

Valid (V) - When set, the corresponding 32-bit sub-block of the cache line contains valid data. V[0] corresponds to address 0 in the cache line, V[1] to address 1, V[2] to address 2 and so on. The D-Cache only has one valid bit per cache line which is replicated for the whole 8-bit diagnostic field.

CTXID - Context ID, used when MMU is enabled

SO - (Supervisor only access) It is used when MMU is enabled and *mmuen* (see Sec. 95.16) generic is set to 2. This bit is set to 1 when the associated page with the tag has access permission of 6 or 7 (supervisor access only) for other access permissions it is set to 0. (For detailed information about access permissions refer to the reference MMU part of the Sparc V8 manual)

TPAR - Byte-wise parity of tag bits, context ID parity is XOR:ed into bit 3.

DPAR - Byte-wise parity of data bits

NOTE: only the necessary bits will be implemented in the cache tag, depending on the cache configuration. As an example, a 4 KiB cache with 16 bytes per line would only have four valid bits and 20 tag bits. The cache rams are sized automatically by the RAM generators in GRLIB.

95.10.6 ASI 0xF (alternate), FT register file parity read-out

In the FT version, an alternate function to ASI 0xF is selected by enabling the RFT bit in the cache control register. When enabled, this will override (shadow) the D-Cache data ASI function.

GRIP
Apr 2024, Version 2024.1

1553

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

This ASI allows you to read out parity bits for the register file. The parity should be read out using a half-word LDUHA instruction. The parity bits are read out simultaneously for the two read ports. This is read only, for write access (fault injection) see section 95.9.5.

The ASI is not address-mapped, instead the registers used in the LDUHA instruction directly select which register's parity bits are returned. For example the instruction:

```
lduha   [%l0 + %l1] 0x0F, %g1
```

will read out the parity bit of %l0 on port 2 and %l1 on port 1, and store those values in register %g1.

The layout is shown in the figure below:

15	8	7	0
RF ECC Port 2		RF ECC port 1	
Figure 246. Register file ECC read-out layout

When the checkbits are read out using LDUHA, bit 29 (RFT) in the cache control register should be set to 1. The desired register should be used as address.

95.10.7 ASI 0x10, 0x11, 0x13, 0x18 - Flush

For historical reasons there are multiple ASIs that flush the cache in different ways.

Writing to ASI 0x10 will flush the entire instruction cache. If MMU is implemented in the core, both instruction and data cache will be flushed.

Writing to ASI 0x11 will flush the data cache only.

Writing to ASI 0x13 will flush the data cache and the instruction cache, only available when MMU is implemented.

Writing to ASI 0x18 (and 0x03), which is available only if MMU is implemented, will flush both the MMU TLB, the I-cache, and the D-cache. This will block execution for a few cycles while the TLB is flushed and then continue asynchronously with the cache flushes continuing in the background.

95.10.8 ASI 0x19 and 0x04 - MMU registers

This ASI provides access to the MMU:s control and status registers. The following MMU registers are implemented:

Table 1877. MMU registers (ASI = 0x19)

Address	Register
0x000	MMU control register
0x100	Context pointer register
0x200	Context register
0x300	Fault status register
0x400	Fault address register

95.10.9 ASI 0x1C - MMU and cache bypass

Performing an access via ASI 0x1C will act as if MMU and cache were disabled. The address will not be translated and the cache will not be used or updated by the access.

95.10.10ASI 0x1E - MMU snoop/physical tags diagnostic access

If the MMU has been configured to use separate snoop (physical) tags, they can be accessed via ASI 0x1E. This is primarily useful for RAM testing, and should not be performed during normal operation. This ASI is addressed the same way as the regular diagnostic ASI:s 0xC, 0xE, and the read/written data has the layout as shown below (example for a 1 KiB/way data cache):

31	10	9	2	1	0
ATAG		RESERVED		PAR	IV
Figure 247. Snoop cache tag layout

[31:10]   Address tag. The physical address tag of the cache line.

[1]:   Parity. The odd parity over the data tag. LEON3FT only.

[0]:   Invalid. When set, the cache line is not valid and will cause a cache miss if accessed by the processor. Only present if fast snooping is enabled.

95.11 Configuration registers

95.11.1 PSR, WIM, TBR registers

The %psr, %wim, %tbr registers are implemented as required by the SPARC V8 manual.

*Table 1878.*LEON3 Processor state register (%psr)

95.11.2 ASR17, LEON3 configuration register

The ancillary state register 17 (%asr17) provides information on how various configuration options were set during synthesis. This can be used to enhance the performance of software, or to support enumeration in multi-processor systems. There are also a few bits that are writable to configure certain aspects of the processor.

*Table 1881.*LEON3 configuration register (%asr17)

31 INDEX 28				DBP 27	NOTAG 26	DBPM 25	REXV 24 23		REXM 22 21		RESERVED 18		CS 17	CF[1] 16
*				0	1	1	*		*				*	*
r				rw*	r	rw*	r		rw*		r		r	r

CF[0] 15	DW 14	SV 13	LD 12	FPU 11		10	M 9	V8 8	NWP 7		5	NWIN 4			0
*	0	0	*	*			*	*	*			*			
r	rw	rw*	r	r			r	r	r			r			

31:28	Processor index (INDEX) - In multi-processor systems, each LEON core gets a unique index to support enumeration. The value in this field is identical to the *hindex* VHDL generic parameter in the VHDL model.
27	Disable Branch Prediction (DBP) - Disables branch prediction when set to '1'. Field is only available if the VHDL generic *bp* is set to the value 2.
26	Tagged arithmetic (NOTAG) - If this read-only field is '1' then the processor supports tagged arithmetic and the compare-and-swap (CASA) instruction. The current version if the LEON3 always supports tagged arithmetic and CASA.
25	Disable Branch Prediction on instruction cache misses (DBPM) - When set to '1' this avoids instruction cache fetches (and possible MMU table walk) for predicted instructions that may be annulled. This feature is on by default (reset value '1'), if branch prediction is programmable then this is also programmable.
24:23	REX version (REXV) - read-only field that is set to '00' if REX is not implemented, '01' if REX is implemented, '10' and '11' values are reserved for future implementations
22:21	REX mode (REXM) - set to '00' for REX enabled, '01' for REX illegal and '10' for REX transparent mode. Writable with reset value '01' when REX support has been enabled
20:18	Reserved for future implementations
17	Clock switching enabled (CS). If set, switching between AHB and CPU frequency is available.
16:15	CPU clock frequency (CF). CPU core runs at (CF+1) times AHB frequency.
14	Disable write error trap (DWT). When set, a write error trap (tt = 0x2b) will be ignored. Set to zero after reset.
13	Single-vector trapping (SVT) enable. If set, will enable single-vector trapping. Fixed to zero if SVT is not implemented. Set to zero after reset.
12	Load delay (LDDEL) - If set, the pipeline uses a 2-cycle load delay. Otherwise, a 1-cycle load delay i s used. Generated from the *lddel* VHDL generic parameter in the VHDL model.
11:10	FPU option. "00" = no FPU; "01" = GRFPU; "10" = Meiko FPU, "11" = GRFPU-Lite
9	If set, the optional multiply-accumulate (MAC) instruction is available
8	If set, the SPARC V8 multiply and divide instructions are available
7:5	Number of implemented watchpoints (NWP) (0 - 4)
4:0	Number of implemented registers windows corresponds to NWIN+1.

95.11.4 ASR22-23 - Up-counter

The ancillary state registers 22 and 23 (%asr22-23) contain an internal up-counter that can be read by software without causing any access on the on-chip AMBA bus. The number of available bits in the counter is implementation dependent and is decided by the number of counter bits in the DSU time tag counter. %ASR23 contains the least significant part of the counter value and %ASR22 contains the most significant part. In case the implementation does not contain a debug support unit connected to the processor then the up-counter is not available (value is always zero).

The time tag value accessible in these registers is the same time tag value used for the system's trace buffers (if implemented) and for all processors connected to the same debug support unit. The time tag counter will increment when any of the trace buffers is enabled, or when the time tag counter is forced to be enabled via the DSU register interface, or when any processor has its %ASR22 Disable Up-counter (DUCNT) field set to zero.

The up-counter value will increment even if all processors have entered power-down mode.

*Table 1883.*LEON3 up-counter MSbs (%ASR22)

31	30	0
DUCNT	UPCNT(62:32)	

31	Disable Up-counter (DUCNT) - Disable upcounter. When set to '1' the up-counter may be disabled. When cleared, the counter will increment each processor clock cycle. Default (reset) value is '1'.
30:0	Counter value (UPCNT(62:32)) - Most significant bits of internal up-counter. Read-only.

*Table 1884.*LEON3 up-counter LSbs (%ASR23)

31	0
UPCNT(31:0)	

| 31:0 | Counter value (UPCNT(31:0)) - Least significant bits of internal up-counter. Read-only. |

95.11.5 ASR24-31, Hardware watchpoint/breakpoint registers

Each breakpoint consists of a pair of ancillary state registers (%asr24/25, %asr26/27, %asr28/29 and %asr30/31) registers; one with the break address and one with a mask:

Figure 248. Watch-point registers

WADDR - Address to compare against

WMASK - Bit mask controlling which bits to check (1) or ignore (0) for match

IF - break on instruction fetch from the specified address/mask combination

DL - break on data load from the specified address/mask combination

GRIP
Apr 2024, Version 2024.1
1559
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

DS - break on data store to the specified address/mask comination

Note: Setting IF=DL=DS=0 disables the breakpoint

When there is a hardware watchpoint match and DL or DS is set then trap 0x0B will be generated. Hardware watchpoints can be used with or without the LEON3 debug support unit (DSU) enabled.

0	0	0		0		0		0		0	0	0		0	
r	r	r*		r*		r*		r*		rw	rw	rw		rw	

31:30	Reserved for future implementations
29	Register file test select (RFT). If set, will allow the read-out of IU register file checkbits via ASI 0x0F. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
28	Parity Select (PS) - if set diagnostic read will return 4 check bits in the lsb bits, otherwise tag or data word is returned. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
	When the technology specific FT scheme is implemented (FT field is "10") then PS selects if correctable or uncorrectable errors should generate cache misses. The recommended setting is to use PS='0' that treats uncorrectable RAM errors in the same way as parity errors would traditionally be handled.
27:24	Test Bits (TB) - if set, check bits will be xored with test bits TB during diagnostic write. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
23	Data cache snoop enable (DS) - if set, will enable data cache snooping.
22	Flush data cache (FD). If set, will flush the data cache. Always reads as zero.
21	Flush Instruction cache (FI). If set, will flush the instruction cache. Always reads as zero.
20:19	FT scheme (FT) - "00" = no FT, "01" = 4-bit checking implemented, "10" - Technology-specific protection implemented
18	Reserved for future implementations
17	Separate snoop tags (ST). This read-only bit is set if separate physical/snoop tags are implemented.
16	Instruction burst fetch (IB). This bit enables burst fill during instruction fetch.
15	Instruction cache flush pending (IP). This bit is set when an instruction cache flush operation is in progress
14	Data cache flush pending (DP). This bit is set when an data cache flush operation is in progress.
13:12	Instruction Tag Errors (ITE) - Number of detected parity errors in the instruction tag cache. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
11:10	Instruction Data Errors (IDE) - Number of detected parity errors in the instruction data cache. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
9:8	Data Tag Errors (DTE) - Number of detected parity errors in the data tag cache. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
7:6	Data Data Errors (DDE) - Number of detected parity errors in the data data cache. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
5	Data Cache Freeze on Interrupt (DF) - If set, the data cache will automatically be frozen when an asynchronous interrupt is taken.
4	Instruction Cache Freeze on Interrupt (IF) - If set, the instruction cache will automatically be frozen when an asynchronous interrupt is taken.
3:2	Data Cache state (DCS) - Indicates the current data cache state according to the following: X0= disabled, 01 = frozen, 11 = enabled.
1:0	Instruction Cache state (ICS) - Indicates the current data cache state according to the following: X0= disabled, 01 = frozen, 11 = enabled.

15	12	11	4	3	2	1	0
LRSIZE		LRSTART		M	SO	RESERVED	
*		*		*	*	0	
r		r		r	r	r	

Bit	Description
31	Cache locking (CL). Set if cache locking is implemented.
30:28	Cache replacement policy (REPL). 00 - no replacement policy (direct-mapped cache), 01 - least recently used (LRU), 10 - least recently replaced (LRR), 11 - random
27	Cache snooping (SN). Set if snooping is implemented.
26:24	Cache associativity (WAYS). Number of ways in the cache: 000 - direct mapped, 001 - 2-way associative, 010 - 3-way associative, 011 - 4-way associative
23:20	Way size (WSIZE). Indicates the size (Kibs) of each cache way. Size = 2^{SIZE}
19	Local ram (LR). Set if local scratch pad ram is implemented.
18:16	Line size (LSIZE). Indicated the size (words) of each cache line. Line size = 2^{LSZ}
15:12	Local ram size (LRSZ). Indicates the size (Kibs) of the implemented local scratch pad ram. Local ram size = 2^{LRSZ}
11:4	Local ram start address (LRSTART). Indicates the 8 most significant bits of the local ram start address.
3	MMU present (M). This bit is set to '1' if an MMU is present.
2	SO (supervisor only access) bit is present. This bit is set if *mmuen* generic is set to 2.
1:0	Reserved for future implementations

95.11.8 ASR16, Register protection control register (FT only)

ASR register 16 (%asr16) is used to control the IU/FPU register file SEU protection. It is possible to disable the SEU protection by setting the IDI/FDI bits, and to inject errors using the ITE/FTE bits. Corrected errors in the register file are counted, and available in ICNT and FCNT fields. The counters saturate at their maximum value (7), and should be reset by software after read-out.

Table 1887. LEON3FT Register protection control register (%asr16)

31 30	29 27	26	25	24 22	21 20	19 18	17	16
FPFT	FCNT	SCREN	SCRDM	RESERVED	EFPFT	EIUFT	FTE	FDI

IUFT	ICNT	RFTB[7:0]	DP	ITE	IDI
*	0	0	0	0	0
r	rw	rw	rw	rw	rw

31:30	FP FT ID - Defines which SEU protection is implemented in the FPU (see table 1874)
29:27	FP RF error counter - Number of detected parity errors in the FP register file.
26	Integer register file scrubber enable
25	Integer register file scrubber data mismatch
24:22	Reserved for future implementations
21:20	Extended IU FT ID - Top bits of IUFT field to indicate FT values higher than 3
19:18	Extended IU FT ID - Top bits of IUFT field to indicate FT values higher than 3
17	FPU RF Test Enable - Enables FPU register file test mode. Parity bits are xored with TB before written to the FPU register file.
16	FP RF protection disable (FDI) - Disables FP RF parity protection when set.
15:14	IU FT ID - Defines which SEU protection is implemented in the IU (see table 1874)
13:11	IU RF error counter - Number of detected parity errors in the IU register file.
10:3	RF Test bits (RFTB) - In test mode, these bits are xored with correct parity bits before written to the register file.
2	DP ram select (DP) - Only applicable if the IU or FPU register files consists of two dual-port rams. See table 1888 below.
1	IU RF Test Enable - Enables register file test mode. Parity bits are xored with TB before written to the register file.
0	IU RF protection disable (IDI) - Disables IU RF parity protection when set.

Table 1888. DP ram select usage

ITE/FTE	DP	Function
1	0	Write to IU register (%i, %l, %o, %g) will only write location of %rs2
		Write to FPU register (%f) will only write location of %rs2
1	1	Write to IU register (%i, %l, %o, %g) will only write location of %rs1
		Write to FPU register (%f) will only write location of %rs1
0	X	IU and FPU registers written nominally

95.11.9 MMU control register

The MMU control register is located in ASI 0x19 offset 0, and the layout can be seen in table 1889.

Table 1889. LEON3 MMU control register

31			28	27		24	23		21	20		18	17	16
IMPL				VER			ITLB			DTLB			PSZ	
0				1			*			*			0	
r				r			r			r			rw*	

15	14	13						2	1	0
TD	ST	SO	RESERVED						NF	E
NR	0	0	0						0	0
rw*	r	rw	r						rw	rw

Bits	Description
31:28	MMU Implementation ID. Hardcoded to "0000"
27:24	MMU Version ID. Hardcoded to "0001".
23:21	Number of ITLB entries. The number of ITLB entries is calculated as 2^{ITLB}. If the TLB is shared between instructions and data, this field indicates to total number of TLBs.
20:18	Number of DTLB entries. The number of DTLB entries is calculated as 2^{DTLB}. If the TLB is shared between instructions and data, this field is zero.
17:16	Page size. The size of the smallest MMU page. 0 = 4 Kib; 1 = 8 Kib; 2 = 16 Kib; 3 = 32 Kib. If the page size is programmable, this field is writable, otherwise it is read-only.
15	TLB disable. When set to 1, the TLB will be disabled and each data access will generate an MMU page table walk. See Section 95.12.3 for detailed information.
14	Separate TLB. This bit is set to 1 if separate instruction and data TLBs are implemented
13	This bit only exists if *mmuen* generic is set to 2. This bit is written to the SO (supervisor only access) part of the TAG during diagnostic writes.
12:2	Reserved for future implementations
1	No Fault. When NF= 0, any fault detected by the MMU causes FSR and FAR to be updated and causes a fault to be generated to the processor. When NF= 1, a fault on an access to ASI 9 is handled as when NF= 0; a fault on an access to any other ASI causes FSR and FAR to be updated but no fault is generated to the processor.
0	Enable MMU. 0 = MMU disabled, 1 = MMU enabled.

95.11.10 MMU context pointer and context registers

The MMU context pointer register is located in ASI 0x19 offset 0x100 and the MMU context register is located in ASI 0x19 offset 0x200. They together determine the location of the root page table descriptor for the current context. Their definition follows the SRMMU specification in the SPARC V8 manual with layouts shown below..

Table 1890. LEON3 MMU context pointer register

31		2	1	0
CONTEXT TABLE POINTER			R	
NR			0

Table 1891. LEON3 MMU context register

31:8	Reserved
7:0	Current context ID

In the LEON3, the context bits are OR:ed with the lower MMU context pointer bits when calculating the address, so one can use less context bits to reduce the size/alignment requirements for the context table.

95.11.11 MMU fault status register

The MMU fault status register is located in ASI 0x19 offset 0x300, and the definition follows the SRMMU specification in the SPARC V8 manual. The SPARC V8 specifies that the fault status register should be cleared on read, on the LEON3 only the FAV bit is cleared on read. The FAV bit is always set on error in the LEON3 implementation, so it can be used as a valid bit for the other fields..

Table 1892. LEON3 MMU fault status register

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16

31:18	Reserved
17:10	External bus error (EBE) - Never set on the LEON3
9:8	Level (L) - Level of page table entry causing the fault
7:5	Access type (AT) - See V8 manual
4:2	Fault type (FT) - See table 1869
1	Fault address valid (FAV) - Cleared on read, always written to 1 on fault
0	Overwrite (W) - Multiple faults of the same priority encountered

95.11.12 MMU fault address register

The MMU fault address register is located in ASI 0x19 offset 0x400, and the definition follows the SRMMU specification in the SPARC V8 manual...

Table 1893. LEON3 MMU fault address register

31	12	11	0
FAULT ADDRESS		RESERVED	
NR		0	
r		r	

31:12	Top bits of virtual address causing translation fault
11:0	Reserved, always 0

95.12 Software considerations

95.12.1 Register file initialization on power up (for LEON3FT)

After power-on, the check bits in the IU and FPU register files are not initialized. This means that access to an un-initialized (un-written) general-purpose register could cause a register access trap (tt = 0x20). Such behavior is considered as a software error, as the software should not read a register before it has been written. It is recommended that the boot code for the processor writes all registers in

GRIP

+46 31 7758650 | frontgrade.com/gaisler

the IU and FPU register files before launching the main application. This can be done also for the regular LEON3 to allow software to be portable to both FT and non-FT versions.

95.12.2 Start-up

After reset, the caches are disabled and the cache control register (CCR) is 0. Before the caches may be enabled, a flush operation must be performed to initialized (clear) the tags and valid bits. A suitable assembly sequence could be:

```
flush
set 0x81000f, %g1
sta %g1, [%g0] 2
```

95.12.3 MMU & TLB

After reset, the MMU is disabled and TLB is configured to be on (will not have any effect until MMU is enabled). Hence with default reset values the TLB has to be flushed before the MMU is being activated to initialize the valid bits in TLB. If the TLB is disabled while the MMU is active, the TLB must be flushed before enabled again.

95.12.4 Data scrubbing (LEON3FT)

There is generally no need to perform data scrubbing on either IU/FPU register files or the cache memory. During normal operation, the active part of the IU/FPU register files will be flushed to memory on each task switch. This will cause all registers to be checked and corrected if necessary. Since most real-time operating systems performs several task switches per second, the data in the register files will be frequently refreshed.

The similar situation arises for the cache memory. In most applications, the cache memory is significantly smaller than the full application image, and the cache contents is gradually replaced as part of normal operation. For very small programs, the only risk of error build-up is if a part of the application is resident in the cache but not executed for a long period of time. In such cases, executing a cache flush instruction periodically (e.g. once per minute) is sufficient to refresh the cache contents.

95.13 LEON3 versions

95.13.1 Overview

The primary way to identify the version of a implemented LEON3 processor is to look at the GRLIB build ID, plug&play device identifier and plug&play core revision (part of plug&play information, see GRLIB User's Manual for additional information). This documentation applies to version 3 of the LEON3 processor. Figure 249 shows the relationship between the different earlier LEON3 versions and the current LEON3v3.

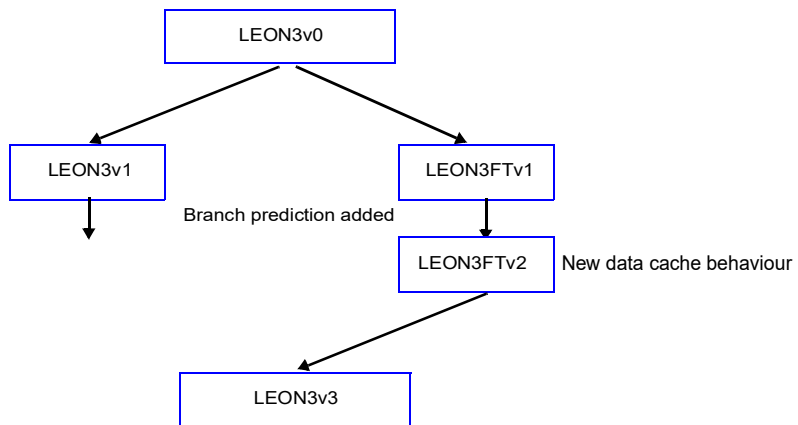
+46 31 7758650 | frontgrade.com/gaisler


Figure 249. LEON3 processor evolution

95.13.2 Data cache and AMBA behavior changes

Earlier versions of the LEON3 processor made use of one separate word access for each accessed word, even with cache enabled. This manual describes LEON3v3 which is the only LEON3 version included by default in the GRLIB IP Library. The table below also show the behaviour of earlier versions of the processor.

Processor operation	Area not cacheable[1]	LEON3FTv1/LEON3v1		LEON3FTv2/LEON3v3	
		Area is cacheable[1]		Area is cacheable[1]	
		Cache enabled[2]	Cache disabled	Cache enabled[2]	Cache disabled
Data load <= 32-bit	*Read access with size specified by load instruction*	*Word access*	*Read access with size specified by load instruction*	Burst of 32-bit accesses to fetch full cache line.	Read access with size specified by load instruction
Data load 64-bit (LDD)	*Burst of two 32-bit accesses*				Burst of two 32-bit accesses
Data store <= 32-bit	Store access with size specified by store instruction.				
Data store 64-bit (STD)	Burst of two 32-bit store accesses				

[1] Cachability is determined by the *cached* VHDL generic, if *cached* is zero then cachability is determined via AMBA PnP.

[2] Bus accesses for reads will only be made on L1 cache miss or forced cache miss.

95.13.3 ASI 0x1 side effects

Reading from ASI 0x1 forces a real AMBA bus read and returns that data to the pipeline, and this behavior is implemented in all LEON3 and LEON3FT versions. However the side effects on the cache state (whether the cache is updated, and whether a line might be allocated) differs between different versions of the LEON3. Customers needing more information on this issue may contact Frontgrade Gaisler.

95.13.4 ASR writes from user mode

Ancillary state registers ASR17 and ASR19-31 were made privileged on write, starting from LEON3v3. To preserve backward compatibility, these registers are still readable from user mode.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

95.13.5 MMU alias handling

LEON3v3 and LEON3FTv2 can handle double-mapped virtual addresses via self-snooping as described in section 95.3.8. This behavior is not available in earlier editions of LEON3, there the aliases can remain with incorrect data indefinitely.

95.13.6 CASA and load delay 2

With the current LEON3 (starting with GRLIB build 4178) CASA is always supported. LEON3 versions before GRLIB build 4161 only supported the compare-and-swap (CASA) instruction when the processor was implemented with load delay 1 (*lddel* VHDL generic set to 1) while the current version supports CASA for all load delays.

For GRLB versions more recent than build 4161, software can check if CASA is supported by reading %asr17 and checking the NOTAG field. For earlier GRLIB versions (prior to GRLIB build 4161) the %asr17 LDDEL field must be set to 0 for CASA to be supported and software can then probe for CASA support by trying to execute the instruction and handle the illegal instruction trap that is generated if CASA is unsupported by the implementation.

95.14   Vendor and device identifiers

The core will have one of two device identifiers depending on if the processor has been implemented with or without fault-tolerance features.

The standard core has vendor identifiers 0x01 (Frontgrade Gaisler) and device identifier 0x003.

If the core has been implemented with fault-tolerance features then the core will be identified with vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x053.

For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

95.15   Implementation

95.15.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

95.15.2 Technology mapping

LEON3 has two technology mapping VHDL generics, *fabtech* and *memtech*. The *fabtech* generic controls the implementation of some pipeline features, while *memtech* selects which memory blocks will be used to implement cache memories and the IU/FPU register file. *fabtech* can be set to any of the provided technologies (0 - NTECH) as defined in the TECHMAP.GENCOMP package. See the GRLIB Users's Manual for available settings for *memtech*.

95.15.3 RAM usage

The LEON3 core maps all usage of RAM memory on the *syncram*, *syncram_2p* and *syncram_dp* components from the technology mapping library (TECHMAP). The type, configuration and number of RAM blocks is described below.

Register file

The register file is implemented with two *synram_2p* blocks for all technologies where the *regfile_3p_infer* constant in TECHMAP.GENCOMP is set to 0. The organization of the syncram_2p is shown in the following table:

Table 1894. syncram_2p sizes for LEON3 register file

Register windows	Syncram_2p organization
2 - 3	64x32
4 - 7	128x32
8 - 15	256x32
16-31	512x31
32	1024x32

If *regfile_3p_infer* is set to 1, the synthesis tool will automatically infer the register. On FPGA technologies, it can be in either flip-flops or RAM cells, depending on the tool and technology. On ASIC technologies, it will be flip-flops. The amount of flip-flops inferred is equal to the number of registers:

Number of flip-flops = ((NWINDOWS *16) + 8) * 32

FP register file

If FPU support is enabled, the FP register file is implemented with four *synram_2p* blocks when the *regfile_3p_infer* constant in TECHMAP.GENCOMP is set to 0. The organization of the syncram_2p blocks is 16x32.

If *regfile_3p_infer* is set to 1, the synthesis tool will automatically infer the FP register file. For ASIC technologies the number of inferred flip-flops is equal to number of bits in the FP register file which is 32 * 32 = 1024.

Cache memories

RAM blocks are used to implement the cache tags and data memories. Depending on cache configuration, different types and sizes of RAM blocks are used.

The tag memory is implemented with one *syncram* per cache way when no snooping is enabled. The tag memory depth and width is calculated as follows:

Depth = (cache way size in bytes) / (cache line size in bytes)

Width = 32 - log2(cache way size in bytes) + (cache line size in bytes)/4 + lrr + lock

For a 2 Kib cache way with lrr replacement and 32 bytes/line, the tag RAM depth will be (2048/32) = 64. The width will be: 32 - log2(2048) + 32/4 + 1 = 32 - 11 + 8 + 1 = 28. The tag RAM organization will thus be 64x28 for the configuration. If the MMU is enabled, the tag memory width will increase with 8 to store the process context ID, and the above configuration will us a 64x36 RAM.

If simple (MMU-less) snooping is enabled, the data cache tag memory will instead of single-port RAM blocks be implemented with a dual-port RAMs (syncram_dp) of the same size.

If physical (MMU-compatible) snooping is enabled, the data cache tag memories will be implemented using two *syncram_2p* components (with one read-only and one write-only port) per way , one memory for virtual and one for physical tags. The size of the virtual tag block will be the same as when snooping is disabled. The physical tag block will have the same depth as above and the data width corresponds to the width of the tag: 32 - log2(way size). A 4 KiB data cache way will thus require a 32 - 12 = 20 bit wide RAM block for the physical tags.

Physical snooping can also be implemented with valid bits placed in flip flops, the tag memories are then implemented using single-port memories and with one bit less in width for the virtual tag.

GRIP
Apr 2024, Version 2024.1

1569

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The data part of the caches (storing instructions or data) is always 32 bit wide. The depth is equal to the way size in bytes, divided by 4. A cache way of 2 KiB will thus use *syncram* component with and organization of 512x32.

Instruction Trace buffer

The instruction trace buffer will use four identical RAM blocks (*syncram*) to implement the buffer memory. The syncrams will always be 32-bit wide. The depth will depend on the *tbuf* VHDL generic, which indicates the total size of trace buffer in KiBs. If *tbuf* = 1 (1 KiB), then four RAM blocks of 64x32 will be used. If *tbuf* = 2, then the RAM blocks will be 128x32 and so on.

Scratch pad RAM

If the instruction scratch pad RAM is enabled, a *syncram* block will be instantiated with a 32-bit data width. The depth of the RAM will correspond to the configured scratch pad size. An 8 KiB scratch pad will use a *syncram* with 2048x32 organization. The RAM block for the data scratch pad will be configured in the same way as the instruction scratch pad.

95.15.4 Double clocking

LEON3 double clocking is described in the LEON/GRLIB Configuration and Development Guide.

95.15.5 Clock gating

LEON3 clock gating is described in the LEON/GRLIB Configuration and Development Guide.

95.15.6 Scan support

Scan test support using signals distributed via the AMBA records is included in the LEON3 as described in the GRLIB User's Manual. It can be enabled using the *scantest* VHDL generic.

95.16 Configuration options

Table 1895 shows the configuration options of the core (VHDL generics).

Table 1895. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB master index	0 - NAHBMST-1	0
fabtech	Target technology	0 - NTECH	0 (inferred)
memtech	Vendor library for regfile and cache RAMs. Bits 16, 17 and 18 of this generic can be used to for the MMU TLB data RAM, IU register file and FP register file to inferred technology: + 2**16: Force inferred technology for MMU TLB data RAM + 2**17: Force inferred technology for IU register file + 2**18: Force inferred technology for FP register file Adding the value (2**17 + 2**18) is equivalent to setting the grlib.gencomp.regfile_3p_infer(memtech) to 1 (used for some technologies to force the register file implementations to inferred).	0 - 16#FFFFFFFF#	0 (inferred)
nwindows	Number of SPARC register windows. Choose 8 windows to be compatible with Bare-C and RTEMS cross-compilers.	2 - 32	8
dsu	Enable Debug Support Unit interface	0 - 1	0

Generic	Function	Allowed range	Default
drepl	Data cache replacement policy. 0 - least recently used (LRU), 1 - least recently replaced (LRR), 2 - random	0 - 1	0
dsets	Number of data cache ways Note: Generic named dsets due to historical reasons.	1 - 4	1
dlinesize	Data cache line size in number of words	4, 8	4
dsetsize	Size of each data cache way in KiB Note: If the processor is implemented with the MMU then the cache way size needs to be equal or less then the MMU page size for hardware cache coherency.	1 - 256	1
dsetlock	Enable data cache line locking. Do not use if cmft > 0	0 - 1	0
dsnoop	Enable data cache snooping Bit 0-1: 0: disable, 1: obsolete, 2: enabled, 3: single-port physical Bit 2: 0: simple MMU-less snooping, 1: save extra physical tags (MMU snooping)	0 - 7	0
ilram	Enable local instruction RAM	0 - 1	0
ilramsize	Local instruction RAM size in kB	1 - 512	1
ilramstart	8 MSB bits used to decode local instruction RAM area	0 - 255	16#8E#
dlram	Enable local data RAM (scratch-pad RAM)	0 - 1	0
dlramsize	Local data RAM size in kB	1 - 512	1
dlramstart	8 MSB bits used to decode local data RAM area	0 - 255	16#8F#
mmuen	Enable memory management unit (MMU) Note: Bus snooping is required to avoid cache aliasing effects when the MMU is enabled if the cache has more than one way. 0 : MMU does not exist. 1 : MMU exists. 2 : MMU exists and the cache tags include an additional bit called SO (supervisor only access). See sec. 95.3.2 for more details. If MMU is going to be instantiated in the processor, it is recommended to set the *mmuen* generic to 2.	0 - 2	0
itlbnum	Number of instruction TLB entries	2 - 64	8
dtlbnum	Number of data TLB entries	2 - 64	8
tlb_type	0 : separate TLB with slow write 1: shared TLB with slow write 2: separate TLB with fast write	0 - 2	1
tlb_rep	LRU (0) or Random (1) TLB replacement	0 - 1	0
lddel	Load delay. One cycle gives best performance, but might create a critical path on targets with slow (data) cache memories. A 2-cycle delay can improve timing but will reduce performance with about 5%.	1 - 2	2
disas	Print instruction disassembly in VHDL simulator console. Has no effect on synthesis (code removed via pragma translate_off)	0 - 1	0
tbuf	Size of instruction trace buffer in kB (0 - instruction trace disabled). For values 1-64 a single-port trace buffer of size *tbuf* is used. For values 65-128 a two-port trace buffer of size *tbuf*-64 is used.	0 - 128	0

95.17 Signal descriptions

Table 1896 shows the interface signals of the core (VHDL ports). There are several top-level entities available for the LEON3 processor. The *leon3x* entity contains all signals and settings. The other entities are wrappers around *leon3x*. The available entities are:

- leon3cg - Top-level with support for clock gating. Deprecated, do not use for new designs.
- leon3ft2x - Top-level with support for FT, double clocking and clock gating.
- leon3ftsh - Entity with support for FT and shared FPU.
- leon3ft - Entity with support for FT and clock gating, no separate FPU clock.
- leon3s2x - Top-level with support for clock gating and double clocking, no separate FPU clock.
- leon3sh - Top-level with support for shared FPU.
- leon3s - Simplest top-level, no FT, clock gating or shared FPU.
- leon3x - Entity with support for all features (double clocking, FT, clock gating, shared FPU)

Table 1896. Signal descriptions

Signal name	Field	Type	Function	Active
leon3x:CLK leon3s2x:CLK leon3ftsh:CLK	N/A	Input	AMBA clock, used in 2x mode. Note that this only applies to the processor entities listed.	-
leon3x:GCLK2 leon3s:CLK leon3sh:CLK leon3s2x:GCLK2 leon3ft:GCLK leon3ftsh:GCLK leon3cg:GCLK leon3ft2x:GCLK2	N/A	Input	Processor clock, can be gated when using an entity where the clock name starts with "G". Note that this clock has different names depending on which top-level entity that is used to instantiate the processor. For example, LEON3S only has one clock input which covers three of the rows in this table (Processor clock, FPU-clock, free running processor clock).	-
leon3x:GFCLK2 leon3s:CLK leon3sh:CLK leon3s2x:GCLK2 leon3ft:CLK leon3ftsh:CLK leon3cg:CLK leon3ft2x:GCLK2	N/A	Input	FPU clock, can be gated Note that this clock has different names depending on which top-level entity that is used to instantiate the processor. For example, LEON3S only has one clock input which covers three of the rows in this table (Processor clock, FPU-clock, free running processor clock).	-

96   LEON4 - High-performance SPARC V8 32-bit Processor

96.1   Overview

LEON4 is a 32-bit processor core conforming to the IEEE-1754 (SPARC V8) architecture. It is designed for embedded applications, combining high performance with low complexity and low power consumption.

The LEON4 core has the following main features: 7-stage pipeline with Harvard architecture, separate instruction and data caches, hardware multiplier and divider, on-chip debug support and multiprocessor extensions.

The LEON4 processor can be enhanced with fault-tolerance against SEU errors. The fault-tolerance is focused on the protection of on-chip RAM blocks, which are used to implement IU/FPU register files and the cache memory. Configuring the processor to implement fault-tolerance enables additional internal register and register fields.
Figure 251. LEON4 processor core block diagram

Note: This manual describes the full functionality of the LEON4 core. Through the use of VHDL generics, parts of the described functionality can be suppressed or modified to generate a smaller or faster implementation.

Please also refer to the *LEON/GRLIB Configuration and Development Guide* for recommendations on system design and LEON4 configuration.

96.1.1   Integer unit

The LEON4 integer unit implements the full SPARC V8 manual, including hardware multiply and divide instructions. The number of register windows is configurable within the limit of the SPARC manual (2 - 32), with a default setting of 8. The pipeline consists of 7 stages with a separate instruction and data cache interface (Harvard architecture).

96.1.2   Cache sub-system

LEON4 has a highly configurable cache system, consisting of a separate instruction and data cache. Both caches can be configured with 1 - 4 ways, 1 - 256 KiB/way, 16 or 32 bytes per line. The instruction cache maintains one valid bit per cache line and uses streaming during line-refill to minimize refill latency. The data cache has one valid bit per cache line, uses write-through policy and imple-

ments a double-word write-buffer. Bus-snooping on the AHB bus can be used to maintain cache coherency for the data cache.

96.1.3 Floating-point unit and co-processor

The LEON4 integer unit provides interfaces for a floating-point unit (FPU), and a custom co-processor. Two FPU controllers are available, one for the high-performance GRFPU and one for the GRFPU-Lite core. The floating-point processors and co-processor execute in parallel with the integer unit, and does not block the operation unless a data or resource dependency exists. Note that the FPUs are provided separately.

96.1.4 Memory management unit

A SPARC V8 Reference Memory Management Unit (SRMMU) can optionally be enabled. The SRMMU implements the full SPARC V8 MMU specification, and provides mapping between multiple 32-bit virtual address spaces and physical memory. A three-level hardware table-walk is implemented, and the MMU can be configured to up to 64 fully associative TLB entries per implemented TLB.

96.1.5 On-chip debug support

The LEON4 pipeline includes functionality to allow non-intrusive debugging on target hardware. To aid software debugging, up to four watchpoint registers can be enabled. Each register can cause a breakpoint trap on an arbitrary instruction or data address range. When the (optional) debug support unit is attached, the watchpoints can be used to enter debug mode. Through a debug support interface, full access to all processor registers and caches is provided. The debug interfaces also allows single stepping, instruction tracing and hardware breakpoint/watchpoint control. An internal trace buffer can monitor and store executed instructions, which can later be read out via the debug interface.

96.1.6 Interrupt interface

LEON4 supports the SPARC V8 interrupt model with a total of 15 asynchronous interrupts. The interrupt interface provides functionality to both generate and acknowledge interrupts.

96.1.7 AMBA interface

The cache system implements an AMBA AHB master to load and store data to/from the caches. The interface is compliant with the AMBA-2.0 standard. During line refill, incremental burst are generated to optimise the data transfer. The AMBA interface can be configured to use a 64 or 128-bit bus on cache line fills. The processor also has a snoop AHB slave input port which is used to monitor the accesses made by other masters, if snooping has been enabled.

96.1.8 Power-down mode

The LEON4 processor core implements a power-down mode, which halts the pipeline and caches until the next interrupt. The processor supports optional clock gating during the power down period by providing a clock-enable signal that can be tied to an external clock gate cell, and by providing a separate clock input for the small part of the CPU that needs to run during power-down to check for wake-up conditions and maintain cache coherency.

96.1.9 Multi-processor support

LEON4 is designed to be used in multi-processor systems. Each processor has a unique index to allow processor enumeration. The write-through caches and snooping mechanism guarantees memory coherency in shared-memory systems.

96.2 LEON4 integer unit

96.2.1 Overview

The LEON4 integer unit implements the integer part of the SPARC V8 instruction set. The implementation is focused on high performance and low complexity. The LEON4 integer unit has the following main features:

- 7-stage instruction pipeline
- Separate instruction and data cache interface
- Support for 2 - 32 register windows
- Hardware multiplier with optional 16x16 bit MAC and 40-bit accumulator
- Radix-2 divider (non-restoring)
- Static branch prediction
- Single-vector trapping for reduced code size

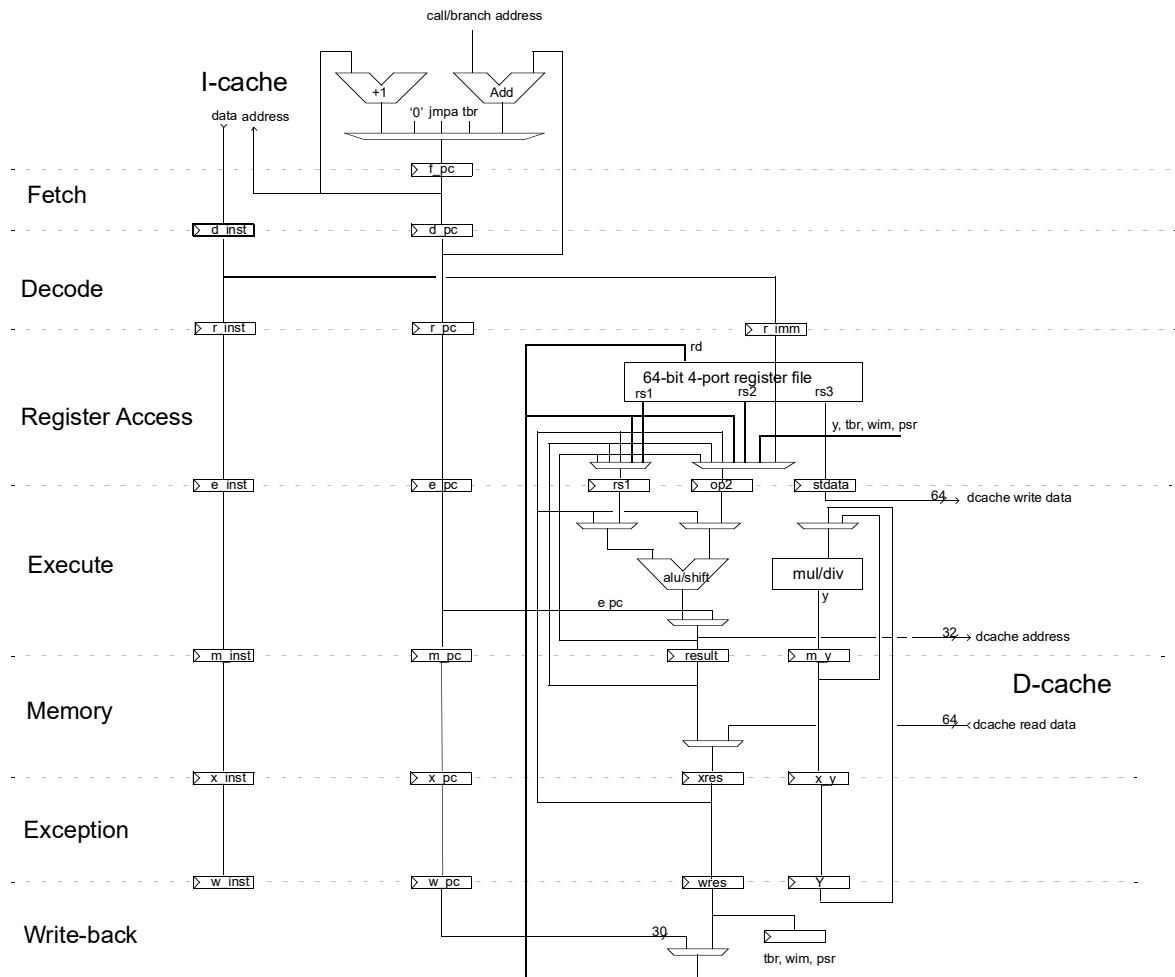
Figure 252 shows a block diagram of the integer unit.


Figure 252. LEON4 integer unit datapath diagram

+46 31 7758650 | frontgrade.com/gaisler

96.2.2 Instruction pipeline

The LEON4 integer unit uses a single instruction issue pipeline with 7 stages:

1. FE (Instruction Fetch): If the instruction cache is enabled, the instruction is fetched from the instruction cache. Otherwise, the fetch is forwarded to the memory controller. The instruction is valid at the end of this stage and is latched inside the IU.
2. DE (Decode): The instruction is decoded and the CALL/Branch target addresses are generated.
3. RA (Register access): Operands are read from the register file or from internal data bypasses.
4. EX (Execute): ALU, logical, and shift operations are performed. For memory operations (e.g., LD) and for JMPL/RETT, the address is generated.
5. ME (Memory): Data cache is accessed. Store data read out in the execution stage is written to the data cache at this time.
6. XC (Exception) Traps and interrupts are resolved. For cache reads, the data is aligned.
7. WR (Write): The result of ALU and cache operations are written back to the register file.

Table 1900 lists the cycles per instruction (assuming cache hit and no icc or load interlock):

*Table 1900.*Instruction timing

Instruction	Cycles (MMU disabled)
JMPL, RETT	3
SMUL/UMUL	1/4*
SDIV/UDIV	35
Taken Trap	5
Atomic load/store	5
All other instructions	**1**

* Multiplication cycle count is 1 clock (1 clock issue rate, 2 clock data latency), for the 32x32 multiplier and 4 clocks (issue rate, 4/5 clocks data latency for standard/pipelined version) for the 16x16 version.

Additional conditions that can extend an instructions duration in the pipeline are listed in the table and text below.

Branch interlock: When a conditional branch or trap is performed 1-2 cycles after an instruction which modifies the condition codes, 1-2 cycles of delay is added to allow the condition to be computed. If static branch prediction is enabled, this extra delay is incurred only if the branch is not taken.

Load delay: When using data resulting on a load shortly after the load, the instruction will be delayed to satisfy the pipeline's load delay. The processor pipeline has one cycle load delay.

Mul latency: For pipelined multiplier implementations there is 1 cycle extra data latency, accessing the result immediately after a MUL or MAC will then add one cycle pipeline delay.

Hold cycles: During cache miss processing or when blocking on the store buffer, the pipeline will be held still until the data is ready, effectively extending the execution time of the instruction causing the miss by the corresponding number of cycles. Note that since the whole pipeline is held still, hold cycles will not mask load delay or interlock delays. For instance on a load cache miss followed by a data-dependent instruction, both hold cycles and load delay will be incurred.

FPU/Coprocessor: The floating-point unit or coprocessor may need to hold the pipeline or extend a specific instruction. When this is done is specific to the FP/CP unit.

Certain specific events that cause these types of locks and their timing are listed in table 1901 below.

Table 1901. Event timing

Event	Cycles
Instruction cache miss processing, MMU disabled	3 + mem latency
Instruction cache miss processing, MMU enabled	5 + mem latency
Data cache miss processing, MMU disabled (read), L2 hit	3 + mem latency
Data cache miss processing, MMU disabled (write), write-buffer empty	0
Data cache miss processing, MMU enabled (read)	5 + mem latency
Data cache miss processing, MMU enabled (write), write-buffer empty	0
MMU page table walk	10 + 3 * mem latency
Branch prediction miss, branch follows ICC setting	2
Branch prediction miss, one instruction between branch and ICC setting	1
Pipeline restart due to register file or cache error correction	7

96.2.3 SPARC Implementor's ID

Frontgrade Gaisler is assigned number 15 (0xF) as SPARC implementor's identification. This value is hard-coded into bits 31:28 in the %psr register. The version number for LEON4 is 3 (same as for LEON3 to provide software compatibility), which is hard-coded in to bits 27:24 of the %psr.

96.2.4 Divide instructions

Full support for SPARC V8 divide instructions is provided (SDIV, UDIV, SDIVCC & UDIVCC). The divide instructions perform a 64-by-32 bit divide and produce a 32-bit result. Rounding and overflow detection is performed as defined in the SPARC V8 manual.

The divide instruction is required for full SPARC V8 compliance but can be configured out to save area using the *v8* VHDL generic.

96.2.5 Multiply instructions

The LEON processor supports the SPARC integer multiply instructions UMUL, SMUL UMULCC and SMULCC. These instructions perform a 32x32-bit integer multiply, producing a 64-bit result. SMUL and SMULCC performs signed multiply while UMUL and UMULCC performs unsigned multiply. UMULCC and SMULCC also set the condition codes to reflect the result. The multiply instructions are performed using a 32x32 pipelined hardware multiplier, or a 16x16 hardware multiplier which is iterated four times. To improve the timing, the 16x16 multiplier can optionally be provided with a pipeline stage.

The multiply instruction is required for full SPARC V8 compliance, but can be configured out to save area using the *v8* VHDL generic.

96.2.6 Multiply and accumulate instructions

To accelerate DSP algorithms, two multiply&accumulate instructions are implemented: UMAC and SMAC. The UMAC performs an unsigned 16-bit multiply, producing a 32-bit result, and adds the result to a 40-bit accumulator made up by the 8 lsb bits from the %y register and the %asr18 register. The least significant 32 bits are also written to the destination register. SMAC works similarly but performs signed multiply and accumulate. The MAC instructions execute in one clock but have two clocks latency, meaning that one pipeline stall cycle will be inserted if the following instruction uses the destination register of the MAC as a source operand.

The UMAC and SMAC instructions occupy the unused opcodes op=10,op3=1111110 for UMAC and op=10,op3=1111111 for SMAC.

GRIP
Apr 2024, Version 2024.1

1582

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Assembler syntax:

```
umac  rs1, reg_imm, rd
smac  rs1, reg_imm, rd
```

Operation:

```
prod[31:0] = rs1[15:0] * reg_imm[15:0]
result[39:0] = (Y[7:0] & %asr18[31:0]) + prod[31:0]
(Y[7:0] & %asr18[31:0]) = result[39:0]
rd = result[31:0]
```

%asr18 can be read and written using the RDASR and WRASR instructions.

The MAC instructions are an optional extension to SPARC V8, and enabled using the *mac* VHDL generic. The multiply and accumulate support also requires MUL/DIV support enabled by the *v8* VHDL generic and can only be used together with a 16x16 multiplier.

96.2.7 Compare and Swap instruction (CASA)

LEON4 implements the SPARC V9 Compare and Swap Alternative (CASA) instruction. The CASA operates as described in the SPARC V9 manual. The instruction is privileged, except when setting ASI = 0xA (user data).

96.2.8 Branch prediction

Static branch prediction can be optionally be enabled, and reduces the penalty for branches preceded by an instruction that modifies the integer condition codes. The predictor uses a branch-always strategy, and starts fetching instruction from the branch address. On a prediction hit, 1 or 2 clock cycles are saved, and there is no extra penalty incurred for misprediction as long as the branch target can be fetched from cache.

96.2.9 Register file data protection

The integer register file can optionally be protected against soft errors using triple modular redundancy (TMR) or technology specific protection (Technology specific protection is further documented in the GRLIB-FT User's Manual). Data errors will then be transparently corrected without impact at application level. The protection is enabled through the *ft* VHDL generic. The floating-point register file should be implemented with registers for applications that need FP register file protection.

96.2.10 Hardware breakpoints

The integer unit can be configured to include up to four hardware breakpoints. Each breakpoint consists of a pair of ancillary state registers (see section 96.11.4). Any binary aligned address range can be watched for instruction or data access, and on a breakpoint hit, trap 0x0B is generated.

96.2.11 Instruction trace buffer

The (optional) instruction trace buffer consists of a circular buffer that stores executed instructions. This is enabled and accessed only through the processor's debug port via the Debug Support Unit. When enabled, the following information is stored in real time, without affecting performance:

- Instruction address and opcode

- Instruction result

- Load/store data and address

- Trap information

- 30-bit time tag

The operation and control of the trace buffer is further described in section 28.4. Note that in multi-processor systems, each processor has its own trace buffer allowing simultaneous tracing of all instruction streams.

The size of the trace buffer is configurable from 1 to 64 KiB through the *tbuf* VHDL generic. If the value of tbuf is in the 65-128 range, a two-port instruction trace buffer of size *tbuf*-64 KiB will be used, allowing contextual reading of instructions while tracing is ongoing.

96.2.12 Processor configuration register

The ancillary state register 17 (%asr17) provides information on how various configuration options were set during synthesis. This can be used to enhance the performance of software, or to support enumeration in multi-processor systems. See section 96.11.4 for layout.

96.2.13 Exceptions

LEON4 adheres to the general SPARC trap model. The table below shows the implemented traps and their individual priority. When PSR (processor status register) bit ET=0, an exception trap causes the processor to halt execution and enter error mode, and the external error signal will then be asserted.

*Table 1902.*Trap allocation and priority

Trap	TT	Pri	Description	Class
reset	0x00	1	Power-on reset	Interrupting
data_store_error	0x2b	2	write buffer error during data store	Interrupting
instruction_access_exception	0x01	3	Error or MMU page fault during instruction fetch	Precise
privileged_instruction	0x03	4	Execution of privileged instruction in user mode	Precise
illegal_instruction	0x02	5	UNIMP or other un-implemented instruction	Precise
fp_disabled	0x04	6	FP instruction while FPU disabled	Precise
cp_disabled	0x24	6	CP instruction while Co-processor disabled	Precise
watchpoint_detected	0x0B	7	Hardware breakpoint match	Precise
window_overflow	0x05	8	SAVE into invalid window	Precise
window_underflow	0x06	8	RESTORE into invalid window	Precise
mem_address_not_aligned	0x07	10	Memory access to un-aligned address	Precise
fp_exception	0x08	11	FPU exception	Deferred
cp_exception	0x28	11	Co-processor exception	Deferred
data_access_exception	0x09	13	Access error during data load, MMU page fault	Precise
tag_overflow	0x0A	14	Tagged arithmetic overflow	Precise
division_by_zero	0x2A	15	Divide by zero	Precise
trap_instruction	0x80 - 0xFF	16	Software trap instruction (TA)	Precise
interrupt_level_15	0x1F	17	Asynchronous interrupt 15	Interrupting
interrupt_level_14	0x1E	18	Asynchronous interrupt 14	Interrupting
interrupt_level_13	0x1D	19	Asynchronous interrupt 13	Interrupting
interrupt_level_12	0x1C	20	Asynchronous interrupt 12	Interrupting
interrupt_level_11	0x1B	21	Asynchronous interrupt 11	Interrupting
interrupt_level_10	0x1A	22	Asynchronous interrupt 10	Interrupting
interrupt_level_9	0x19	23	Asynchronous interrupt 9	Interrupting
interrupt_level_8	0x18	24	Asynchronous interrupt 8	Interrupting
interrupt_level_7	0x17	25	Asynchronous interrupt 7	Interrupting
interrupt_level_6	0x16	26	Asynchronous interrupt 6	Interrupting
interrupt_level_5	0x15	27	Asynchronous interrupt 5	Interrupting
interrupt_level_4	0x14	28	Asynchronous interrupt 4	Interrupting
interrupt_level_3	0x13	29	Asynchronous interrupt 3	Interrupting
interrupt_level_2	0x12	30	Asynchronous interrupt 2	Interrupting
interrupt_level_1	0x11	31	Asynchronous interrupt 1	Interrupting

The prioritization follows the SPARC V8 manual.

The fp/cp_exception traps may be either deferred or precise depending on implementation, for the GRFPU and GRFPU-Lite implementations they are deferred. The data_store_error is delivered as a deferred exception but is non-resumable and therefore classed as interrupting in above table.

96.2.14 Single vector trapping (SVT)

Single-vector trapping (SVT) is an SPARC V8e option to reduce code size for embedded applications. When enabled, any taken trap will always jump to the reset trap handler (%tbr.tba + 0). The trap type will be indicated in %tbr.tt, and must be decoded by the shared trap handler. SVT is enabled by setting bit 13 in %asr17. The model must also be configured with the VHDL generic *svt* = 1.

96.2.15 Address space identifiers (ASI)

In addition to the address, a SPARC processor also generates an 8-bit address space identifier (ASI), providing up to 256 separate, 32-bit address spaces. During normal operation, the LEON4 processor accesses instructions and data using ASI 0x8 - 0xB as defined in the SPARC manual. Using the LDA/STA instructions, alternative address spaces can be accessed. The different available ASIs are described in section 96.10.

96.2.16 Partial WRPSR

Partial write %PSR (WRPSR) is a SPARC V8e option that allows WRPSR instructions to only affect the %PSR.ET field. If the processor has been implemented with support for partial WRPSR and the WRPSR instruction's rd field is non-zero, then the WRPSR write will only update ET.

The model must be configured with the VHDL generic pwrpsr = 1 for partial WRPSR to be supported. Implementations that do not support partial WRPSR will write the full %PSR register regardless of the value of the WRPSR instruction's rd field.

96.2.17 Power-down

The processor can be configured to include a power-down feature to minimize power consumption during idle periods. The power-down mode is entered by performing a WRASR instruction to %asr19:

```
wr %g0, %asr19
```

During power-down, the pipeline is halted until the next interrupt occurs. Signals inside the processor pipeline and caches are then static, reducing power consumption from dynamic switching.

Note: %asr19 must always be written with the data value zero to ensure compatiblity with future extensions.

Note: This instruction must be performed in supervisor mode with interrupts enabled.

When resuming from power-down, the pipeline will be re-filled from the point of power-down and the first instruction following the WRASR instruction will be executed prior to taking the interrupt trap. Up to six instructions after the WRASR instruction will be fetched (possibly with cache miss if they are not in cache) prior to fetching the trap handler.

96.2.18 Processor reset operation

The processor is reset by asserting the RESET input for at least 4 clock cycles. The following table indicates the reset values of a subset of the registers which are affected by the reset..

Table 1903. Processor reset values

Register	Reset value
Trap Base Register	Trap Base Address field reset (value given by *rstaddr* VHDL generic)
PC (program counter)	0x0 (*rstaddr* VHDL generic)
nPC (next program counter)	0x4 (*rstaddr* VHDL generic + 4)
PSR (processor status register)	ET=0, S=1

GRIP
Apr 2024, Version 2024.1
1586
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

By default, the execution will start from address 0. This can be overridden by setting the *rstaddr* VHDL generic in the model to a non-zero value. The reset address is always aligned on a 4 KiB boundary. If *rstaddr* is set to 16#FFFFF#, then the reset address is taken from the signal IRQI.RST-VEC. This allows the reset address to be changed dynamically.

96.2.19 Multi-processor systems

In multiprocessor systems, the ID of the processor on which the code is executing can be read out by reading the index field of the LEON4 configuration register. Only processor 0 starts executing after reset, the others are in power-down mode and are activated by a signal from the interrupt controller.

96.2.20 LEON-REX extension

The processor can be built with support for the LEON-REX addition to the SPARC instruction set, allowing a more compact code representation than the regular SPARC machine code. The details of the extension are given in a separate document. The extension is implemented when the *rex* VHDL generic is set.

Detection of whether support is present can be done by checking the REXV field in the asr17 register (see section 96.11.2). The REX support can be set to enabled, illegal or transparent mode via the REXEN/REXILL bits in the asr17 register, after reset the default setting is illegal so any LEON-REX code will cause an illegal instruction trap.

The extension is implemented as a decompressor internally inside the pipeline and does not affect the behavior of the caches, MMU or AHB bus interfaces.

When the *rex* generic is set, the instruction trace buffer entries are changed so the two most significant bits of the time tag are instead used to represent REX mode enabled status, and bit 1 of the program counter. The instructions opcodes logged into the trace buffer are the regular SPARC opcodes that are generated internally in the pipeline, not the LEON-REX opcodes that are in memory and cache.

96.3   Cache system

96.3.1   Overview

The LEON4 processor pipeline implements a Harvard architecture with separate instruction and data buses, connected to two separate cache controllers. As long as the execution does not cause a cache miss, the cache controllers can serve one beat of an instruction fetch and one data load/store per cycle, keeping the pipeline running at full speed. Each cache controller can be configured with different sizes and replacement policy.

On cache miss, the cache controller will assert a hold signal freezing the IU pipeline, and after delivering the data the hold signal is again lifted so execution continues. For accessing the bus, the cache controllers share the same AHB connection to the on-chip bus. Certain parts of the MMU (table walk logic, and depending on configuration also TLB buffer) are also shared between the two caches.

Another important component included in the data cache is the write buffer, allowing stores to proceed in parallel to executing instructions.

Cachability (memory areas that are cachable) for both caches is controlled through the AHB plug&play address information or using a VHDL generic, see section 96.7.2.

96.3.2   Cache operation

Each cache controller has two main memory blocks, the tag memory and the data memory. At each address in the tag memory, a number of cache entries, ways, are stored for a certain set of possible memory addresses. The data memory stores the data for the corresponding ways.

For each way, the tag memory contains the following information:

GRIP
Apr 2024, Version 2024.1

1587

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Valid bits saying if the entry contains valid data or is free. Both caches have a single valid bit for each cache line.

- The tag, all bits of the cached memory address that are not implied by the set

- If MMU is enabled, the context ID of the cache entry

- If MMU is enabled with *mmuen* generic set to 2, SO bit (supervisor only access)

- If LRR is used, a bit specifying the replacement order

- If FT is enabled, check bits for detecting errors (depending on the fault-tolerance implementation selected the check bits may or may not be visible to the user)

When a read from cache is performed, the tags and data for all cache ways of the corresponding set are read out in parallel, the tags and valid bits are compared to the desired address and the matching way is selected. In the hit case, this is all done in the same cycle to support the full execution rate of the processor.

In the miss case, the cache will at first deliver incorrect data. However on the following cycle, a hold signal will be asserted to prevent the processor from proceeding with that data. After the miss has been processed, the correct data is injected into the pipeline using a memory data strobe (mds) signal, and afterwards the hold signal can be released. If the missed address is cacheable, then the data read in from the cache miss will be stored into the cache, possibly replacing one of the existing ways.

In the instruction streaming case, the processor pipeline is stepped one step for every received instruction. If the processor needs extra pipeline cycles to stretch a multi-cycle instruction or due to an interlock condition (see section 96.2), or if the processor jumps/branches away, then the instruction cache will hold the pipe, fetch the remainder of the cache line, and the pipeline will then proceed normally.

96.3.3 Cache configuration options

Each cache controller can be configured to implement a single-way (direct-mapped) cache or a multi-way cache with set associativity of 2 - 4. The way size is configurable to 1 - 256 KiB, divided into cache lines with 16 or 32 bytes of data.

In multi-way configurations, one of three replacement policies can be selected:

- Least-recently-used (LRU) - This maintains the order of usage for each set in the cache and replaces the one which has was used last. The LRU information needs to be updated on every cache hit and is therefore not stored with the tags but in separate flip flops. When the LRU option is enabled the replacement policy becomes dynamically configurable between LRU, Least-recently-replaced, pseudo-random and a direct-mapped mode.

- Least-recently-replaced (LRR) - This stores the index of the oldest replaced way along with the tags and uses this to select which way to replace. This policy can only be implemented when the number of ways is set to 2.

- Pseudo-random - This method samples a free-running counter to select which way to replace. System jitter (AMBA bus delay variations) will help to randomize the selected value.

Note that when using locking together with LRU and more than two ways, this will add extra lookup tables to determine which way to replace and this might become a critical path in the core.

96.3.4 Address mapping

The addresses seen by the CPU are divided into tag, index and offset bits. The index is used to select the set in the cache, therefore only a limited number of cache lines with the same index part can be stored at one time in the cache. The tag is stored in the cache and compared upon read.

Figure 253. Cache address mapping examples

96.3.5 Data cache policy

The data cache employs a write-through policy, meaning that every store made on the CPU will propagate, via the write buffer, to the bus and there are no "dirty" lines in the cache that has not yet been written out apart from what is in the buffer. The store will also update the cache if the address is present, however a new line will not be allocated in that case.

*Table 1904.*LEON4 Data caching behavior

Operation	In cache	Cacheable	Bus action	Cache action	Load data
Data load	No	No	Read	No change	Bus
	No	Yes	Read	Line allocated/replaced	Bus
	Yes	-	None	No change	Cache
Data load with forced cache miss (ASI 1)	No	No	Read	No change	Bus
	No	Yes	Read	Line allocated/replaced	Bus
	Yes	-	Read	Data updated	Bus
Data load with MMU bypass (ASI 0x1C)	-	-	Read (phys addr)	No change	Bus
Data store	No	No	Write (via buffer)	No change	(N/A)
	No	Yes	Write (via buffer)	No change	(N/A)
	Yes	-	Write (via buffer)	Data updated	(N/A)
Data store with MMU bypass (ASI 0x1C)	-	-	Write (via buffer, phys addr)	No change	(N/A)

96.3.6 Write buffer

The data cache contains a write buffer able to hold a single 8,16,32, or 64-bit write. For half-word or byte stores, the stored data replicated into proper byte alignment for writing to a word-addressed device. The write is processed in the background so the system can keep executing while the write is being processed. However, any following instruction that requires bus access will block until the write buffer has been emptied. Loads served from cache will however not block, due to the cache policy used there can not be a mismatch between cache data and store buffer (the effect of this behavior on SMP systems is discussed in section 96.7).

Since the processor executes in parallel with the write buffer, a write error will not cause an exception to the store instruction. Depending on memory and cache activity, the write cycle may not occur until several clock cycles after the store instructions has completed. If a write error occurs, the currently

GRIP

Apr 2024, Version 2024.1

executing instruction will take trap 0x2b. This trap can be disabled using the DWT configuration (see section 96.11.2).

Note: a 0x2b trap handler should flush the data cache, since a write hit would update the cache while the memory would keep the old value due the write error

96.3.7 Operating with MMU

When MMU is enabled, the virtual addresses seen by the running code no longer correspond directly to the physical addresses on the AHB bus. The cache uses tags based on the virtual addresses, as this avoids having to do any additional work to translate the address in the most timing-critical hit case. However, any time a bus access needs to be made, a translation request has to be sent to the MMU to convert the virtual address to a physical address. For the write buffer, this work is included in the background processing of the store. The translation request to the MMU may result in memory accesses from the MMU to perform table walk, depending on the state of the MMU.

The MMU context ID is included in the cache tags in order to allow switching between multiple MMU contexts mapping the same virtual address to different physical addresses. Note that the cache does not detect aliases to the same physical address so in that case the same physical address may be cached in multiple ways (also see snooping below).

96.3.8 Snooping

The data cache can be configured to support AHB bus snooping. The AHB bus the processor is connected to, is monitored for writes from other masters to an address which is in the cache. If a write is done to a cached address, that cache line is marked invalid and the processor will be forced to fetch the (new) data from memory the next time it is read.

For using snooping together with the MMU, an extra tag memory storing physical tags must be added to allow comparing with the physical address on the AHB bus (called separate snoop tags or physical tags).

The processor can snoop on itself and invalidate any other cache lines aliased to the same physical address in case there are multiple virtual mappings to the same physical address that is being written. However, note that this does not happen until the write occurs on the bus so the other virtual aliases will return the old data in the meantime.

Snooping requires the way size of the cache to be equal or smaller than the MMU page size, otherwise the index into the physical and virtual tag RAM:s may not match, resulting in aliasing problems.

96.3.9 Enabling and disabling cache

Both I and D caches are disabled after reset. They are enabled by writing to the cache control register (see 96.11.5). Before enabling the caches after a reset they must be flushed to ensure that all tags are marked invalid.

96.3.10 Cache freeze

Each cache can be in one of three modes: disabled, enabled and frozen. If disabled, no cache operation is performed and load and store requests are passed directly to the memory controller. If enabled, the cache operates as described above. In the frozen state, the cache is accessed and kept in sync with the main memory as if it was enabled, but no new lines are allocated on read misses.

If the DF or IF bit is set, the corresponding cache will be frozen when an asynchronous interrupt is taken. This can be beneficial in real-time system to allow a more accurate calculation of worst-case execution time for a code segment. The execution of the interrupt handler will not evict any cache lines and when control is returned to the interrupted task, the cache state is identical to what it was before the interrupt. If a cache has been frozen by an interrupt, it can only be enabled again by

GRIP
Apr 2024, Version 2024.1
1590
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

enabling it in the CCR. This is typically done at the end of the interrupt handler before control is returned to the interrupted task.

96.3.11 Flushing

Both instruction and data cache are flushed either by executing the FLUSH instruction, setting the FI/FD bits in the cache control register, or by writing to certain ASI address spaces.

Cache flushing takes one clock cycle per cache set, during which the IU will not be halted, but during which the caches are disabled. When the flush operation is completed, the cache will resume the state (disabled, enabled or frozen) indicated in the cache control register. Diagnostic access to the cache is not possible during a flush operation and will cause a data exception (trap=0x09) if attempted.

Note that while the SPARC V8 specifies only that the instructions pointed to by the FLUSH argument will be flushed, the LEON4 will additionally flush the entire I and D cache (which is permitted by the manual as the additional flushing only affects performance and not operation). While the LEON4 currently ignores the address argument, it is recommended for future compatibility to only use the basic flush %g0 form if you want the full flush behavior.

96.3.12 Locking

Cache line locking is not supported by LEON4. The VHDL generics to enable this feature are present in the LEON4 component declaration, but are unused.

96.3.13 Diagnostic access

The cache tag and data contents can be directly accessed for diagnostics and for locking purposes via various ASI:s, see section 96.10.5.

96.3.14 Local scratch pad RAM

Local scratch pad RAM is not supported by LEON4. The VHDL generics to enable this feature are present in the LEON4 component declaration, but are unused.

96.3.15 Fault tolerance support

The instruction and data cache can be protected a using mechanism implemented in the processor core (byte-parity codes) or by using functionality from SYNCRAMFT and SYNCRAM_2PFT. The most common option is to use parity protection that is provided by the processor. Use of the SYNCRAM protection allows the processor to use technology specific protection and this can lead to savings in resource utilization on target technologies that have built-in protection of SRAM blocks

On a detected error, the corresponding cache (I or D) will be flushed and the data will be refetched from external memory. This is done transparently to execution, and incur the same timing penalty as a regular cache miss. Enabling of the data protection is done through the *ft* VHDL generic and can only be implemented in GRLIB-FT releases.

96.4 Memory management unit

96.4.1 Overview

A memory-management unit can optionally be enabled. This is compatible with the SPARC V8 reference MMU (SRMMU) architecture described inthe SPARC V8 manual, appendix H.

The MMU provides address translation of both instructions and data via page tables stored in memory.When needed, the MMU will automatically access the page tables to calculate the correct physical address. The latest translations are stored in a special cache called the translation lookaside buffer (TLB), also referred to as Page Descriptor Cache (PDC) in the SRMMU specification. The MMU also

GRIP

Apr 2024, Version 2024.1

1591

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

provides access control, making it possible to "sandbox" unpriviledged code from accessing the rest of the system.

96.4.2 MMU/Cache operation

When the MMU is disabled, the MMU is bypassed and the caches operate with physical address mapping. When the MMU is enabled, the cache tags store the virtual address and also include an 8-bit context field. Both the tag address and context field must match to generate a cache hit. When *mmuen* generic is set to 2 and MMU is enabled, the cache tags store a bit in addition to context called SO bit (supervisor only access). The SO bit is used to check the access permission of the data and instructions that resides in the level-1 caches when MMU is enabled. Without SO bit, access permissions of the load operations that hit in the data cache or the instruction accesses that hit in the instruction cache will not be checked properly.

If cache snooping is used, physical tags (separate snoop tags) must be enabled for it to work when address translation is used, see section 96.3.8.

Because the cache is virtually tagged, no extra clock cycles are needed in case of a cache load or instruction cache hit. In case of miss or write buffer processing, a translation is required which might add extra latency to the processing time, depending on TLB configuration and if there is a TLB miss.

The TLB can be configured in three different ways:

*   Separate TLBs, slow access. TLB lookup adds 2 extra clock cycles.

*   Shared TLB, slow access. TLB lookup adds 2 extra clock cycles, the TLB may be used by the other cache, leading to up to 4 extra cycles lookup time in the worst case.

*   Separate TLBs, fast access. TLB lookup is done at the same time as tag lookup and therefore add no extra clock cycles.

If there is a TLB miss the page table must be traversed, resulting in up to four AMBA read accesses and one possible writeback operation. See the SRMMU specification for the exact format of the page table.

An MMU page fault will generate trap 0x09 for the D-cache and trap 0x01 for the I cache, and update the MMU status registers according to table 1905 and the SRMMU specification. In case of multiple errors, they fault type values are prioritized as the SRMMU specification requires. The cache and memory will not be modified on an MMU page fault.

Table 1905. LEON4 MMU Fault Status Register, fault type values

Fault type	SPARC V8 ref	Priority	Condition
6	Internal error	1	Never issued by LEON SRMMU
4	Translation error	2	AHB error response while performing table walk. Translations errors as defined in SPARC V8 manual. A translation error caused by an AMBA ERROR response will overwrite all other errors. Other translation errors do no overwrite existing translation errors when FAV = 1.
1	Invalid address error	3	Page table entry for address was marked invalid
3	Privilege violation error	4	Access denied based on page table and su status (see SRMMU spec for how privilege and protection error are prioritized)
2	Protection error	5	
0	None	-	No error (inside trap this means the trap occurred when fetching the actual data)

96.4.3 Translation look-aside buffer (TLB)

The MMU can be configured to use a shared TLB, or separate TLB for instructions and data. The number of TLB entries (for each implemented TLB) can be set to 2 - 64 via VHDL generics. The

organisation of the TLB and number of entries is not visible to the software and does thus not require any modification to the operating system. The TLB can be flushed using an STA instruction to ASI 0x18, see section 96.10.6.

96.4.4 Variable minimum page sizes

The standard minimum page size for the SRMMU is 4 KiB. The minimum page size can also be configured to 8, 16 or 32 KiB in order to allow for large data cache ways. The page size can either be configured hard at implementation time or made software-configurable via the MMU control register. The page sizes for level 1, 2 and 3 is seen in the table below:

Table 1906. MMU page size

Scheme	Level-1	Level-2	Level-3
4 KiB (default)	16 MiB	256 KiB	4 KiB
8 KiB	32 MiB	512 KiB	8 KiB
16 KiB	64 MiB	1 MiB	16 KiB
32 KiB	256 MiB	2 MiB	32 KiB

The layouts of the indexes are chosen so that PTE page tables can be joined together inside one MMU page without leaving holes.

Note that most operating systems are hard-coded for a specific page size and using one other than 4 KiB usually requires reconfiguration/recompilation of the operating system kernel.

96.5 Floating-point unit

The SPARC V8 architecture defines two (optional) co-processors: one floating-point unit (FPU) and one user-defined co-processor. Two different FPU's can be interfaced the LEON4 pipeline: Frontgrade Gaisler's GRFPU and GRFPU-Lite. Selection of which FPU to use is done through the VHDL model's VHDL generic map. The characteristics of the FPU's are described in the next sections.

96.5.1 Frontgrade Gaisler's floating-point unit (GRFPU)

The high-performance GRFPU operates on single- and double-precision operands, and implements all SPARC V8 FPU operations including square root and division. The FPU is interfaced to the LEON4 pipeline using a LEON4-specific FPU controller (GRFPC) that allows FPU instructions to be executed simultaneously with integer instructions. Only in case of a data or resource dependency is the integer pipeline held. The GRFPU is fully pipelined and allows the start of one instruction each clock cycle, with the exception is FDIV and FSQRT which can only be executed one at a time. The FDIV and FSQRT are however executed in a separate divide unit and do not block the FPU from performing all other operations in parallel.

All instructions except FDIV and FSQRT has a latency of three cycles, but to improve timing, the LEON4 FPU controller inserts an extra pipeline stage in the result forwarding path. This results in a

GRIP

Apr 2024, Version 2024.1

1593

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

latency of four clock cycles at instruction level. The table below shows the GRFPU instruction timing when used together with GRFPC:

*Table 1907.*GRFPU instruction timing with GRFPC

Instruction	Throughput	Latency
FADDS, FADDD, FSUBS, FSUBD,FMULS, FMULD, FSMULD, FITOS, FITOD, FSTOI, FDTOI, FSTOD, FDTOS, FCMPS, FCMPD, FCMPES. FCMPED	1	4
FDIVS	14	16
FDIVD	15	17
FSQRTS	22	24
FSQRTD	23	25

The GRFPC controller implements the SPARC deferred trap model, and the FPU trap queue (FQ) can contain up to 7 queued instructions when an FPU exception is taken. When the GRFPU is enabled in the model, the version field in %fsr has the value of 2.

The GRFPU does not handle denormalized numbers as inputs and will in that case cause an fp_exception with the FPU trap type set to unfinised_FPOP (tt=2). There is a non-standard mode in the FPU that will instead replace the denormalized inputs with zero and thus never create this condition.

96.5.2 GRFPU-Lite

GRFPU-Lite is a smaller version of GRFPU, suitable for FPGA implementations with limited logic resources. The GRFPU-Lite is not pipelined and executes thus only one instruction at a time. To improve performance, the FPU controller (GRLFPC) allows GRFPU-Lite to execute in parallel with the processor pipeline as long as no new FPU instructions are pending. Below is a table of worst-case throughput of the GRFPU-Lite:

*Table 1908.*GRFPU-Lite worst-case instruction timing with GRLFPC

Instruction	Throughput	Latency
FADDS, FADDD, FSUBS, FSUBD,FMULS, FMULD, FSMULD, FITOS, FITOD, FSTOI, FDTOI, FSTOD, FDTOS, FCMPS, FCMPD, FCMPES. FCMPED	8	8
FDIVS	31	31
FDIVD	57	57
FSQRTS	46	46
FSQRTD	65	65

The GRLFPC controller implements the SPARC deferred trap model, but the FPU trap queue (FQ) can contain only one queued instructions when an FPU exception is taken.When the GRFPU-Lite is enabled in the model, the version field in %fsr has the value of 3.

96.6 Co-processor interface

No implementation for the user-defined co-processor is currently provided.

96.7 AMBA interface

96.7.1 Overview

The LEON4 processor has one AHB master interface. The types of AMBA accesses supported and performed by the processor depend on the accessed memory area's cachability, the maximum bus width, if the corresponding cache is enabled, and if the accessed memory area has been marked as being on the wide bus.

GRIP
Apr 2024, Version 2024.1
1594
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Cacheable instructions are fetched with a burst of 32-bit accesses, or 64- or 128-bit accesses depending on the cache line size and the AHB bus width.

The HPROT signals of the AHB bus are driven to indicate if the accesses is instruction or data, and if it is a user or supervisor access.

*Table 1909.*HPROT values

Type of access	User/Super	HPROT
Instruction	User	1100
Instruction	Super	1110
Data	User	1101
Data	Super	1111
MMU	Any	1101

In case of atomic accesses, a locked access will be made on the AMBA bus to guarantee atomicity as seen from other masters on the bus.

96.7.2 Cachability

Cachability for both caches can be controlled through the AHB plug&play address information or set manually via the *cached* VHDL generic.

For plug'n'play based cachability, the memory mapping for each AHB slave indicates whether the area is cachable, and this information is used to (statically) determine which access will be treated as cacheable. This approach means that the cachability mapping is always coherent with the current AHB configuration.

When the *cached* VHDL generic is not zero, it is treated as a 16-bit field, defining the cachability of each 256 MiB address block on the AMBA bus. For example, a value of 16#00F3# will define cachable areas in 0 - 0x20000000 and 0x40000000 - 0x80000000.

In order to access the plug'n'play information, the processor takes the ahbso vector as input. Only the static hconfig signals are used so the use of this input will be eliminated through constant propagation during synthesis.

96.7.3 AMBA access size

Cacheable data is fetched in a burst of 64- or 128-bit accesses, depending on the cache line size and AHB bus width. Data access to uncacheable areas may only be done with 8-, 16- and 32-bit accesses, i.e. the LDD and STD instructions may not be used.

If an area is marked as cacheable then the data cache will automatically try to use 64- or 128-bit accesses. This means that if 64- or 128-bit accesses need to be avoided, for example when performing Flash programming or if a slave does not support 64- or 128-bit accesses and is mapped as cacheable (this is a system design error), then software should only perform data accesses with using the cache bypass ASI and no 64-bit loads (LDD) when accessing the slave. One example of how to use cache bypass for loads is given by the following function:

```
static inline int load(int addr)
{
    int tmp;
    asm volatile(" lda [%1]0x1c, %0 "
        : "=r"(tmp)
        : "r"(addr)
        );
    return tmp;
}
```

The type of AMBA accesses used, and supported by the processor, for a memory area depends on the area's cachability and the values of the *wbmask* and *busw* VHDL generics.

GRIP
Apr 2024, Version 2024.1
1595
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The area which supports 64- or 128-bit access is indicated in the *wbmask* VHDL generic. This VHDL generic is treated as a 16-bit field, defining the 64/128-bit capability of each 256 MiB address block on the AMBA bus. A value of 16#00F3# will thus define areas in 0 - 0x20000000 and 0x40000000 - 0x80000000 to be 64/128-bit capable. The maximum access size to be used in the area(s) marked with WBMASK is determined by the *busw* VHDL generic.

Store instructions result in a AMBA access with size corresponding to the executed instruction, 64-bit store instructions (STD) are always translated to 64-bit accesses (never converted into two 32-bit stores as is done for LEON3). The table below indicates the access types used for instruction and data accesses depending on cachability, wide bus mask (wbmask), and cache configuration.

Processor operation	Accessed memory area is 32-bit only, wbmask(address) = 0			Accessed memory area is on wide bus wbmask(address) = 1		
	Area not cacheable[1]	Area is cacheable[1]		Area not cacheable[1]	Area is cacheable[1]	
		Cache enabled[2]	Cache disabled		Cache enabled[2]	Cache disabled
Instruction fetch	Burst of 32-bit read accesses	Burst of 32-bit read accesses		Burst of 64- or 128-bit accesses[5]		
Data load <= 32-bit	Read access with size specified by load instruction	**Illegal**[3,6] Burst of 32-bit accesses, software may get incorrect data	Read access with size specified by load instruction	Read access with size specified by load instruction	Burst of 64- or 128-bit accesses[5]	Read access with size specified by load instruction
Data load <= 32-bit with ASI 0x01						
Data load <= 32-bit with ASI 0x1C		Read access with size specified by load instruction[6]			Read access with size specified by load instruction[6]	
Data load 64-bit (LDD)	**Illegal**[4] Single 64-bit access will be performed	**Illegal**[3] Burst of 64- or 128-bit accesses[5]	**Illegal**[3] Single 64-bit access will be performed	**Illegal**[4] Single 64-bit access will be performed	Burst of 64- or 128-bit accesses[5]	Single 64-bit read access
Data store <= 32-bit	Store access with size specified by store instruction.					
Data store 64-bit (STD)	**Illegal (64-bit store performed to 32-bit area)** 64-bit store access will be performed.			64-bit store access		

Cells with red text show unsupported combinations of settings for wide bus and cacheability. The LEON4 core requires that all cacheable areas are can handle wide bus accesses (64- or 128-bit). Implementing the core with cacheable areas where wbmask is 0 is unsupported. The table lists the behaviour in these cases for completeness.

[1] Cachability is determined by the *cached* VHDL generic, if *cached* is zero then cachability is determined via AMBA PnP.

[2] Bus accesses for reads will only be made on L1 cache miss, load with forced cache miss or loads with cache bypass.

[3] LEON4 is designed to always make use of wide bus accesses for cacheable data. Cacheable data can only be handled with 64- or 128 bit accesses.

[4] Data accesses to uncachable areas may only be done with 8-, 16- and 32-bit accesses.

[5] 64- or 128-bit accesses depending on *busw* VHDL generic.

[6] Loads with cache bypass (ASI 0x1C) can be used to perform single accesses to cachable slaves.

96.7.4 Error handling

An AHB ERROR response received while fetching instructions will normally case an instruction access exception (tt=0x1). However if this occurs during streaming on an address that is not needed, the I cache controller will just not set the corresponding valid bit in the cache tag. If the IU later fetches an instruction from the failed address, a cache miss will occur, triggering a new access to the failed address.

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

An AHB ERROR response while fetching data into the data cache will normally trigger a data_access_exception trap (tt=0x9). If the error was for a part of the cache line other than what was currently being requested by the pipeline, a trap is not generated and the valid bit for that line is not set.

An ERROR response during an MMU table walk will lead the MMU to set the fault type to Internal error (1) and generate an instruction or data access exception, depending on which type of access that caused the table walk.

96.7.5 Snoop port

For the snooping logic, the LEON4 has an ahbsi input. For correct function, this must be tied to the same AHB bus that the master interface. It is not possible to snoop on another bus or to add extra pipeline registers to the snoop port, because the snoop logic must be in sync with the master interface.

96.8 Multi-processor system support

This section gives an overview of issues when using the LEON4 in multi-processor configuration.

Using the features described in earlier sections together with a multiprocessor capable IRQ controller (IRQMP, IRQ(A)MP), the LEON4 processor can support symmetric multiprocessing (SMP) configurations with shared memory, with up to 16 processors attached to the same AHB bus.

Enabling SMP features (sleeping on reset for CPU 1-N) is done by setting the *smp* VHDL generic to 1 or higher. Cache snooping should always be enabled in SMP systems to maintain data cache coherency between the processors.

96.8.1 Start-up

In multiprocessor systems, only the first processor will start after reset and all other processors will remain halted in power-down mode. After the system has been initialized, the remaining processors can be started by writing to the 'multiprocessor status register', located in the multiprocessor interrupt controller. The halted processors start executing from the reset address (0 or *rstaddr* VHDL generic, see section 96.2.18).

An application in a multiprocessor system can determine which processor it is executing on by checking the processor index field in the LEON4 configuration register (%asr17). As all processors typically have the same reset start address value, boot software must check the processor index and perform processor specific setup (e.g. initialization of stack pointer) based on the value of the processor index.

In recent versions of the LEON4, and if the IRQ controller is configured with the extended boot register extension, it is possible for one processor to monitor and reboot another processor.via the interrupt controller. This requires careful software design.

For earlier versions of the LEON4, this is not supported and if software detects that one processor is unresponsive and needs to restart the processor then the full system should be reset, for example by triggering the system's watchdog, if implemented. In order for software to monitor that all processors in a system are up and running it is recommended to implement a heartbeat mechanism in software.

While it is possible to have more fine-grained control over processor behaviour via the Debug Support Unit (if implemented) this is not recommended as the debug support unit is typically disabled in production mode.

96.8.2 Shared memory model

Each processor core has it's own separate AHB master interface and the AHB controller will arbitrate between them to share access to the on-chip bus.

If caches are not used, the processors will form a sequentially consistent (SC) system, where every processor will execute it's loads, stores and atomics to memory in program order on the AHB bus and

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

the different processors operations will be interleaved in some order through the AHB arbitration. The shared memory controller AHB slave is assumed to not reorder accesses so a read always returns the latest written value to that location on the bus.

When using caches with snooping (and with separate physical tags, also called separate snoop tags, if using the MMU), the shared memory will act according to the slightly weaker SPARC Total Store Order (TSO) model. The TSO model is close to SC, except that loads may be reordered before stores coming from the same CPU. The stores and atomics are conceptually placed in a FIFO (see the diagrams in the SPARC manual) and the loads are allowed to bypass the FIFO if they are not to the same address as the stores. Loaded data from other addresses may therefore be either older or newer, with respect to the global memory order, than the stores that have been performed by the same CPU.

In the LEON4 case this happens because cache hits are served without blocking even when there is data in the write buffer. The loaded data will always return the stored data in case of reading the same address, because if it is cached, the store updates the cache before being put in the write buffer, and if it was not in cache then the load will result in a miss which waits for the write buffer to complete. Loaded data from a different address can be older than the store if it is served by cache before the write has completed, or newer if it results in a cache miss or if there is a long enough delay for the store to propagate to memory before reading.

See relevant literature on shared memory systems for more information. These details are mainly of concern for complex applications using lock-free data structures such as the Linux kernel, the recommendation for applications is to instead avoid concurrent access to shared structures by using mutexes/semaphores based on atomic instructions, or to use message passing schemes with one-directional circular buffers.

96.8.3 Memory-mapped hardware

Hardware resources (IP cores) are normally memory mapped on uncacheable address spaces. They will be accessible from all the CPU:s in a sequentially consistent manner. Since software drivers usually expect to be "alone" accessing the IP core and the IP cores register interfaces are not designed for concurrent use by multiple masters, using a bare-C application designed for single-processor usage on multiple cores at the same time will generally not work. This can be solved by partitioning the applications so that each IP core is only accessed by one of the CPU:s. This partitioning also need to be done between the interrupts so the IP core's interrupts will be received by the correct processor.

96.9 Fault tolerance

96.9.1 Overview

The LEON3 processor can be enhanced with fault-tolerance against SEU errors (referred to as LEON3FT). The fault-tolerance is focused on the protection of on-chip RAM blocks, which are used to implement IU register file and the cache memory.

The LEON4 with FT features is licensed separately, and in the commercial LEON4 releases setting the FT VHDL generic will not have any effect.

96.9.2 Integer register file protection

The SEU protection for the integer unit register file can be implemented in two different ways, depending on target technology and available RAM blocks. The SEU protection scheme is selected

GRIP

Apr 2024, Version 2024.1

1598

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

during synthesis, using the *ft* VHDL generic. Table 1910 below shows the implementation characteristics of the four possible SEU protection schemes.

Table 1910. Integer unit SEU protection schemes

ID	Implementation	Description	Usage
0	No protection (hardening at lower level)	No error checking, equivalent to non-FT version. Register file hardness must be ensured separately, for example by mapping the register file memories to SEU hardened flip-flops.	IU
4	Memory triplication	Memory blocks triplicated and bit by bit voted on outputs. Correction on-the-fly without pipeline restart, no error injection interface or error counters. Note that care must be taken by the implementer to ensure that the TMR is not collapsed in optimization by synthesis tools.	IU
6	Technology specific	Implement register files using native ECC capability of the technology (via syncram_2pft in the techmap library). Only valid for subset of (FPGA) technologies. Correction on-the-fly without pipeline restart. Error injection and error counters may be supported depending on technology. Technology specific protection is further documented in the GRLIB-FT User's Manual (grlib-ft.pdf).	IU

An uncorrectable error in the IU register file will cause trap 0x20 (*r_register_access_error*). A dedicated counter exists in ASR16 to count the number of register file corrections.

The register file is implemented using scheme 0 if the regfile_4p_infer array is set for the selected memory technology in the techmap library, or if bits 16-17 of the memtech VHDL generic are set.

96.9.3 Floating-point register file protection

The FPU register file is implemented with registers.

Note that the restrictions on protection scheme is not enforced, so it is recommended to simulate the configuration with error injection to ensure that the scheme chosen is functioning correctly. It is also recommended to confirm in the netlist that the expected register file type (memory block or flip flops) was implemented.

96.9.4 Cache protection

Each word in the tag or data memories is normally protected by four check bits. Use of the SYNCRAM protection allows the processor to use technology specific protection and this can lead to savings in resource utilization on target technologies that have built-in protection of SRAM blocks. If separate physical tags for snooping are enabled, the physical tag memory is also protected. An error during cache access will cause an invalidation of the cache, and a re-execution of the failing instruction. This will ensure that the complete cache line (tags and data) is refilled from external memory.

If snooping is enabled, an error detected in the tags while snooping a write to that set will lead to that cache data being invalidated (since the tag before the error might have matched the written address).

96.10 ASI assignments

96.10.1 Summary

The table shows the ASI usage for LEON.

Table 1911. ASI usage

ASI	Usage
0x01	Forced cache miss.
0x02	System control registers (cache control register)
0x08, 0x09	Not supported
0x0A	Access level is determined by 'S' bit in %psr when MMU is enabled and *mmuen* generic is set to 1
	User Access when MMU is enabled and *mmuen* generic is set to 2
	Sets HPROT to user data regardless of MMU
0x0B	Access level is determined by 'S' bit in %psr when MMU is enabled and *mmuen* generic is set to 1
	Supervisor Access when MMU is enabled and *mmuen* generic is set to 2, otherwise normal cache access
	Sets HPROT to supervisor data regardless of MMU
0x0C	Instruction cache tags
0x0D	Instruction cache data
0x0E	Data cache tags
0x0F	Data cache data
0x0F	Register file diagnostic parity read-out (FT only)
0x10	Flush instruction cache (and also data cache when system is implemented with MMU)
0x11	Flush data cache
0x13	MMU only: Flush instruction and data cache
0x14	MMU only: MMU diagnostic D context cache access (deprecated, do not use)
0x15	MMU only: MMU diagnostic I cache context access (deprecated, do not use)
0x18, 0x03	MMU only: Flush TLB and I/D cache
0x19, 0x04	MMU only: MMU registers
0x1C	MMU and cache bypass
0x1D	MMU only: MMU diagnostic access (deprecated, do not use)
0x1E	MMU only: MMU snoop tags diagnostic access

96.10.2 ASI 0x1, Forced cache miss

ASI 1 is used for systems without cache coherency, to load data that may have changed in the background, for example by DMA units. It can also be used for other reasons, for example diagnostic purposes, to force a AHB load from memory regardless of cache state.

The address mapping of this ASI is matched with the regular address space, and if MMU is enabled then the address will be translated normally. Stores to this ASI will perform the same way as ordinary data stores.

For situations where you want to guarantee that the cache is not modified by the access, the MMU and cache bypass ASI, 0x1C, can be used instead.

96.10.3 ASI 0x2, System control registers

ASI 2 contains a few control registers that have not been assigned as ancillary state registers. These should only be read and written using 32-bit LDA/STA instructions.

GRIP

Apr 2024, Version 2024.1

1600

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

All cache registers are accessed through load/store operations to the alternate address space (LDA/STA), using ASI = 2. The table below shows the register addresses:

Table 1912. ASI 2 (system registers) address map

Address	Register
0x00	Cache control register
0x04	Reserved
0x08	Instruction cache configuration register
0x0C	Data cache configuration register

96.10.4 ASI 0x8-0xB, Data/Instruction

These ASIs are assigned by the SPARC manual for normal data and instruction fetches.

Accessing the instruction ASIs explicitly via LDA/STA instructions is not supported in the LEON4 implementation.

Using LDA/STA with the user/supervisor data ASI (0xA,0xB) will behave as the affect the HPROT signal emitted by the processor according to section 96.7.1. If *mmuen* generic is set to 2, MMU access control will be done according to the indicated user or supervisor ASI inline with reference MMU description in Sparc V8 manual. If *mmuen* generic is set to 1, MMU access control will be done depending on the SU bit in the %psr register.

96.10.5 ASI 0xC-0xF, ICache tags/data, DCache tags/data

ASI 0xC-0xF provide diagnostic access to the instruction cache memories. These ASIs should only be accessed by 32-bit LDA/STA instructions. These ASIs can not be used while a cache flush is in progress and will cause a data exception (trap=0x09) if attempted. Diagnostic accesses to the instruction cache can only be performed when the instruction cache is disabled and will cause a a data exception (trap=0x09) when the instruction cache is enabled.

The same address bits used normally as index are used to index the cache also in the diagnostic access. For a multi-way cache, the lowest bits above the index part, the lowest bits that would normally be used as tag, are used to select which way to read/write. The remaining address bits are don't cares, leading the address map to wrap around.

If fault tolerance is enabled, the tag parity, context and SO bits can also be read out through these ASIs by setting the PS bit in the cache configuration register. When this bit is set, the parity data is read instead of the ordinary data. When writing the tag bits, the context bits will always be written with the current context in the MMU control register. The SO bit in the tag will be written with the SO bit value in the MMU control register (SO bit in MMU control register only exists in the tag when *mmuen* generic is set to 2). The parity to be written is calculated based on the supply write-value, the context ID and optionally SO bit (if mmuen is set to 2) in the MMU control register. The parity bits can be modified via the TB field in the cache control register.

Example for 1 KiB way, 32 bytes/line, 4 ways

Tag diagnostic ASIs (ASI 0xC,E):

31		12	11	10	9		5	4		0
Addr:	(don't care)		Way		Index			(don't care)		

31		10	9	8	7		0
Data:	ATAG		LRR	0	VALID		

31	23	16	15	14		4	3		0
Parity:	Reserved	CTXID	SO	Reserved			TPAR		

Data diagnostic ASIs (ASI 0xD,F):

31		12	11	10	9		5	4		0
Addr:	(don't care)		Way		Index			Offset		

31		0
Data:	Cached data word	

31		4	3		0
Parity:	Reserved		DPAR		

Figure 254. ASI 0xC-0xF address mapping and data layout

Field Definitions:

Address Tag (ATAG) - Contains the tag address of the cache line.

LRR - Used by LRR algorithm to store replacement history, otherwise 0.

Valid (V) - When set, the cache line contains valid data. The LEON4 caches only have one valid bit per cache line which is replicated for the whole 8-bit diagnostic field to keep software backward compatibility.

CTXID - Context ID, used when MMU is enabled.

SO - (Supervisor only access) It is used when MMU is enabled and *mmuen* (see Sec. 96.15) generic is set to 2. This bit is set to 1 when the associated page with the tag has access permission of 6 or 7 (supervisor access only) for other access permissions it is set to 0. (For detailed information about access permissions refer to the reference MMU part of the Sparc V8 manual)

TPAR - Byte-wise parity of tag bits, context ID parity is XOR:ed into bit 3.

DPAR - Byte-wise parity of data bits

NOTE: only the necessary bits will be implemented in the cache tag, depending on the cache configuration. As an example, a 4 KiB cache with 16 bytes per line would only have four valid bits and 20 tag bits. The cache rams are sized automatically by the RAM generators in GRLIB.

96.10.6 ASI 0x10, 0x11, 0x13, 0x18 - Flush

For historical reasons there are multiple ASIs that flush the cache in different ways.

Writing to ASI 0x10 will flush the entire instruction cache. If MMU is implemented in the core, both instruction and data cache will be flushed.

Writing to ASI 0x11 will flush the data cache only.

GRIP
Apr 2024, Version 2024.1
1602
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Writing to ASI 0x13 will flush the instruction cache and data cache. Only available when MMU is implemented.

Writing to ASI 0x18 and 0x03, which is available only if MMU is implemented, will flush both the MMU TLB, the I-cache, and the D-cache. This will block execution for a few cycles while the TLB is flushed and then continue asynchronously with the cache flushes continuing in the background.

96.10.7 ASI 0x19 and 0x04 - MMU registers

This ASI provides access to the MMU:s control and status registers. The following MMU registers are implemented:

Table 1913. MMU registers (ASI = 0x19)

Address	Register
0x000	MMU control register
0x100	Context pointer register
0x200	Context register
0x300	Fault status register
0x400	Fault address register

96.10.8 ASI 0x1C - MMU and cache bypass

Performing an access via ASI 0x1C will act as if MMU and cache were disabled. The address will not be translated and the cache will not be used or updated by the access.

96.10.9 ASI 0x1E - MMU physical/snoop tags diagnostic access

If the MMU has been configured to use separate snoop (physical) tags, they can be accessed via ASI 0x1E. This is primarily useful for RAM testing, and should not be performed during normal operation. This ASI is addressed the same way as the regular diagnostic ASI:s 0xC, 0xE, and the read/written data has the layout as shown below (example for a 1 KiB/way data cache):

31	10 9	2 1 0
ATAG	"0000"	PAR IV
Figure 255. Snoop cache tag layout

[31:10]   Address tag. The physical address tag of the cache line.
[1]:   Parity. The odd parity over the data tag. Only used when processor is implemented with fault-tolerance features.
[0]:   Invalid. When set, the cache line is not valid and will cause a cache miss if accessed by the processor. Only present if fast snooping is enabled.

96.11.2 ASR17, LEON4 configuration register

The ancillary state register 17 (%asr17) provides information on how various configuration options were set during synthesis. This can be used to enhance the performance of software, or to support enumeration in multi-processor systems. There are also a few bits that are writable to configure certain aspects of the processor.

*Table 1917.*LEON4 configuration register (%asr17)

31	30	29	28	27	26	25	24	23	22	21			18	17	16
INDEX				DBP	RES	DBPM	REXV		REXM		RESERVED			CS	CF[1]
*				0	0	0	*		*		0			*	*
r				rw	r	rw	r		rw*		r			r	r

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0

*	*	0	0	*		*	*		*				*		
r	rw	rw*	r	r		r	r		r				r		

31:28	Processor index (INDEX) - In multi-processor systems, each LEON core gets a unique index to support enumeration. The value in this field is identical to the *hindex* VHDL generic parameter in the VHDL model.
27	Disable Branch Prediction (DBP) - Disables branch prediction when set to '1'. Default value is '0'.
26	Reserved for future implementations
25	Disable Branch Prediction on instruction cache misses (DBPM) - When set to '1' this avoids instruction cache fetches (and possible MMU table walk) for predicted instructions that may be annullated. This feature is on by default (reset value '1').
24:23	REX version (REXV) - read-only field that is set to '00' if REX is not implemented, '01' if REX is implemented, '10' and '11' values are reserved for future implementations
22:21	REX mode (REXM) - set to '00' for REX enabled, '01' for REX illegal and '10' for REX transparent mode. Writable with reset value '01' when REX support has been enabled
20:18	Reserved for future implementations
17	Clock switching enabled (CS). If set, switching between AHB and CPU frequency is available.
16:15	CPU clock frequency (CF). CPU core runs at (CF+1) times AHB frequency.
14	Disable write error trap (DWT). When set, a write error trap (tt = 0x2b) will be ignored. Set to zero after reset.
13	Single-vector trapping (SVT) enable. If set, will enable single-vector trapping. Fixed to zero if SVT is not implemented. Set to zero after reset.
12	Load delay. 1-cycle load delay i s used.
11:10	FPU option. "00" = no FPU; "01" = GRFPU; "11" = GRFPU-Lite
9	If set, the optional multiply-accumulate (MAC) instruction is available
8	If set, the SPARC V8 multiply and divide instructions are available
7:5	Number of implemented watchpoints (NWP) (0 - 4)
4:0	Number of implemented registers windows corresponds to NWIN+1.

96.11.3 ASR22-23 - Up-counter

The ancillary state registers 22 and 23 (%asr22-23) contain an internal up-counter that can be read by software without causing any access on the on-chip AMBA bus. The number of available bits in the counter is implementation dependent and is decided by the number of counter bits in the DSU time tag counter. %ASR23 contains the least significant part of the counter value and %ASR22 contains the most significant part. In case the implementation does not contain a debug support unit connected to the processor then the up-counter is not available (value is always zero).

The time tag value accessible in these registers is the same time tag value used for the system's trace buffers (if implemented) and for all processors connected to the same debug support unit. The time tag counter will increment when any of the trace buffers is enabled, or when the time tag counter is forced to be enabled via the DSU register interface, or when any processor has its %ASR22 Disable Up-counter (DUCNT) field set to zero.

The up-counter value will increment even if all processors have entered power-down mode.

Table 1918. LEON4 up-counter MSbs (%ASR22)

31	30	0
DUCNT	UPCNT(62:32)	

31	Disable Up-counter (DUCNT) - Disable upcounter. When set to '1' the up-counter may be disabled. When cleared, the counter will increment each processor clock cycle. Default (reset) value is '1'.
30:0	Counter value (UPCNT(62:32)) - Most significant bits of internal up-counter. Read-only.

Table 1919. LEON4 up-counter LSbs (%ASR23)

31	0
UPCNT(31:0)

```

Figure 256. Watch-point registers

WADDR - Address to compare against

WMASK - Bit mask controlling which bits to check (1) or ignore (0) for match

IF - break on instruction fetch from the specified address/mask combination

DL - break on data load from the specified address/mask combination

DS - break on data store to the specified address/mask combination

Note: Setting IF=DL=DS=0 disables the breakpoint

When there is a hardware watchpoint match and DL or DS is set then trap 0x0B will be generated. Hardware watchpoints can be used with or without the LEON4 debug support unit (DSU) enabled.

96.11.5 Cache control register

The cache control register located at ASI 0x2, offset 0, contains control and status registers for the I and D cache.

Table 1920. LEON4 Cache Control Register (CCR)

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
R	STE	R	PS	TB				DS	FD	FI	FT		R	ST	R
0	*	0	*	0				0	0	0	*		0	*	0
r	rw*	r	rw*	rw*				rw	rw	rw	r		r	r	r

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
IP	DP	ITE		IDE		DTE		DDE		DF	IF	DCS		ICS	
0	0	0		0		0		0		0	0	0		0	
r	r	rw*		rw*		rw*		rw*		rw*	rw*	rw		rw	

31		Reserved
30		Snoop Tag Flag (STE) - Set when parity error is detected in the data physical (snoop) tags. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
29		Reserved
28		Parity Select (PS) - if set diagnostic read will return 4 check bits in the lsb bits, otherwise tag or data word is returned. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
		When the technology specific FT scheme is implemented (FT field is "10") then PS selects if correctable or uncorrectable errors should generate cache misses. The recommended setting is to use PS='0' that treats uncorrectable RAM errors in the same way as parity errors would traditionally be handled.
27:24		Test Bits (TB) - if set, check bits will be xored with test bits TB during diagnostic write. Only available if fault-tolerance is enabled (FT field in this register is "01").
23		Data cache snoop enable (DS) - if set, will enable data cache snooping.
22		Flush data cache (FD). If set, will flush the data cache. Always reads as zero.
21		Flush Instruction cache (FI). If set, will flush the instruction cache. Always reads as zero.
20:19		FT scheme (FT) - "00" = no FT, "01" = 4-bit checking implemented, "10" - Technology-specific protection implemented.
18		Reserved for future implementations
17		Separate snoop tags (ST). This read-only bit is set if separate physical/snoop tags are implemented.
16		Reserved
15		Instruction cache flush pending (IP). This bit is set when an instruction cache flush operation is in progress
14		Data cache flush pending (DP). This bit is set when an data cache flush operation is in progress.
13:12		Instruction Tag Errors (ITE) - Number of detected parity errors in the instruction tag cache. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
11:10		Instruction Data Errors (IDE) - Number of detected parity errors in the instruction data cache. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
9:8		Data Tag Errors (DTE) - Number of detected parity errors in the data tag cache. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
7:6		Data Data Errors (DDE) - Number of detected parity errors in the data data cache. Only available if fault-tolerance is enabled (FT field in this register is non-zero).
5		Data Cache Freeze on Interrupt (DF) - If set, the data cache will automatically be frozen when an asynchronous interrupt is taken.
4		Instruction Cache Freeze on Interrupt (IF) - If set, the instruction cache will automatically be frozen when an asynchronous interrupt is taken.
3:2		Data Cache state (DCS) - Indicates the current data cache state according to the following: X0= disabled, 01 = frozen, 11 = enabled.
1:0		Instruction Cache state (ICS) - Indicates the current data cache state according to the following: X0= disabled, 01 = frozen, 11 = enabled.

96.11.6 I-cache and D-cache configuration registers

The configuration of the two caches if defined in two registers: the instruction and data configuration registers. These registers are read-only, except for the REPL field that may be writable, and indicate the size and configuration of the caches. They are located under ASI 2 at offset 8 and 12.

*Table 1921.*LEON4 Cache configuration register

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16

RESERVED												M	SO	RESERVED	
0												*	*	0	
r												r	r	r	

31	Cache locking (CL). Set if cache locking is implemented (always zeo)
30:28	Cache replacement policy (REPL). 00 - no replacement policy (direct-mapped cache), 01 - least recently used (LRU), 10 - least recently replaced (LRR), 11 - random. This field is writable when LRU policy is implemented.
27	Cache snooping (SN). Set if snooping is implemented.
26:24	Cache associativity (WAYS). Number of ways in the cache: 000 - direct mapped, 001 - 2-way associative, 010 - 3-way associative, 011 - 4-way associative
23:20	Way size (WSIZE). Indicates the size (KiB) of each cache way. Size $= 2^{SIZE}$
19	Local ram (LR). Set if local scratch pad ram is implemented. (Always zero for LEON4)
18:16	Line size (LSIZE). Indicated the size (words) of each cache line. Line size $= 2^{LSZ}$
15:4	RESERVED
3	MMU present (M). This bit is set to '1' if an MMU is present.
2	SO (supervisor only access) bit is present. This bit is set if *mmuen* generic is set to 2.
1:0	Reserved for future implementations

96.11.7 MMU control register

The MMU control register is located in ASI 0x19 offset 0, and the layout can be seen in table 1922.

*Table 1922.*LEON4 MMU control register

31			28	27			24	23		21	20		18	17	16
IMPL				VER				ITLB			DTLB			PSZ	
0				1				*			*			0

*Table 1922.*LEON4 MMU control register

27:24	MMU Version ID. Hardcoded to "0001".
23:21	Number of ITLB entries. The number of ITLB entries is calculated as 2^{ITLB}. If the TLB is shared between instructions and data, this field indicates to total number of TLBs.
20:18	Number of DTLB entries. The number of DTLB entries is calculated as 2^{DTLB}. If the TLB is shared between instructions and data, this field is zero.
17:16	Page size. The size of the smallest MMU page. 0 = 4 Kib; 1 = 8 Kib; 2 = 16 Kib; 3 = 32 Kib. If the page size is programmable, this field is writable, otherwise it is read-only.
15	TLB disable. When set to 1, the TLB will be disabled and each data access will generate an MMU page table walk. See Section 96.12.3 for detailed information.
14	Separate TLB. This bit is set to 1 if separate instruction and data TLBs are implemented
13	This bit only exists if *mmuen* generic is set to 2. This bit is written to the SO (supervisor only access) part of the TAG during diagnostic writes.
13:2	Reserved for future implementations
1	No Fault. When NF= 0, any fault detected by the MMU causes FSR and FAR to be updated and causes a fault to be generated to the processor. When NF= 1, a fault on an access to ASI 9 is handled as when NF= 0; a fault on an access to any other ASI causes FSR and FAR to be updated but no fault is generated to the processor.
0	Enable MMU. 0 = MMU disabled, 1 = MMU enabled.

96.11.8 MMU context pointer and context registers

The MMU context pointer register is located in ASI 0x19 offset 0x100 and the MMU context register is located in ASI 0x19 offset 0x200. They together determine the location of the root page table descriptor for the current context. Their definition follows the SRMMU specification in the SPARC V8 manual with layouts shown below..

*Table 1923.*LEON4 MMU context pointer register

31	2	1	0
CONTEXT TABLE POINTER		RES	
NR		0	
rw		r	

31:2	Context table pointer, physical address bits 35:6 (note address is shifted 4 bits)
1:0	Reserved, always 0

*Table 1924.*LEON4 MMU context register

31	8	7	0
RESERVED		CONTEXT	
0		0	
r		rw	

31:8	Reserved
7:0	Current context ID

In the LEON4, the context bits are OR:ed with the lower MMU context pointer bits when calculating the address, so one can use less context bits to reduce the size/alignment requirements for the context table.

96.11.9 MMU fault status register

The MMU fault status register is located in ASI 0x19 offset 0x300, and the definition is based on the SRMMU specification in the SPARC V8 manual. The SPARC V8 specifies that the fault status regis-

96.11.10 MMU fault address register

The MMU fault address register is located in ASI 0x19 offset 0x400, and the definition follows the SRMMU specification in the SPARC V8 manual..

Table 1926. LEON4 MMU fault address register

31	12	11	0
FAULT ADDRESS		RESERVED	
NR		0	
r		r

11:0   Reserved, always 0

96.12   Software considerations

96.12.1 Register file initialization on power up

It is recommended that the boot code for the processor writes all registers in the IU and FPU register files before launching the main application. This allows software to be portable to both FT and non-FT versions of the LEON3 and LEON4 processors.

96.12.2 Start-up

After reset, the caches are disabled and the cache control register (CCR) is 0. Before the caches may be enabled, a flush operation must be performed to initialized (clear) the tags and valid bits. A suitable assembly sequence could be:

```
flush
set 0x81000f, %g1
sta %g1, [%g0] 2
```

96.12.3 MMU & TLB

After reset, the MMU is disabled and TLB is configured to be on (will not have any effect until MMU is enabled). Hence with default reset values the TLB has to be flushed before the MMU is being activated to initialize the valid bits in TLB. If the TLB is disabled while the MMU is active, the TLB must be flushed before enabled again.

96.12.4 Data scrubbing (for fault-tolerant implementations)

There is generally no need to perform data scrubbing on either IU/FPU register files or the cache memory. During normal operation, the active part of the IU/FPU register files will be flushed to memory on each task switch. This will cause all registers to be checked and corrected if necessary. Since most real-time operating systems performs several task switches per second, the data in the register files will be frequently refreshed.

The similar situation arises for the cache memory. In most applications, the cache memory is significantly smaller than the full application image, and the cache contents is gradually replaced as part of normal operation. For very small programs, the only risk of error build-up is if a part of the application is resident in the cache but not executed for a long period of time. In such cases, executing a cache flush instruction periodically (e.g. once per minute) is sufficient to refresh the cache contents.

96.13 Vendor and device identifiers

The core has vendor identifiers 0x01 (Frontgrade Gaisler) and device identifiers 0x048. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

96.14 Implementation

96.14.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

96.14.2 Technology mapping

LEON4 has two technology mapping VHDL generics, *fabtech* and *memtech*. The *fabtech* generic controls the implementation of some pipeline features, while *memtech* selects which memory blocks will be used to implement cache memories and the IU/FPU register file. *Fabtech* can be set to any of the provided technologies (0 - NTECH) as defined in the TECHMAP.GENCOMP package. See the GRLIB Users's Manual for available settings for *memtech*.

96.14.3 RAM usage

The LEON4 core maps all usage of RAM memory on the *syncram*, *syncram_2p* and *syncram_dp* components from the technology mapping library (TECHMAP). The type, configuration and number of RAM blocks is described below.

Register file

The register file is implemented with six *synram_2p* blocks for all technologies where the *regfile_4p_infer* constant in TECHMAP.GENCOMP is set to 0. The organization of the syncram_2p is shown in the following table:

*Table 1927.*syncram_2p sizes for LEON4 register file

Register windows	Syncram_2p organization
2 - 3	32x32
4 - 7	64x32
8 - 15	128x32
16-31	256x31
32	512x32

If *regfile_4p_infer* is set to 1, the synthesis tool will automatically infer the register. On FPGA technologies, it can be in either flip-flops or RAM cells, depending on the tool and technology. On ASIC technologies, it will be flip-flops. The amount of flip-flops inferred is equal to the number of registers:

Number of flip-flops = ((NWINDOWS *16) + 8) * 32

FP register file

If FPU support is enabled, the FP register file is implemented with four *synram_2p* blocks when the *regfile_3p_infer* constant in TECHMAP.GENCOMP is set to 0. The organization of the syncram_2p blocks is 16x32.

If *regfile_3p_infer* is set to 1, the synthesis tool will automatically infer the FP register file. For ASIC technologies the number of inferred flip-flops is equal to number of bits in the FP register file which is 32 * 32 = 1024.

Cache memories

RAM blocks are used to implement the cache tags and data memories. Depending on cache configuration, different types and sizes of RAM blocks are used.

The tag memory is implemented with one *syncram* per cache way when no snooping is enabled. The tag memory depth and width is calculated as follows:

Depth = (cache way size in bytes) / (cache line size in bytes)

Width = 32 - log2(cache way size in bytes) + 1

For a 2 KiB cache way with 32 bytes/line, the tag RAM depth will be (2048/32) = 64. The width will be: 32 - log2(2048) + 1 = 32 - 11 + 1 = 22. The tag RAM organization will thus be 64x22 for the configuration. If the MMU is enabled, the tag memory width will increase with 8 to store the process context ID, and the above configuration will us a 64x30 RAM.

If simple (MMU-less) snooping is enabled, the data cache tag memory will instead of single-port RAM blocks be implemented with a dual-port RAMs (syncram_dp) of the same size.

If physical (MMU-compatible) snooping is enabled, the data cache tag memories will be implemented using two *syncram_2p* components (with one read-only and one write-only port) per way, one memory for virtual and one for separate physical tags. The size of the virtual tag block will be the same as when snooping is disabled. The physical tag block will have the same depth as above and the data width corresponds to the width of the tag: 32 - log2(way size). A 4 KiB data cache way will thus require a 32 - 12 = 20 bit wide RAM block for the physical tags.

The data part of the caches (storing instructions or data) is either 64 or 128 bit wide, depending on the setting of the *busw* VHDL generic. The depth is equal to the way size in bytes, divided by 8 (BUSW=64) or 16 (BUSW=128). A 64-bit cache way of 4 KiB will use two *syncram* components with and organization of 512x32. If the 128-bit AHB bus option is used, the data RAM will be divided on four 32-bit RAM blocks to allow loading of a 16-bit cache line in one clock. A 4 KiB data cache will then use four 256x32 RAM blocks.

Instruction Trace buffer

The instruction trace buffer will use four identical RAM blocks (*syncram*) to implement the buffer memory. The syncrams will always be 32-bit wide. The depth will depend on the *tbuf* VHDL generic, which indicates the total size of trace buffer in KiBs. If *tbuf* = 1 (1 KiB), then four RAM blocks of 64x32 will be used. If *tbuf* = 2, then the RAM blocks will be 128x32 and so on.

96.14.4 Double clocking

LEON4 implements double clocking in the same way as LEON3. Please refer to the LEON3 Double-Clocking section in the LEON/GRLIB Configuration and Development Guide.

96.14.5 Clock gating

LEON4 clock gating is described in the LEON/GRLIB Configuration and Development Guide.

+46 31 7758650 | frontgrade.com/gaisler

96.14.6 Scan support

If the *scantest* VHDL generic is set to 1, support for scan testing is enabled. This will make use of the AHB scan support signals in the following manner: when AHBI.testen and AHBI.scanen are both '1', the select signals to all RAM blocks (cache RAM, register file and DSU trace buffers) are disabled. This means that when the scan chain is shifted, no accidental write or read can occur in the RAM blocks. The scan signal AHBI.testrst is not used as there are no asynchronous resets in the LEON4 core.

96.15   Configuration options

Table 1928 shows the configuration options of the core (VHDL generics).

Table 1928. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB master index	0 - NAHBMST-1	0
fabtech	Target technology	0 - NTECH	0 (inferred)
memtech	Vendor library for regfile and cache RAMs. Bits 16, 17 and 18 of this generic can be used to for the MMU TLB data RAM, IU register file and FP register file to inferred technology: + 2**16: Force inferred technology for MMU TLB data RAM + 2**17: Force inferred technology for IU register file + 2**18: Force inferred technology for FP register file Adding the value (2**17) is equivalent to setting the grlib.gencomp.regfile_4p_infer(memtech) to 1 (used for some technologies to force the register file implementations to inferred). Adding the value (2**18) is equivalent to setting the grlib.gencomp.regfile_3p_infer(memtech) to 1 (used for some technologies to force the register file implementations to inferred).	0 - 16#FFFFFFFF#	0 (inferred)
nwindows	Number of SPARC register windows. Choose 8 windows to be compatible with Bare-C and RTEMS cross-compilers.	2 - 32	8
dsu	Enable Debug Support Unit interface	0 - 1	0
fpu	Floating-point Unit 0 : no FPU 1 - 7: GRFPU 1 - inferred multiplier, 2 - DW multiplier, 3 - Module Generator multiplier 8 - 14: GRFPU-Lite 8 - simple FPC, 9 - data forwarding FPC, 10 - non-blocking FPC 16 - 31: as above (modulo 16) but use netlist 32 - 63: as above (modulo 32) but uses shared GRFPU interface Netlist or technology specific multiplier is recommended when using Synplify to target Virtex-5.	0 - 63	0

ilramstart	8 MSB bits used to decode local instruction RAM area (not used at this point)	0 - 255	16#8E#
dlram	Enable local data RAM (scratch-pad RAM) (not used at this point)	0 - 1	0
dlramsize	Local data RAM size in kB (not used at this point)	1 - 512	1
dlramstart	8 MSB bits used to decode local data RAM area (not used at this point)	0 - 255	16#8F#
mmuen	Enable memory management unit (MMU) Note: Bus snooping is required to avoid cache aliasing effects when the MMU is enabled if the cache has more than one way. 0 : MMU does not exist. 1 : MMU exists. 2 : MMU exists and the cache tags include an additional bit called SO (supervisor only access). See sec. 96.4.2 for more details. If MMU is going to be instantiated in the processor, it is recommended to set the *mmuen* generic to 2.	0 - 2	0
itlbnum	Number of instruction TLB entries	2 - 64	8
dtlbnum	Number of data TLB entries	2 - 64	8
tlb_type	0 : separate TLB with slow write 1: shared TLB with slow write 2: separate TLB with fast write	0 - 2	1
tlb_rep	LRU (0) or Random (1) TLB replacement	0 - 1	0
lddel	Unused. LEON4 is always implemented with load delay 1.	1 - 2	2
disas	Print instruction disassembly in VHDL simulator console.	0 - 1	0
tbuf	Size of instruction trace buffer in kB (0 - instruction trace disabled). For values 1-64 a single-port trace buffer of size *tbuf* is used. For values 65-128 a two-port trace buffer of size *tbuf*-64 is used.	0 - 128	0
pwd	Power-down. 0 - disabled, 1 - area efficient, 2 - timing efficient.	0 - 2	1
svt	Enable single-vector trapping	0 - 1	0
rstaddr	Default reset start address. This generic sets the 20 most significant bits of the reset address. The reset address must always be aligned on a 4 KiB address boundary. If this generic is set to 16#fffff# the processor will read its start address from the interrupt controller interface signal IRQI.RSTVEC (dynamic reset start address). See section 96.2.18 for more information.	$0 - (2^{20}-1)$	0
smp	Enable multi-processor support 0: SMP support disabled 1- 15: SMP enabled, cpu index is taken from hindex generic 16-31: SMP enabled, cpu index is taken from irqi.index signal	0 - 31	0
cached	Fixed cacheability mask. See sections 96.3 and 96.7 for more information.	0 - 16#FFFF#	0
clk2x	Enables double-clocking. See section 96.14.4 and the LEON/GRLIB Design and Configuration Guide. Not present on all top-level entites.	0 - 15	0
scantest	Enable scan test support	0 - 1	0

97 LEON5SYS - High-performance SPARC V8 32-bit Processor Subsystem

97.1 Overview

LEON5 is a 32-bit processor core conforming to the IEEE-1754 (SPARC V8) architecture. It is designed for embedded applications, combining high performance with low complexity and low power consumption.

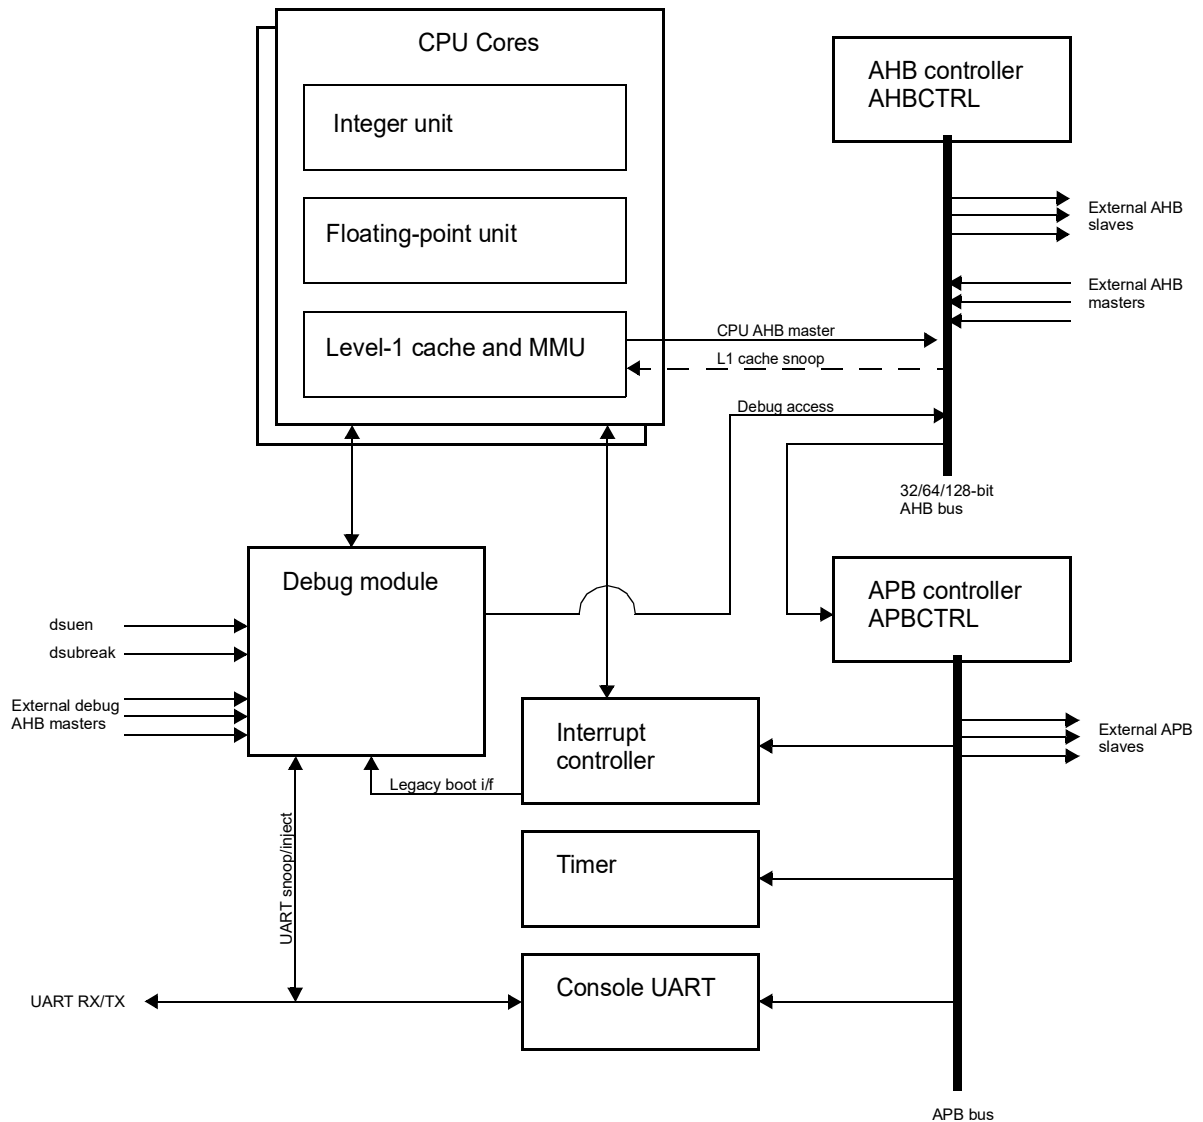
The LEON5SYS block combines the LEON5 processor with essential peripherals needed to create a LEON5-based system-on-chip.


Figure 258. LEON5SYS subsystem block diagram

97.1.1 Integer unit

The LEON5 integer unit implements the full SPARC V8 specification, including hardware multiply and divide instructions. The processor has 8 register windows. The dual-issue pipeline consists of 8 stages with a separate instruction and data cache interface (Harvard architecture).

GRIP

Apr 2024, Version 2024.1   1622   Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

97.1.2 Level 1 cache

LEON5 has a separate instruction and data cache. The instruction cache maintains one valid bit per cache line and performs buffer forwarding during line-refill to minimize refill latency. The data cache has one valid bit per cache line, uses write-through policy and implements a four double-word write-buffer. Bus-snooping on the AHB bus is used to maintain cache coherency for the data cache. Optionally, tightly coupled memory can be added to the caches that can be accessed with the same speed as data in the cache.

97.1.3 Floating-point unit

The LEON5 integer interfaces a floating-point unit (FPU). Two FPU options are available, one for the high-performance GRFPU and one for the NanoFPU core. The floating-point processor executes in parallel with the integer unit, and does not block the operation unless a data or resource dependency exists. Note that the GRFPU is provided separately.

97.1.4 Memory management unit

A SPARC V8 Reference Memory Management Unit (SRMMU) is integrated into the LEON5 cache controller. The SRMMU implements the full SPARC V8 MMU specification, and provides mapping between multiple 32-bit virtual address spaces and physical memory. A three-level hardware table-walk is implemented, and the MMU has a separate fully associative TLB for instruction and data.

97.1.5 On-chip debug support

The LEON5 subsystem includes functionality to allow non-intrusive debugging on target hardware. Interfaces to access the debug functionality are connected using a dedicated AHB port that does not interfere with normal operation.

To aid software debugging, hardware watchpoint registers can be enabled in the integer pipeline. Each register can cause a breakpoint trap on an arbitrary instruction or data address range. The watchpoints can be used to put the processor in stopped state for debugging.

When accessed through the debug module, full access to all processor registers and caches is provided, as well as direct read/write access to the AHB bus. The debug interfaces also allows single stepping, instruction tracing and hardware breakpoint/watchpoint control. An internal trace buffer can monitor and store executed instructions, which can later be read out via the debug interface.

97.1.6 Interrupt interface

An interrupt controller is included in the subsystem, collecting interrupts from external and internal sources and presenting them to the integer units.

The LEON5 integer unit supports the SPARC V8 interrupt model with a total of 15 asynchronous interrupt levels, and the interrupt controller provides extended interrupt support used to get up to 31 interrupts. More interrupts can be handled via interrupt sharing in software.

97.1.7 Standard peripherals

The LEON5SYS block includes standard APBUART and GPTIMER peripherals as are typically expected by software.

97.1.8 AMBA interface

An AMBA 2.0 AHB bus is included in the subsystem. Each processor's cache system implements an AMBA AHB master to load and store data to/from the caches that is connected to the AHB bus. During line refill, incremental burst are generated to optimise the data transfer. The AMBA interface can be configured to 32, 64 or 128-bit data width.

External slaves (memory controllers) and masters (peripheral DMA) are connected to the subsystem via ports. The external AHB slaves may either be narrow (support maximum 32-bit width) or wide (support full width of AMBA bus) and it is possible to have a mix of narrow and wide AHB slaves.

An APB controller is also included in the subsystem for the internal peripherals, and additional external peripherals may be connected via a subsystem port.

97.1.9 Power-down mode

The LEON5 processor core implements a power-down mode, which halts the pipeline and caches until the next interrupt. The processor supports optional clock gating during the power down period by providing a clock-enable signal that can be tied to an external clock gate cell, and by providing a separate clock input for the small part of the CPU that needs to run during power-down to check for wake-up conditions and maintain cache coherency.

97.1.10 Multi-processor support

LEON5 is designed to be used in multi-processor systems both in SMP and AMP configurations. Each processor has a unique index to allow processor enumeration. The write-through caches combined with the snooping mechanism guarantees memory coherency in shared-memory systems consistent with the SPARC TSO (Total Store Order) memory model. A CPU to CPU interface is provided to allow the processors to start and stop each other.

97.2 LEON5 integer unit

97.2.1 Overview

The LEON5 integer unit contains the main processor pipeline and implements the integer part of the SPARC V8 instruction set. The implementation is focused on high performance. The LEON5 integer unit has the following main features:

- 8-stage dual issue instruction pipeline

- Separate instruction and data cache interface

- Hardware multiplier

- Radix-2 divider (non-restoring)

- Branch prediction and branch target buffer

- Late ALU for load and multiply results

- Debug support

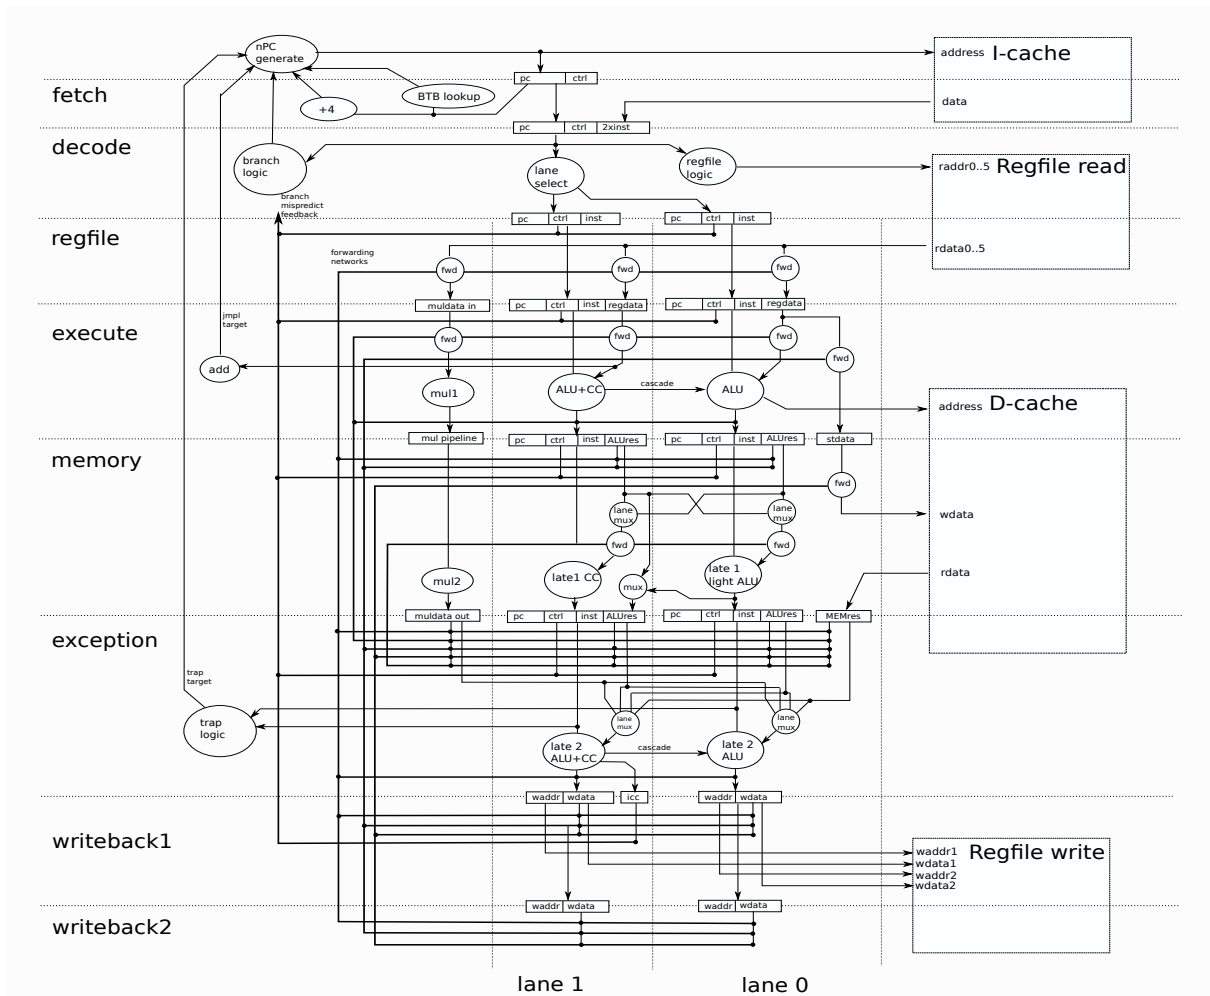
Figure 259 shows a block diagram of the integer unit.


Figure 259. LEON5 integer unit datapath diagram

1625

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

97.2.2 Instruction pipeline

The LEON5 integer unit uses a dual instruction issue pipeline with 8 stages:

1. FE (Instruction Fetch): A 64-bit word (holding two instructions) is fetched from the instruction cache. The instruction is valid at the end of this stage and is latched inside the IU. Branch target buffer and branch history is also accessed during this stage.
2. DE (Decode): The two instructions are decoded and the CALL/Branch target addresses are generated. It is determined if dual issue is possible, which instruction goes into which lane of the following stages. Floating point operations stalls in this stage if any data dependency exists.
3. RA (Register access): Operands are read from the register file or from internal data bypasses. Stalls due to data dependencies, or multi-cycle operations (like division, atomic) are generated in this stage.
4. EX (Execute): ALU, logical, and shift operations are performed in both lanes. Forwarding to the ALU inputs from XC stage is performed to reduce the LOAD/MUL latency to 1. The two lanes' ALU:s may be cascaded if lane 0 depends on lane 1s result. For memory operations (e.g., LD) and for JMPL/RETT, the address is generated.
5. ME (Memory): Read data is received from the data cache is accessed. Store data is generated and fed into the data cache inputs at this time. ALU:s with reduced functionality are included in this stage to allow delayed dependency resolution in some cases.
6. XC (Exception) Traps and interrupts are resolved. For cache reads, the data is aligned. For cache writes, the data update takes place inside the cache memory on this cycle. Late ALU:s with full functionality are included in this stage to allow delayed dependency resolution.
7. WR1 (Write): Pipeline stage to avoid long paths through the XC stage logic into register file data inputs.
8. WR2 (Write): The result of ALU and cache operations are written back to the register file.

Table 1933 lists the cycles per instruction, not considering dual issue (assuming cache hit and no icc or load interlock):

*Table 1933.*Instruction timing

Instruction	Cycles	Comment
JMPL/RETT	4	Including delay slot
CALL	2	Including delay slot
SMUL/UMUL	1	
Load	1	
Store, 32/64 bit	1 / 2	Two cycles if following instruction is load or 8/16 bit store
Store, 8/16 bit	1 / 2	Two cycles if following instruction is load or store
SDIV/UDIV	35	
Taken Trap	6	
Atomic load/store	5	
All other instructions	**1**	

97.2.3 Branch predictor and branch target buffer

The pipeline implements a branch predictor in the decode stage. The predictor uses a two level adaptive predictor scheme with 128 entries and 4 length history buffer. The pipeline can also be switched over to a static always-taken prediction mode to improve timing predictability.

A branch target buffer is implemented to predict branch buffer targets in the fetch stage to avoid a one-cycle gap between branches and the target instruction. The branch target buffer is only used for branches in the first part of a pair (on address multiple of 8) as the delay slot will take up the following cycle in the other case.

97.2.4 Late ALU

Late ALUs are implemented to allow ALU and ALUcc operations normally done in the EX stage to be deferred to the ME or XC states. This allows masking the load and multiply to ALU operation latency.

GRIP
Apr 2024, Version 2024.1

1626

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The late ALU in the ME stage is reduced in functionality to only handle the most common operations, other cases will be deferred to the late ALU in the XC stage.

Arithmetic operations that can use Late ALU are ADD, AND, OR, XOR, SUB, ANDN, ORN, XNOR, SLL, SRL, SRA, ADDCC, ANDCC, ORCC, XORCC, SUBCC, ANDNCC, ORNCC and XNORCC.

97.2.5 Interlocks

Additional conditions that can extend an instructions duration in the pipeline are listed in the table and text below.

Branch target interlock: When the least significant 3-bits of the program counter of a branch is 0x0 and the branch is predicted to be taken, if branch target buffer lookup is a miss or branch target buffer is disabled one cycle interlock is incurred in which branch target address is calculated. For branches with PC ending with 0x4, the delay slot is fetched while calculating the target address so no interlock is incurred.

Load delay: When using data resulting on a load shortly after the load, if late ALU is enabled and the instruction can use late alu (see) no delay cycle is incurred. Otherwise there can be up to two cycle delay.

Mul delay: Same as load delay.

Late alu delay: If an operation depends on the result of a late alu operation and it can not itself use the late alu (see) there can be up to three cycle delays. If a store operation needs to store the result of a late alu operation there can be at most 1 cycle delay.

Hold cycles: During cache miss processing or when blocking on the store buffer, the pipeline will be held still until the data is ready, effectively extending the execution time of the instruction causing the miss by the corresponding number of cycles. Note that since the whole pipeline is held still, hold cycles will not mask load delay or interlock delays. For instance on a load cache miss followed by a data-dependent instruction, both hold cycles and load delay may be incurred.

FPU/Coprocessor: The floating-point unit or coprocessor may need to hold the pipeline or extend a specific instruction. When this is done is specific to the FP/CP unit.

97.2.6 Branch Handling

When branch prediction is enabled, instructions following the branch are fetched speculatively until branch resolution happens. Branch resolution can happen on any stage between the decode stage and the exception stage, meaning that it can take 2-6 cycles until a branch is resolved. If the branch prediction is correct, then no extra delay is incurred while the branch is resolved regardless in which stage it is resolved, since instructions from predicted path are fetched. If there is a branch misprediction, mispredicted instructions are annulled and the true target of the branch is fetched, leading to up to 6 cycles of effective timing penalty depending on in which stage the branch is resolved.

If branch prediction is configured to be disabled, and condition codes are not resolved when a branch reaches the regfile access stage, the branch will stall there. In addition, only the delay slot instruction will be in the pipeline so there can be up to two bubbles inserted on fetch and decode stages. The number of stall cycles of a branch can be up to three cycles if late alu is enabled, an instruction updating the condition code is immediately before the conditional branch, and the instruction updating the condition codes gets calculated in late alu,

97.2.8 SPARC Implementor's ID

Frontgrade Gaisler is assigned number 15 (0xF) as SPARC implementor's identification. This value is hard-coded into bits 31:28 in the %psr register. The version number for LEON5 is 5, which is hard-coded in to bits 27:24 of the %psr.

97.2.9 Divide instructions

Full support for SPARC V8 divide instructions is provided (SDIV, UDIV, SDIVCC & UDIVCC). The divide instructions perform a 64-by-32 bit divide and produce a 32-bit result. Rounding and overflow detection is performed as defined in the SPARC V8 manual.

97.2.10 Multiply instructions

The LEON processor supports the SPARC integer multiply instructions UMUL, SMUL UMULCC and SMULCC. These instructions perform a 32x32-bit integer multiply, producing a 64-bit result. SMUL and SMULCC performs signed multiply while UMUL and UMULCC performs unsigned multiply. UMULCC and SMULCC also set the condition codes to reflect the result. The multiply instructions are performed using a 32x32 pipelined hardware multiplier.

97.2.11 Compare and Swap instruction (CASA)

LEON5 implements the SPARC V9 Compare and Swap Alternative (CASA) instruction. The CASA operates as described in the SPARC V9 manual. The instruction is privileged, except when setting ASI = 0xA (user data).

For compatibility with existing LEON3 and LEON4 software, when CASA is used with ASI 0xA, MMU translation and permissions checking will be done using the current priviledge level as determined by PSR.

97.2.12 Hardware breakpoints

The integer unit can be configured with up to four hardware breakpoints (two in the standard implementation). Each breakpoint consists of a pair of ancillary state registers (see section 97.12.5). Any binary aligned address range can be watched for instruction or data access, and on a breakpoint hit, trap 0x0B is generated.

97.2.13 Instruction trace buffer

The instruction trace buffer consists of a circular buffer that stores executed instructions. This is enabled and accessed only through the processor's debug port via the Debug Support Unit. When enabled, the following information is stored in real time, without affecting performance:

- Instruction address and opcode
- Instruction result
- Load/store data and address
- Trap information
- 30-bit time tag

Note that in multi-processor systems, each processor has its own trace buffer allowing simultaneous tracing of all instruction streams.

97.2.14 Processor configuration register

The ancillary state register 17 (%asr17) and the LEON5 configuration register provides information on how various configuration options were set during synthesis. This can be used to enhance the per-

formance of software, or to support enumeration in multi-processor systems. See section 97.12.5 for layout.

97.2.15 Exceptions

LEON5 adheres to the general SPARC trap model. The table below shows the implemented traps and their individual priority. When PSR (processor status register) bit ET=0, an exception trap causes the processor to halt execution and enter error mode, and in the case of CPU0 the external error signal will then be asserted.

Table 1936. Trap allocation and priority

Trap	TT	Pri	Description	Class
reset	0x00	1	Power-on reset	Interrupting
cache_state_error	0x60	2	bad state detected in cache memories	Interrupting
data_store_error	0x2b	2	write buffer error during data store	Interrupting
instruction_access_exception	0x01	3	Error or MMU page fault during instruction fetch	Precise
privileged_instruction	0x03	4	Execution of privileged instruction in user mode	Precise
illegal_instruction	0x02	5	UNIMP or other un-implemented instruction	Precise
fp_disabled	0x04	6	FP instruction while FPU disabled	Precise
cp_disabled	0x24	6	CP instruction while Co-processor disabled	Precise
watchpoint_detected	0x0B	7	Hardware breakpoint match	Precise
window_overflow	0x05	8	SAVE into invalid window	Precise
window_underflow	0x06	8	RESTORE into invalid window	Precise
mem_address_not_aligned	0x07	10	Memory access to un-aligned address	Precise
fp_exception	0x08	11	FPU exception	Deferred
cp_exception	0x28	11	Co-processor exception	Deferred
data_access_exception	0x09	13	Access error during data load, MMU page fault	Precise
tag_overflow	0x0A	14	Tagged arithmetic overflow	Precise
division_by_zero	0x2A	15	Divide by zero	Precise
trap_instruction	0x80 - 0xFF	16	Software trap instruction (TA)	Precise
interrupt_level_15	0x1F	17	Asynchronous interrupt 15	Interrupting
interrupt_level_14	0x1E	18	Asynchronous interrupt 14	Interrupting
interrupt_level_13	0x1D	19	Asynchronous interrupt 13	Interrupting
interrupt_level_12	0x1C	20	Asynchronous interrupt 12	Interrupting
interrupt_level_11	0x1B	21	Asynchronous interrupt 11	Interrupting
interrupt_level_10	0x1A	22	Asynchronous interrupt 10	Interrupting
interrupt_level_9	0x19	23	Asynchronous interrupt 9	Interrupting
interrupt_level_8	0x18	24	Asynchronous interrupt 8	Interrupting
interrupt_level_7	0x17	25	Asynchronous interrupt 7	Interrupting
interrupt_level_6	0x16	26	Asynchronous interrupt 6	Interrupting
interrupt_level_5	0x15	27	Asynchronous interrupt 5	Interrupting
interrupt_level_4	0x14	28	Asynchronous interrupt 4	Interrupting
interrupt_level_3	0x13	29	Asynchronous interrupt 3	Interrupting
interrupt_level_2	0x12	30	Asynchronous interrupt 2	Interrupting
interrupt_level_1	0x11	31	Asynchronous interrupt 1	Interrupting

The prioritization follows the SPARC V8 manual.

GRIP
Apr 2024, Version 2024.1
1630
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The data_store_error is delivered as a deferred exception but is non-resumable and therefore classed as interrupting in above table. The traps related to cache/memory access are described further in the cache controller decription.

97.2.16 Address space identifiers (ASI)

In addition to the address, a SPARC processor also generates an 8-bit address space identifier (ASI), providing up to 256 separate, 32-bit address spaces. During normal operation, the LEON5 processor accesses instructions and data using ASI 0x8 - 0xB as defined in the SPARC manual. Using the LDA/STA instructions, alternative address spaces can be accessed. The different available ASIs are described in section 97.11.2.

97.2.17 Partial WRPSR

Partial write %PSR (PWRPSR) is a SPARC V8e option that allows WRPSR instructions to only affect the %PSR.ET field. If the WRPSR instruction's rd field is non-zero, then this is interpreted as a PWRPSR instruction and the WRPSR write will only update ET. This allows for disabling traps with a single instruction. PWRPSR support is always enabled on LEON5.

97.2.18 Power-down

The processor can be configured to include a power-down feature to minimize power consumption during idle periods. The power-down mode is entered by performing a WRASR instruction to %asr19:

```
wr %g0, %asr19
```

During power-down, the pipeline is halted until the next interrupt occurs. Signals inside the processor pipeline and caches are then static, reducing power consumption from dynamic switching.

Note: %asr19 must always be written with the data value zero to ensure compatiblity with future extensions.

Note: This instruction must be performed in supervisor mode with interrupts enabled.

When resuming from power-down, the pipeline will be re-started from the instruction following the power-down.

97.2.19 Debug and control interface

The integer pipeline provides a command/status interface for starting / controlling and debugging the pipeline. An interface is provided to allow the debug module access the registers of the integer pipeline when it has been stopped for debugging. These features are described further in sections 97.9 and 97.10.

97.2.20 Multi-processor systems

In multiprocessor systems, the ID of the processor on which the code is executing can be read out by reading the index field of the LEON4 configuration register. Only processor 0 starts executing after reset, the others are in power-down mode and are activated over the CPU-to-CPU interface or via the legacy interrupt controller interface. See section 97.9 for further details.

97.3 Cache system

97.3.1 Overview

The LEON5 processor pipeline internally implements a Harvard architecture with separate instruction and data buses, connected to two separate caches. As long as the execution does not cause a cache

miss, the cache controllers can serve one beat of an instruction fetch and one data load/store per cycle, keeping the pipeline running at full speed.

On cache miss, the cache controller will assert a hold signal freezing the IU pipeline, and after delivering the data the hold signal is again lifted so execution continues. The miss processing is handled by a state machine common to both the instruction and data caches.

Another important component included in the data cache is the write buffer, allowing stores to proceed in parallel to executing instructions.

Cachability (memory areas that are cachable) for both caches is controlled through the AHB plug&play address information or using a VHDL generic, see section 97.3.17.

97.3.2 Enabling and disabling cache

Both I and D caches are disabled after reset. They are enabled by writing to the cache control register (see 97.12.6). The cache tags are initialized automatically after reset to ensure that all tags are invalid.

97.3.3 Cache operation

Each cache controller has two main memory blocks, the tag memory and the data memory. At each address in the tag memory, a number of cache entries, ways, are stored for a certain set of possible memory addresses. The data memory stores the data for the corresponding ways.

For each way, the tag memory contains the following information:

• Valid bits saying if the entry contains valid data or is free. Both caches have a single valid bit for each cache line.

• The tag, all bits of the cached memory address that are not implied by the set

When a read from cache is performed, the tags and data for all cache ways of the corresponding set are read out in parallel, the tags and valid bits are compared to the desired address and the matching way is selected. In the hit case, this is all done in the same cycle to support the full execution rate of the processor.

In the miss case, the cache will at first deliver incorrect data. However on the following cycle, a hold signal will be asserted to stall the pipeline and preventing it from proceeding with that data. After the miss has been processed, the correct data is injected into the pipeline using a memory data strobe (mds) signal, and afterwards the hold signal can be released. If the missed address is cacheable, then the data read in from the cache miss will be stored into the cache, possibly replacing one of the existing ways.

The instruction cache implements a buffer forwarding scheme to reduce instruction cache miss latency. While the cache line is being read in from the AHB bus and stored into the cache memories, the data is stored temporarily in a flip flop buffer inside the cache controller. The cache can serve instructions to the pipeline directly out of this partially filled buffer, this works even in case of branches as long as the instruction flow stays on the same cache line.

97.3.4 Cache configuration

The cache controller supports different size configurations, selected by the *perfcfg* generic.

*Table 1937.*Supported cache configurations

perfcfg value	I-cache size (ways x waysize)	I-cache line size	D-cache size (ways x waysize)	D-cache line size	ITLB entries	DTLB entries
0	4 x 4 KiB	32 bytes	4 x 4 KiB	32 bytes	24	24
1	4 x 4 KiB	32 bytes	4 x 4 KiB	32 bytes	16	16
2	1 x 4 KiB	32 bytes	1 x 4 KiB	32 bytes	4	4

GRIP
Apr 2024, Version 2024.1

1632

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The cache controller implements a 32 byte cache line length.

Least-recently-used (LRU) replacement policy is used for the caches. This maintains the order of usage for each set in the cache and replaces the one which has was used last. The LRU information needs to be updated on every cache hit and is therefore not stored with the tags but in separate flip flops.

97.3.5 Address mapping

The addresses seen by the CPU are divided into tag, index and offset bits. The index is used to select the set in the cache, therefore only a limited number of cache lines with the same index part can be stored at one time in the cache. The tag is stored in the cache and compared upon read.

1 KiB way, 32 bytes/line

31	10	9	5	4	0
Tag		Index		Offset	

4 KiB way, 16bytes/line

31	12	11	4	3	0
Tag		Index		Offset	
Figure 260. Cache address mapping examples

97.3.6 Data cache policy

The data cache employs a write-through policy, meaning that every store made on the CPU will propagate, via the write buffer, to the bus and there are no "dirty" lines in the cache that has not yet been written out apart from what is in the buffer. The store will also update the cache if the address is present, however a new line will not be allocated in that case.

*Table 1938.*LEON5 Data caching behavior

Operation	In cache	Cacheable	Bus action	Cache action	Load data
Data load	No	No	Read	No change	Bus
	No	Yes	Read	Line allocated/replaced	Bus
	Yes	-	None	No change	Cache
Data load with forced cache miss (ASI 1)	No	No	Read	No change	Bus
	No	Yes	Read	Line allocated/replaced	Bus
	Yes	-	Read	Data updated	Bus
Data load with MMU bypass (ASI 0x1C)	-	-	Read (phys addr)	No change	Bus
Data store	No	No	Write (via buffer)	No change	(N/A)
	No	Yes	Write (via buffer)	No change	(N/A)
	Yes	-	Write (via buffer)	Data updated	(N/A)
Data store with MMU bypass (ASI 0x1C)	-	-	Write (via buffer, phys addr)	No change [1]	(N/A)

[1] If snooping is enabled, the snooping logic will see the write on the AHB bus and invalidate any data cache lines to the same address.

97.3.7 Write buffer

The data cache contains a write buffer able to hold up to four 8,16,32, or 64-bit writes. For half-word or byte stores, the stored data replicated into proper byte alignment for writing to a word-addressed device.

The write is processed in the background so the system can keep executing while the write is being processed. The write buffer acts as a FIFO where new stores can be added continuously to allow one store per cycle throughput. Only "regular" stores that hit in the TLB are handled through the write buffer, other types of writes (for example special register access via ASI) will be handled separately.

While a store is ongoing, any following instruction or data access that requires bus access will block until the write buffer has been emptied. Loads served from cache will however not block, due to the cache policy used there can not be a mismatch between cache data and store buffer (the effect of this behavior on SMP systems is discussed in section 97.3.16).

Since the processor executes in parallel with the write buffer, a write error will not cause an exception to the store instruction immediately but may deliver an exception at a later point in time when the error is detected. How write errors are handled is discussed in more detail in section 97.3.21.

97.3.8 Operating with MMU

The MMU functionality is integrated into the cache controller. When MMU is enabled, the virtual addresses seen by the running code no longer correspond directly to the physical addresses on the AHB bus. The cache will translate each accesses virtual addresses to its physical addresses in parallel with looking up the tag for that access.

The cache uses a virtually-indexed-physically-tagged (VIPT) approach, where the tags are based on the physical addresses but the address into the cache memory is based on the virtual address. Every virtual address is translated on the fly to physical address prior to the tag comparison. If a virtual address is not present in the translation lookaside buffer, the cache will stall the pipeline to translate the addres, and then re-do the tag comparison once the physical address is known

97.3.9 Snooping

The data cache includes support for AHB bus snooping. The AHB bus the processor is connected to, is monitored for writes from other masters to an address which is in the cache. If a write is done to a cached address, that cache line is marked invalid and the processor will be forced to fetch the (new) data from memory the next time it is read.

The snooping logic needs to be able to access the data cache tags whenever a store happens which might be at the same time as a normal loads or store needs to access the tags. This is accomplished either by adding an extra snoop tag memory or by making the data cache tag memory dual ported. The snoop logic also needs to be able to clear valid bits on a snoop hit which is handled either by having a two-ported memory for the regular data cache tags or by putting the valid bits into flip flops. The subsystem allows for some different implementations via the cmemconf generic.

The processor normally avoids snooping on its own writes (as otherwise every store would lead to invalidating its own cache line) but does in some cases snoop on itself in order to detect MMU updating page table entries. Writes done by storing to the MMU/cache bypass ASI are also snooped.

Snooping requires the way size of the data cache to be equal or smaller than the MMU page size, otherwise the index into the physical and virtual tag RAM:s may not match, resulting in aliasing problems. All the standard configurations of the LEON5 subsystems satisfy this requirement.

97.3.10 Cache freeze

Each cache can be in one of three modes: disabled, enabled and frozen. If disabled, no cache operation is performed and load and store requests are passed directly to the memory controller. If enabled, the

GRIP
Apr 2024, Version 2024.1
1634
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

cache operates as described above. In the frozen state, the cache is accessed and kept in sync with the main memory as if it was enabled, but no new lines are allocated on read misses.

If the DF or IF bit is set, the corresponding cache will be frozen when an asynchronous interrupt is taken. This can be beneficial in real-time system to allow a more accurate calculation of worst-case execution time for a code segment. The execution of the interrupt handler will not evict any cache lines and when control is returned to the interrupted task, the cache state is identical to what it was before the interrupt. If a cache has been frozen by an interrupt, it can only be enabled again by enabling it in the CCR. This is typically done at the end of the interrupt handler before control is returned to the interrupted task.

97.3.11 Flushing

Both instruction and data cache are flushed either by executing the FLUSH instruction, setting the FI/FD bits in the cache control register, or by writing to certain ASI address spaces.

Cache flushing takes one clock cycle per cache set, during which the IU will be halted. When the flush operation is completed, the cache will resume the state (disabled, enabled or frozen) indicated in the cache control register.

Note that while the SPARC V8 specifies only that the instructions pointed to by the FLUSH argument will be flushed, the LEON5 has a special case for LEON3/LEON4 compatibility, where it will flush the entire I and D cache if the address given is zero (which is permitted by the manual as the additional flushing only affects performance and not operation).

97.3.12 Region flush

The cache controller supports a region flush function where the cache tags are scanned and cache lines matching a specified physical address and mask are invalidated. Note that depending on how the address mask is set, the flushed will require scanning a different amount of cache tags and it will take different amounts of time to complete the flush. The region flush function will block the pipeline until the flush has been completed.

97.3.13 Write combining

The cache controller has an optional write combining feature, to automatically merge 64-bit stores to adjacent addresses into larger bursts, up to a full cache line's worth of data.

The write combining can improve performance in some cases. A system-level example of such a case is when writing out a large buffer to memory through a level-2 cache that does not have individual dirty/valid tracking bits for every 64-bit word. With individual stores, the first 64-bit store of each cache line would lead to an unnecessary fetching in from memory of the remaining cache line data that will immediately just be overwritten by the following stores. When combined into a burst, the cache can see that the entire cache line is written and simply allocate the line, write in the data, and mark the entire cache line as dirty.

The feature can however come with some performance cost in other cases. Since the cache controller can not know if a double store will be followed by another store in the executing program, the store needs to be held by the cache controller for a few cycles to see if another store to the following address is coming after it. This added store latency can result in reduced overall performance.

The write combining can be set into an automatic hold-off mode where double stores are automatically held for a few cycles to see if another store comes in. It can also be set into a manual mode where the write combining is off in the normal case but a write combining hint will activate the write combining for the following store coming in.

GRIP
Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

97.3.14 Memory barrier

In virtually all normal situations, explicit barriers are not needed on SPARC as the processor follows the total store order model and load-to-load, store-to-store and load-to-store ordering is implicitly guaranteed for all operations.

An explicit barrier instruction is provided for any special cases where store-to-load ordering is required or where lookaside reads must be avoided. The barrier is created using the STBAR instruction defined in SPARC V8, but setting certain otherwise unused bits. This is aligned with how a the corresponding memory barrier MEMBAR is defined in SPARC V9.

Table 1939. LEON5 memory barrier operation

31 30	29 25	24 19	18 14	13	12 9	8	7	6	5	4	3 2	1	0
op=10	rd=00000	op3=101000	01111	0	unused	WCH	un-used	Sync	MIs	LA	unused	SL	unused

8	Write combining hint for following store
7	Reserved
6	'Synchronization barrier
5	Memory issue barrier
4	Lookaside barrier
3 : 2	Ignored (used for StoreStore and LoadStore in V9)
1	StoreLoad barrier
0	Ignored (used for LoadLoad barrier in V9)

The barrier operations are in practice implemented the same on LEON, as they will cause the processor to stall the pipeline until current stores in the store buffer have completed and passed through the snoop pipeline. In the future, the StoreLoad barrier may be optimized further as that does not need to block in all cases.

The STBAR instruction is also used to encode a write combining hint, using a normally unused bit 8. The write combining feature is explained further in section 97.3.13.

97.3.15 Diagnostic access

The cache tag and data contents can be directly accessed for diagnostics via various ASI:s, see section 97.11.2 for ASI assignments.

When accessing the diagnostic ASIs, the address should be formed in the same way as a regular virtual address as shown in figure 260. The part of the address that would normally be used to index the cache is used as the index. The lowest two bits of the tag part are used to select which way to access. The remaining parts of the tag are ignored and recommended to clear for forward compatibilty. The offset part of the address is used as offset for data accesses, but ignored for tag accesses. For a 4 KiB way cache with 32 byte cache lines, that means address bits 11:5 are used as the index and address bits 13:12 are used to select the cache way.

The data read and written also follows the address format in figure 260, except that in this case it is the tag part of the address that has the actual contents of the cache and the index part is ignored. When reading/writing tags, the valid bit is put on bit zero of the data. For software compatibility with earlier LEON models, the valid bit is replicated across all data bits 7:0. In configurations where the valid bit is implemented in flip flops, the valid bits are still written via the diagnostic ASI for data cache tags which makes the difference transparent to software.

Diagnostic access to the snoop tags, as well as writes into the regular data cache tags, are made in a way that allows to do these accesses when there are potential snoop traffic ongoing on the AHB bus in parallel. If the diagnostic access is made on the same cycle as a snoop lookup (corresponding to the address phase of a write access being observed on the AHB bus), the diagnostic access is stalled until the following cycle. In order to avoid a (very unlikely) livelock situation where the diagnostic access stalls forever due to back-to-back stores from the other masters, the cache controller implements a

GRIP
Apr 2024, Version 2024.1

1636

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

timeout. If the diagnostic access is stalled for more than 32 cycles, the cache controller raises the bus request signal on the processor bus to produce an idle cycle on the bus, leading to . This functionality is transparent to software.

97.3.16 AMBA interface

The LEON5 cache controller has one AHB master interface to the surrounding system. The types of AMBA accesses supported and performed by the processor depend on the accessed memory area's cachability, the maximum bus width, if the corresponding cache is enabled, and if the accessed memory area has been marked as supporting wide bus accesses.

Cacheable instructions are fetched with a burst of 32-bit accesses, or 64- or 128-bit accesses depending on the cache line size and the AHB access size supported by the accessed slave.

The HPROT signals of the AHB bus are driven to indicate if the accesses is instruction or data, and if it is a user or supervisor access.

*Table 1940.*HPROT values

Type of access	User/Super	HPROT
Instruction	User	1100
Instruction	Super	1110
Data	User	1101
Data	Super	1111
MMU	Any	1101

In case of atomic accesses, a locked access will be made on the AMBA bus to guarantee atomicity as seen from other masters on the bus.

97.3.17 Cachability

Cachability for both caches can be controlled through the AHB plug&play address information or set manually via the *cached* VHDL generic.

For plug'n'play based cachability, the memory mapping for each AHB slave indicates whether the area is cachable, and this information is used to (statically) determine which access will be treated as cacheable. This approach means that the cachability mapping is always coherent with the current AHB configuration.

When the *cached* VHDL generic is not zero, it is treated as a 16-bit field, defining the cachability of each 256 MiB address block on the AMBA bus. For example, a value of 16#00F3# will define cachable areas in 0 - 0x20000000 and 0x40000000 - 0x80000000.

In order to access the plug'n'play information, the processor takes the ahbso vector as input. Only the static hconfig signals are used so the use of this input will be eliminated through constant propagation during synthesis.

Note that when the MMU is enabled, cacheablility is configured explicitly by the user via the page tables (C bit of the Page Table Entry) which will override the mechanisms described in this section. It is on the user to ensure that accesses that need to be as uncached single accesses (such as configuration registers) are done through an address mapping set as uncached.

97.3.18 Wide bus support

The cache controller's AHB master can be configured to support wide (64 or 128-bit) AHB bus accesses in accordance with the wide-bus support built into GRLIB (see GRLIB User's Manual). The wide bus support has been designed to allow backward compatibility where existing non-wide capable (32-bit) cores can coexist on the same AHB bus. The wide-bus operation is optional and the cache

GRIP

Apr 2024, Version 2024.1

1637

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

controller can also be configured for only 8/16/32-bit AHB access for compatibility with existing LEON3 systems.

Because wide bus capability is not managed automatically via the AMBA plug'n'play infrastructure, information on wide bus capability has to be provided manually into the processor system through two generics, busw and wbmask. These must be correctly configured by the system designer in order to avoid illegal AMBA access combinations.

The area which supports wide access is indicated in the *wbmask* VHDL generic. This VHDL generic is treated as a 16-bit field, defining the 64/128-bit capability of each 256 MiB address block on the AMBA bus. A value of 16#00F3# will thus define areas in 0 - 0x20000000 and 0x40000000 - 0x80000000 to be 64/128-bit capable. The maximum access size to be used in the area(s) marked with *wbmask* is determined by the *busw* VHDL generic.

In a system with only 32-bit wide masters and slaves, the *busw* should be set to 32. All AHB accesses will then be performed using 32-bit bursts or 8/16/32-bit single accesses. The *wbmask* option is ignored in this configuration

97.3.19 AMBA access types

Cacheable data is fetched in a burst of 32-bit, 64-bit, or 128-bit accesses, depending on the cache line size, AHB bus width, and whether the access is to a narrow or wide area (see section 97.3.18).

Uncacheable data is fetched using a single access with the same size as the AHB bus for a wide area, or 32-bit width in case of access to a narrow area. A 64-bit uncached load from a 32-bit AHB bus or a narrow area will be performed using two single 32-bit reads.

Store data is performed using the same access size as the store whenever possible. In the case of a 64-bit store on a 32-bit AHB bus or to a narrow area, the store will be performed using a two-beat burst.

Instruction fetches are performed in the same way as cacheable data. Instructions are always fetched in full cache lines regardless of whether instruction cache is enabled or not.

97.3.20 Read error handling

An AHB ERROR response received while fetching instructions will cause the cache controller to assert an internal error signal into the pipeline when delivering the remaining instructions on that cache line, and the valid bit written into the cache tag will be set to zero to force a re-fetch on the next access. The internal error signal will cause an instruction access exception trap (tt=0x1) when the delivered instructions reach the exception stage. However because there are cases where the instructions fetched do not get executed in the processor pipeline (due to traps, branches etc), there is no guarantee that a trap will always occur. If the IU later needs to execute the instruction, as it will be fetched again, a cache miss will occur, triggering a new access to the failed address. Instruction access exception traps that are "lost" in this way are however logged in a status bit in the trap register and the AHB error is still captured by the general AHB error logging of the cache controller.

An AHB ERROR response while fetching data into the data cache will signal an error to the pipeline that triggers a data_access_exception trap (tt=0x9) on the load instruction.

An ERROR response during an MMU table walk will lead the MMU to set the fault type to Internal error (1) and generate an instruction or data access exception, depending on which type of access that caused the table walk.

97.3.21 Write error handling

Error responses on the AHB bus for writes will cause a data_store_error trap (tt=0x2b) to be delivered to the running application. Because stores are buffered in the cache controller, the store instruction that caused the write has already retired and the data_store_error trap is instead delivered to an instruction later on in the execution flow that may be unrelated to the failing store.

GRIP

Apr 2024, Version 2024.1

1638

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

If a store that causes an error response is issued in the application while traps are enabled but an interrupt or other unrelated trap happens before the data_store_error trap is delivered, this could lead to the data_store_error trap being delivered while ET=0 which puts the processor in error mode. The cache controller can be configured into a few different modes via the AHB error register (section 97.12.10) in order to configure how such cases should be handled:

- In direct mode, the data store error trap is always delivered immediately. and will trigger error mode if ET=0.

- In deferred mode, store errors for stores made while ET=1 are only delivered if ET=1 and there are no intervening traps. If any traps occur then the error is "lost". A specific register field in the cache trap register indicates if any such lost traps have occurred. Errors for stores made while ET=0 will still be delivered immediately and cause error mode.

- In interrupting mode, data_store_error traps are only delivered while ET=1 and can therefore never trigger error mode. Store errors occurring while ET=0 will be left pending in the cache controller, and gets delivered first when traps are enabled.

- In disabled mode, the store error never leads to any trap being delivered.

For backward compatibility with earlier generations of LEON processor, the store error trap delivery can also be blocked (regardless of mode setting used above) using the DWT bit in ASR17.

A write error can also happen when the MMU writes back a page table entry in order to set the referenced or modified bit. These write errors are also delievered as data_store_error traps, in the same way as for stores, and the delivery can be configured in the same way as described above. A status bit exists in the trap register that allows the data_store_error trap handler to determine whether the error was caused by a store instruction or an MMU writeback. The MMU write-back case is very rarely triggered since the MMU already successfully read from the same address location.

97.3.22 Error logging

The cache controller monitors the processor bus if any AHB errors occur and logs them into the AHB error register. Both errors for accesses generated by other masters and by the cache controller itself are logged but an error from the processor itself will have priority and overwrite an earlier logged error from another master.

97.3.23 Read error masking

AHB errors can be masked from causing data_access_exception traps when loading data by setting the MDAE bit in the AHB error register. If this bit is set, execution will continue as if the error had not happened and the data_access_exception trap will not be generated. AHB errors during instruction fetch and MMU accesses will still generate traps as usual. Errors will still be logged into the AHB error register, and this can be checked after with errors ignored to see if any error occurred.

When the ignore errors mode is enabled, the cache controller can be configured to either pass on the contents of the read data bus at the time of the error, or replace the data with all-ones or all-zeros. If the memory read is cacheable, the replaced data from the error will also be written into cache, so a cache flush may be needed if this is a concern on system level.

There is a similar AHB error masking capability for instructions, enabled using the MIAE bit in the AHB error register. The part of the cache line that could not be fetched due to error will be replaced by an all-zero value, representing an UNIMP instruction, and if execution reaches that instruction it will trigger an unimplemented_instruction trap. However if execution never reaches that instruction, the error will not impact execution and it allows the other part of the cache line can be cached.

97.3.24 Internal error trap

The cache controller can signal certain internal errors to the pipeline using an implementation-defined trap (tt=0x60). The reason for the trap is encoded in the trap register. This trap would be an indication

GRIP

Apr 2024, Version 2024.1

1639

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

of corrupted state inside the cache memories and normally could be considered a fatal error as incorrect instructions/data may have been delivered to the application at that point.

97.3.25 Tightly coupled memory

The cache controller provides an option to add tightly coupled memory (TCM) to the instruction and/or data cache. The TCM is a local memory that can be accessed with the same speed as cached data, but is not backed by external memory. The instruction TCM can only hold code to execute and can not be accessed using regular load/store instructions, while the data TCM on the other hand can only hold data to access using load/store instructions and can not be executed from.

The address of the TCM can be configured at run-time through a configuration register. The TCM can also be disabled so that it is not visible at any memory address, however the contents can always be accessed through dedicated ASIs.

When using MMU, the TCM is mapped directly to a specific virtual address and will appear on the same address regardless of page table contents. The TCM can be set to be visible only in a single MMU context, or in all MMU contexts.

The TCM size can be any power of 2, and the size determines how many bits get implemented in the registers for configuring the TCM's location. For finer control of implementation memory usage, the TCM can be built with its memory space only partially filled (between 9/16 and 15/16 of the size, in steps of 1/16). In partially filled configuration, the unused part of the TCM memory space will return undefined data on read and ignore any writes. The size and presence of TCM can be probed through the LEON5's configuration registers.

The TCM memory contents are not automatically cleared on reset, but can be cleared by setting the wipe TCM bits in the TCM configuration register. The wipe function is non-blocking so execution will continue immediately in parallel with the wipe, however the TCM memory will be inaccessible until the wipe has completed. To see when the wipe has completed, the wipe TCM bits can be polled to see when they have returned to zero. Before a TCM wipe can be started, all previously started TCM wipes will need to have competed. The wipe will initialize the data TCM to zero and the instruction TCM to all-ones (UNIMP instruction opcode).

The TCM is configurable with permission bits to separately allow or deny supervisor read, supervisor write, user read, and user write for data TCM, and supervisor execute and user execute for instruction TCM.

97.4   Memory management unit

97.4.1   Overview

The memory management unit is integrated into the cache controller. This is compatible with the SPARC V8 reference MMU (SRMMU) architecture described in the SPARC V8 manual, appendix H.

The MMU provides address translation of both instructions and data via page tables stored in memory. When needed, the MMU will automatically access the page tables to calculate the correct physical address. The latest translations are stored in a special cache called the translation lookaside buffer (TLB), also referred to as Page Descriptor Cache (PDC) in the SRMMU specification. The MMU also provides access control, making it possible to "sandbox" unpriviledged code from accessing the rest of the system.

97.4.2   MMU/Cache operation

When the MMU is disabled, the MMU is bypassed and the caches operate with physical address mapping. When the MMU is enabled, the cache tags store the physical address and each access from the pipeline is translated from virtual to physical in parallel with the tag memory read-out.

GRIP
Apr 2024, Version 2024.1
1640
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

No additional clock cycles are needed for the MMU for instruction fetch, data fetch, or stores, as long as the virtual pages accessed are already cached inside the TLB. If there is a TLB miss the page table must be traversed, resulting in up to four AMBA read accesses and one possible writeback operation. See the SRMMU specification for the exact format of the page table.

An MMU page fault will generate trap 0x09 for the D-cache and trap 0x01 for the I cache, and update the MMU status registers according to table 1941 and the SRMMU specification. In case of multiple errors, they fault type values are prioritized as the SRMMU specification requires. The cache and memory will not be modified on an MMU page fault.

*Table 1941.*LEON5 MMU Fault Status Register, fault type values

Fault type	SPARC V8 ref	Priority	Condition
6	Internal error	1	Never issued by LEON SRMMU
4	Translation error	2	AHB error response while performing table walk. Translations errors as defined in SPARC V8 manual. A translation error caused by an AMBA ERROR response will overwrite all other errors. Other translation errors do no overwrite existing translation errors when FAV = 1.
1	Invalid address error	3	Page table entry for address was marked invalid
3	Privilege violation error	4	Access denied based on page table and su status (see SRMMU spec for how privilege and protection error are prioritized)
2	Protection error	5	
0	None	-	No error (inside trap this means the trap occurred when fetching the actual data)

97.4.3 Translation look-aside buffer (TLB)

Separate TLBs are implemented for instruction and data, the number of entries depending on configuration as listed in table 1937.

The TLBs are replaced using a pseudo-LRU algorithm. Each TLB entry has a single 'visited' bit that is set when that TLB entry is accessed, when all visited bits are set to 1 then they are all cleared and the process starts over. When replacing an entry in the TLB, the lowest entry with the visited bit not set will be chosen.

97.4.4 MMU flush and probe

A flush and probe interface is provided for the MMU mapped to ASI 0x1B.

A 32-bit read from the ASI triggers a probe that works as described in section H-3 of the SPARC V8 specification. If the type of the probe is "entire" (type 4), the ITLB and DTLB are checked for a match before falling back to page table walk, the other types always lead to table walk and do not check the TLB:s. The probe does not cause an update to the TLB contents.

A 32-bit write to the ASI triggers a flush function that works as described in section H-3 of the SPARC V8 specification. The flush done is precise as defined in the specification.

31:12	Physical address of mapping. Depending on mapping size, the lower bits of the address should be zero.
11:6	Reserved for future use
5 :3	Access settings, copy of ACC field of PTE
2	Set to 1 if the physical address is on a wide AHB capable address range.
1	Cacheability setting, 1 if accesses are cacheable
0	Cached state of modified bit of PTE

97.5 Floating-point unit

The SPARC V8 architecture defines two (optional) co-processors: one floating-point unit (FPU) and one user-defined co-processor. Two different FPU's can be interfaced the LEON5 pipeline: Frontgrade Gaisler's GRFPU5 and NanoFPU. The characteristics of the FPU's are described in the next sections.

97.5.1 Frontgrade Gaisler's floating-point unit (GRFPU5)

The high-performance GRFPU5 operates on single- and double-precision operands, and implements all SPARC V8 FPU operations including square root and division. The FPU is interfaced to the LEON5 pipeline using a LEON5-specific FPU controller (GRFPC5) that allows FPU instructions to be executed simultaneously with integer instructions. Only in case of a data or resource dependency is the integer pipeline held. The GRFPU5 is fully pipelined and allows the start of one instruction each clock cycle, with the exception is FDIV and FSQRT which can only be executed one at a time. The FDIV and FSQRT are however executed in a separate divide unit and do not block the FPU from performing all other operations in parallel.

All instructions except FDIV and FSQRT has a latency of four cycles, but to improve timing, the LEON5 FPU controller inserts an extra pipeline stage in the result forwarding path. This results in a

GRIP
Apr 2024, Version 2024.1

1642

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

latency of five clock cycles at instruction level. The table below shows the GRFPU instruction timing when used together with GRFPC:

*Table 1944.*GRFPU5 instruction timing with GRFPC5

Instruction	Throughput	Latency
FADDS, FADDD, FSUBS, FSUBD,FMULS, FMULD, FSMULD, FITOS, FITOD, FSTOI, FDTOI, FSTOD, FDTOS, FCMPS, FCMPD, FCMPES. FCMPED	1	5
FCMPS, FCMPD, FCMPES, FCMPED	1	3
FDIVS	16	17
FDIVD	16.5 (15/18)	17.5 (16/19)
FSQRTS	24	25
FSQRTD	24.5 (23/26)	25.5 (24/27)

The GRFPC5 controller implements the SPARC deferred trap model, and the FPU trap queue (FQ) can contain up to 8 queued instructions when an FPU exception is taken. When the GRFPU5 is enabled in the model, the version field in %fsr has the value of 4.

The GRFPU5 can handle the full IEEE-754 standard including denormalized numbers as inputs and outputs. Denormalized inputs will make the operation take one extra cycle for MUL, DIV, and SQRT, but has zero penalty for other operations. Denormalized outputs have zero penalty compared to normal outputs.

The GRFPU5 can also be configured to trigger an fp_exception with the FPU trap type set to unfinised_FPOP (tt=2) when there is an input or output with a denormalized number. It can also be programmed to flush denormalized numbers to 0.

97.5.2 NanoFPU

The NanoFPU is a tiny combined FPC and FPU implementation using less than 1500 register bits (including 512 bits for the register file) and a single 16x16 multiplier that can be mapped into a DSP block on most FPGAs.

The NanoFPU performs one operation at a time in a sequential fashion. The operation is performed in parallel with the integer pipeline but any following FPU operation or FPU load/store will stall the pipeline until the operation has completed.

Traps are delivered using the deferred trap model, but with the deferred floating-point queue containing only a single operation.

When the NanoFPU is enabled in the model, the version field in %fsr has the value of 5.

97.5.3 Floating-point state access

The LEON5 provides an interface that allows the CPU or debugger to read/write the state of the floating-point controller. It is accessed through ASI 0x20.

Floating point registers can be read and written through the ASI interface, which saves having to go through memory. The ASI interface supports 64-bit loads and stores from the processor using LDDA/STDA instructions.

The current exception pending state including deferred floating point queue contents can be read out, and to restore this state at a later stage.

97.5.4 Co-processor interface

No implementation for the user-defined co-processor is currently provided.

97.6 Fault tolerance features

97.6.1 Overview

Note that the features described in this section are only available in FT and FT-FPGA releases of GRLIB.

The LEON5 processor can be built with functionality to handle bit errors occuring in the SRAM memories included in the processor. The intent with this functionality is to handle random single-event upsets in the memories. Errors encountered are corrected automatically without any visible side effects to software except for a small delay. A scrubber function is included to prevent error build-up.

Two different modes of memory protection are supported, one intended for FPGA usage and one for ASIC and generic usage. The FPGA native ECC uses error detection and correction functionality already built into the FPGA memory blocks, while the generic version intended for ASIC implements error detection and correction codes entirely in RTL. The generic version is also usable for FPGAs lacking built-in ECC and for FPGA prototyping of ASIC designs.

97.6.2 Cache memory protection

The instruction cache tags, instruction cache data, data cache tags, data cache data, and tightly coupled memories (if enabled) can be protected with error correcting codes using either an RTL EDAC or using FPGA native error correction.

When the RTL/ASIC ECC is enabled, an error correcting code is used to protect the memories that has been designed for low impact on maximum frequency and capability to detect many types of multi-bit upset (the code is described further in section 97.6.8). The error detection part of the ECC decoding is performed in parallel with the cache tag/data lookup in order to allow execution to proceed without any performance overhead in the error-free case.

Detected errors during cache operation (tag/data lookups) are handled in the controller by entering a "correction cycle" where the location with the error is read out, corrected and written back while the processor pipeline is held. After the correction cycle, the requested cache lookup is performed again, and depending on cache hit/miss result, either execution continues or the cache miss is processed as usual. From the point of view of the processor pipeline, the cache controller behavior during the correction cycle is exactly the same as for a normal cache miss, but as the correction cycle is done internally in the tag memories there is no access to the processor bus.

The default behavior on multi-bit errors that are not correctable by the ECC, is to invalidate the cache line with the tag and re-fetch the data from memory. In the event of a multi-bit error in a cache tag, all tags belonging to the same set in the cache are invalidated. Note that because the cache is write-through, the latest contents of any memory location is always available in external memory. With this approach, errors in the cache that are uncorrectable from a local ECC point of view are correctable on system level. This approach is similar to how earlier generation of LEON processors (that only had error detection capability) handle errors in the cache.

The processor can be configured to other behaviors in the event of detecting multi-bit errors. It can be set to flush the entire cache where the error was detected. It can also be set to generate an internal error trap.

For the AHB bus snooping functionality, when ECC is enabled, then the snoop tags are checked for errors and corrected on the fly before they are compared with the address of the AHB store. An extra pipeline stage is added to the snoop pipeline to allow for this error correction without impacting maximum clock frequency. After a snoop tag correction, the corrected snoop tags are stored in a register to be written back into the snoop tag memory at the earliest point where the snoop pipeline is free. Uncorrectable errors in the snoop tag are handled by invalidating all ways of the corresponding cache set. The behavior of the snoop tag error correction is not affected by the configuration registers and errors in the snoop tags do not trigger traps.

GRIP
Apr 2024, Version 2024.1

1644

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The FPGA native ECC mode by default operates the same way as described above, with correction cycles when an error is detected. Because the FPGA built-in ECC produces the corrected data immediately on the same cycle as the memory is read, an additional error handling option is available where correction cycles are not performed but the data is simply taken on the fly and the error is left to be corrected later by the scrubber.

97.6.3 Tightly coupled memory protection

The tightly coupled memory is protected in the same way as described for the cache memory.

Unlike cache memory, the tightly coupled memory does not have a copy of its contents in external memory and errors that are not correctable by the ECC are therefore not possible to mitigate automatically. When uncorrectable errors occur in the instruction TCM, the cache controller replaces the contents with UNIMP instructions which will trigger a trap if the instructions are executed. For uncorrectable errors in the data TCM, the processor can be configured to either deliver all-0 or all-1 data, or to trigger an internal error trap.

97.6.4 Integer register file protection

When the integer register file used for the general purpose registers (globals and register windows) is implemented with SRAM memories, the processor provides options for ECC protection. As in the cache case, there is an RTL variant and a native FPGA variant.

Any errors in the register file that are detected during operation are corrected and written back with an automatic pipeline restart of the instruction that needed the register. This processing is transparent to software.

The RTL/ASIC ECC protection adds parity on the registers which allows bit errors to be detected. Because the register file is made up of four two-port memories holding the same data (in order to provide the four read ports), correction can be performed by getting the register contents from another port that is backed by a different memory. In order to get the correct data, the processor pipeline performs a correction where the register that had the detected error is read from all memories and the first copy found without a parity error is taken as the correct value and written into all memories. In parallel with this correction, the instruction where the error occurred is restarted in the pipeline and gets re-executed. In the unlikely case that all the five copies of the register have a parity error, the instruction will trap with r_register_access_error trap (tt=0x20).

When using FPGA native error correction, correctable errors can be configured to either be corrected with a restart as for the RTL correction, or for the corrected values to be taken on the fly without a pipeline restart. Uncorrectable errors are handled using a pipeline restart and fetch from a redundant copy in the same way as a parity error is handled in the RTL-based case.

When using the flip flop register file, protection options are not available on the IP core level (the flip flops are assumed to be hardened or protection applied through other means). The same applies for the floating-point register file is always in flip flops in LEON5.

97.6.5 Hardware scrubber

When the processor has been configured with some form of error correction (either cache memory, TCM or integer register file protection), a hardware scrubber function is also included. The scrubber can be enabled or disabled and the scrub rate is configurable through a configuration register. The intention of the scrubber is to prevent build-up of errors in parts of the cache or register file that are not accessed or replaced regularly.

Each iteration of the scrubber, one location of every tag and data memory in parallel, as well as one register of the integer register file, are read to check for errors and written back in the event of a detected error. The processor pipeline is stalled during the scrubber iteration.

Under normal conditions, a scrub cycle stalls the processor for 7 cycles. The time required may be extended slightly if there is snoop activity on the AHB bus since the access to the snoop tag RAM has

GRIP
Apr 2024, Version 2024.1

1645

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

to be arbitrated. This is handled in a way similar to diagnostic accesses to the snoop tags as described in section 97.3.15.

For a cache with 4 ways, 4 KiB/way and 32 bytes cache line, it will take 128 scrubber iterations to loop through the tag memories and 512 iterations to loop through the data memories. The time it takes to loop through the TCM depends on selected size, as 64 bits of data can be scrubbed per iteration. In a standard 8-register window configuration, it takes 256 scrubber iterations to loop through all integer registers.

The interval to set for the scrubber should be determined based on the necessary scrub rate needed to avoid error buildup, which would come from a system level analysis. If, as an example, a 100 Hz scrub rate is required for all the memories inside the processor and the processor is running at 500 MHz, the scrub period would have to be set to (10000 / 512) * 500 = 9765 cycles.

Setting very low scrubber periods (below the order 50 cycles) is not recommended as it will slow down execution significantly, and very low periods can make the execution to almost appear stalled.

Error in cache memories and tightly coupled memories that are not correctable by the ECC are handled in the same way as when they are discovered functionally as described in sections 97.6.2 and 97.6.3. Uncorrectable errors in the register file (parity or uncorrectable error in all copies) are handled by leaving the error in the register file to be discovered later by a functional access.

97.6.6 Error counting and reporting

The processor contains two bit wide error counters for correctable errors and one bit wide counters for uncorrectable errors. The counters are saturating in order to avoid accidentally wrapping around to zero. The counters are not reset in order to allow for post-mortem analysis following a crash and a reset. They will therefore contain random values on power up and need to be read out and cleared manually by software before they are used.

In order to not account twice for correctable errors that are found during execution and corrected with a correction cycle, the correctable error counter is only incremented when the the error is first encountered and the correction cycle is entered and is then not incremented again in the correction cycle when the value is re-read and corrected.

In addition to the error counters, there is also a counter for the number of times a correction cycle has been triggered. This can be checked to determine if a correctable error was found by the scrubber (not triggering a correction cycle) or found functionally (when loading/fetching instructions).

97.6.7 Error injection

The cache controller supports error injection into the cache tag and data memories, and the TCM data memories. The error injection interface has been designed to allow for easily injecting errors from software running on the processor.

The error injection is performed in two steps. First the error injection is "armed" by configuring the error injection register. Secondly, the error injection is performed by performing a diagnostic ASI read from the memory and location where the error should be injected. The cache controller will during the ASI read perform the normal diagnostic read, but in addition perform a write-back of the value with the selected error injected. By performing the injection with one ASI read access, the error injection is "atomic" from point of view of the cache state, and there is no risk of for example a cache line getting replaced between reading and writing back the value.

The diagnostic read used to inject the error will first correct any existing correctable errors. Therefore errors will not accumulate when injecting errors multiple times into the same location.

For the native FPGA ECC implementation, not all FPGA technologies have support for error injection. There is a read-only field in the error injection register indicatin whether error injection is supported for the current configuration.

97.6.8 Error correcting code description

The cache controller uses an error correcting code that has been designed for low error detection overhead in the cache lookup path, correction of single bit errors, and detection of all wide (up to 4 adjacent bits) errors caused by multiple bit upsets. The code can be viewed as a concatenation of a parity check and a BCH-like code.

The code adds 8 check bits to a data word that is typically 32 bits but can be up to 44 data bits.

Conceptually the code is built up as follows (this example assuming 32 bit wide data):

Step 1: The data is split into four 8-bit parts ("slices") with each slice having one bit of each nibble (i.e data bits 31,27,...,7,3 in one slice, data bits 30,26,...,6,2 in one slice, data bits 29,25,...,5,1 in one slice, and data bits 28,24,...,4,0 in one slice).

Step 2: For each slice, four checkbits are formed by taking different XOR combinations of the 8 data bits of the slice, similar to a BCH encoder. Each data bit gets included in a unique combination of two or more checkbits.

Step 3: The 4x4 checkbits for the separate parts are combined by bitwise XOR into one set of 4 checkbits. This forms the lower four output checkbits of the encoding process.

Step 4: For the remaining four checkbits, the data bits and the lower four checkbits are viewed as one data word and again split into four parts with each part having one bit of each nibble. All the 9 bits of each part are now XOR:ed to create a parity bit of each part. The four generated parity bits are taken as the top four output checkbits of the encoding process

Since all computations made are based on exclusive-or gates, the steps above to create the different checkbits can be combined into a single XOR function of the data bits.

Decoding is done in two stages. First a parity check is made comparing the four top check bits read out to the XOR of the data bits together with the four lower check bits computed in the same way as in step 4 of the encoding process described above. The parity check generates an "error detected" signal for the cache controller to stop the current access and enter into a correction cycle.

For the error correction, a syndrome is created by generating the lower four checkbits using identical steps to the encoder steps 1-3 above and bitwise XOR:ing the resulting check bits with the check bits read out from the memory. With the result of the parity check indicating which part of the data word has the error, and the syndrome, a look up table can determine which bit caused the error should be corrected. Note that a syndrome with one bit set would be an indication of a bit error in the check bit itself. A parity check showing errors in more than one slice or a syndrome not matching any single-bit error would be an indication of an uncorrectable error at the decoder level. Note that as explained in section 97.6.2, uncorrectable errors in the cache memories can be recovered at higher level by the cache controller by re-reading from memory.

As is the case with any error correcting code, multi-bit error cases that are beyond what the ECC can handle will defeat the check and may result in incorrect data delivered either without any indication of error at all or incorrect data indicated as a correctable error.

A special case exists with this code, where some multi-bit error cases can defeat the initial parity check but are still detected by the syndrome check. These are called "late detected errors". As the data may have already have been delivered by the cache controller by the time the error is detected, it may be too late to recover from the error. In this case the cache controller can be configured generate an internal error trap to break execution. If the pipeline was held at the time this happens for any reason (for example due to an unrelated cache miss), this gives extra time to act on the error and the pipeline will handle the error in the same way as it would for a regular uncorrectable error. The scrubber will always have the extra time to catch a late detected error so such errors found by the scrubber will always be acted on as uncorrectable errors. Two separate one-bit counters exist for non-recovered and recovered late errors.

97.7 Block redundancy

97.7.1 Overview

Note that the features described in this section are only available in FT and FT-FPGA releases of GRLIB.

Note: Applying block-level TMR on the processor pipeline is still under development and not yet recommended for production designs.

The processor core can be built in a configuration where selected sub-blocks are instantiated multiple times (dual or triple redundant) with comparison logic and voters at the sub-block boundary. This can be used to implement dual core lock step or as an alternative to tool-inserted TMR for certain technologies.

For block redundancy, the processor core has been divided into the following five parts:

- Main processor logic, including processor pipeline, cache controller, MMU, and floating point controller (also including NanoFPU if used).

- Integer register file

- Cache memory, including ECC logic if FT is enabled. Note this cache memory normally expected to be protected with ECC rather than block redundancy, but included for completeness.

- GRFPU5, if GRFPU5 selected as floating point unit

- Floating point register file, if GRPFU5 seleceted as floating point unit

Each of these five parts can be individually configured as redundant via the redconf generic.

97.7.2 Error signaling

A brerr signal is added to the subsystem top level to indicate that a fatal error was detected on one of the processor cores. For dual-redundant blocks, any miscompare between the two copies would be considered an uncorrectable eror as it is impossible to determine which of the two copies have the correct output value. For triplicated blocks, an uncorrectable error would occur when two sub-blocks fail at exactly the same time, or a second sub-block copy failing before a prior error has been properly washed (as explained below).

It is up to the system designer to decide how to use this signal, but typical usage would be to reset the system. The system designer may also choose to ignore the signal, or possibly delay the reset for some time, as there is a chance of the processor still functioning correctly.

Internally, both uncorrectable and correctable errors are reported via the block-redundancy status register and can be configured to trigger a custom trap 0x61.

97.7.3 Block TMR error recovery

Since there are only voters on the block boundaries, block-redundant TMR configuration requires custom recovery procedures to ensure the state inside a failing block is re-synchronized the same state as the other two working copies.

For the GRFPU5, the recovery is implemented fully in hardware by applying a reset the FPU whenever there are no ongoing floating-point operations. As the GRFPU5 does not need to keep any state between operations there is no additional handling required. Therefore, the GRFPU5 in block-TMR configuration normally requires no special handling by software. Extremely floating point intensive applications may want to occasionally ensure no FPU operations are in progress for a few cycles, however in practice normal software housekeeping activities such as timer interrupt handling and task switching, etc, will achieve this as a side effect.

GRIP

Apr 2024, Version 2024.1

1648

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

For integer and floating point register files implemented with block TMR, error recovery is achieved by re-writing all registers. This could be done periodically, or only when an error is detected (via the trap 0x61 handler).

The processor pipeline in block-TMR configuration requires a more complex procedure to recover. The process consists of first dumping processor state to RAM, commanding the debug module to perform a "self-reboot" all three copies via the cpu-to-cpu interface ASI. Onced rebooted the cores then restoring back the state.

97.7.4 Fault domain merging

When the pipeline block and another sub-block have been configured with the same type of redundancy (dual or triple), the fault domains can be configured to be merged. When this is done, the voters and error checkers beween the blocks are removed and each string is connected 1:1 to a string of the other sub-block. This can save on resources and avoid crossing between the strings in the internal interfaces, but has the downside of errors not being detected until the pipelines miscompares and requiring a full pipeline recovery procedure.

Note that when the pipeline and register files have been merged into the same fault domain, washing register files is no longer possible simply by reading and writing back registers as voters will no longer crossed in the read-to-write path between the pipeline and register file. Instead the processor needs to make sure the data passes through the debug module's stash area, or through memory.

97.7.5 Combining block redundancy and ECC

Normally only one of either ECC or block redundancy is used for a specific block (cache or register file), but the two types of protection can be used at the same time. When the cache or register file with ECC enable is triplicated, the correctable error signals are combined with logical OR instead of majority voting in order to ensure correctable errors are accounted and handled rather than voted out.

97.8 Subsystem integration

97.8.1 AMBA bus fabric

The subsystem includes an AMBA 2.0 AHB and APB bus fabric, using the GRLIB AHBCTRL and APBCTRL IP cores. Ports are included to connect external AHB masters and AHB slaves to the processor bus, and to connect additional APB slaves to the APB peripheral bus. The system uses the AMBA Plug and play support and interrupt steering capabilities provided by GRLIB infrastructure (see GRLIB IP Library User's Manual).

In order to guarantee that software plug'n'play scanning routines find the built in peripherals before any cores (such as additional UARTs) connected externally to the subsystem, the leon5sys block per-

GRIP

forms a reordering of the AHB and APB slaves relative to how they appear externally to the subsystem.

*Table 1945.*Processor AHB bus masters

*Table 1946.*Processor AHB bus slaves

Slave index, internal/actual	Slave index, external view	
0	nextslv	APB bridge controller (APBCTRL)
1	0	External slave 0
...	...	...
nextslv	nextslv-1	External slave (nextslv-1)

*Table 1947.*APB bus slaves

Slave index, internal/actual	Slave index, external view	
0	nextapb	Console UART (APBUART)
1	nextapb+1	IRQ controller (IRQMP)
2	nextapb+2	Timer (GPTIMER)
3	0	External APB slave 0
...	...	...
(nextapb+2)	(nextapb-1)	External APB slave (nextapb-1)

97.8.2 Standard peripherals

The following standard peripherals are included in the subsystem block:

- IRQ controller (IRQMP), used to deliver interrupts to the processors
- General purpose timer (GPTIMER), used for time keeping
- Console UART (APBUART), used for standard console output

The peripherals are connected to the subsystem's APB bus.

97.8.3 Reset and start up

The processors are reset indirectly by the debug module, which is in turn reset by the external reset signal. The other parts of the subsystem are directly reset by the external reset signal.

The debug module ensures that the reset pulse is stretched to the number of cycles required by the pipeline and then starts up the first processor (unless the break signal is asserted).

While running, the debug module supports resetting and rebooting individual processors in a controlled way. This is commanded through the CPU to CPU interface

97.8.4 Alternative boot address function

An optional feature exists to have several alternative fixed boot addresses and alternate between them on each reboot of the processor. This may allow recovery from cases where the regular boot ROM is corrupted and causes execution to crash by booting up from a back-up ROM after a watchdog reset.

This functionality is implemented with a small block that monitors the reset signal, and steps up a counter indicating which boot address to use next. This block needs a separate reset signal of its own, which should only be asserted on power-up. The boot-retry block can run in a different (typically slower) clock domain to the processor system.

97.9 Multiprocessing support

97.9.1 Overview

LEON5 is designed to be used in multi-processor systems both in SMP and AMP configurations. The write-through caches combined with the snooping mechanism built into the level-1 cache controllers guarantees memory coherency in shared-memory systems consistent with the SPARC TSO (Total Store Order) memory model. A CPU to CPU interface is provided to allow the processors to start and stop each other.

97.9.2 Cache coherency

Cache coherency is ensured by snooping writes on the processor AHB bus and invalidating cache lines written to by other processors. For this to work, all running processors must have snooping enabled in their cache control register.

Provided snooping is enabled, the processors will achive a memory model compliant with SPARC Total Store Order (TSO), as seen from software running in parallel on the cores.

97.9.3 Processor start-up

The debug module will start up CPU0 after reset and leave the other processors in stopped state. The other processors will have to be started up by software running on one of the already running processors. Software wishing to only execute on one processor may simply ignore that any of the other processors exist and run on CPU0 as if it was a single-core system.

For LEON3 and LEON4 system compatibility, a legacy method is supported where CPU0 writes to the multiprocessor status register to wake up the other processors, that will then start executing from the same reset address as CPU0. The software at the reset address has to be made SMP-aware by typically checking the processor ID (through ASR17) and jumping directly to the entry point when processors other than CPU0 are running.

The LEON5 CPU-to-CPU interface provides a more flexible interface for CPU0 to control the other processors. Processors may be started, stopped, and rebooted to start at any entry point. A 32-bit "boot word" can be set by the controlling CPU to each of the controlled CPUs. The contents of the boot word is for the that may for example be used to hold a unique virtual processor ID, or a pointer to a per-CPU data structure.

97.9.4 Processor execution control

When viewed from the outside, the integer unit execution follows a state machine model as shown in figure 261 and table 1948. The integer unit always resets into a stopped state, and has to be started by the debug module. The debug module also has additional commands to force the processor into a specific state.

GRIP

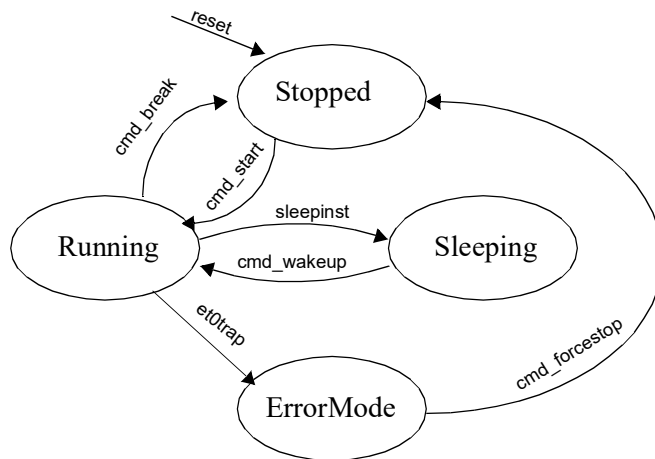
+46 31 7758650 | frontgrade.com/gaisler


Figure 261. LEON5 state machine model

*Table 1948.*Processor pipeline externally visible state descriptions

State	Encoding	Description
Stopped	00	Reset state. Waiting for debug module to start operation. Debug access allowed
Running	01	Processor executing code. Stopped on error mode condition, sleep instruction, or command from debug module. The processor may also go to stopped state on certain conditions for debugging if enabled via Bx signals from the debug module.
Sleeping	11	Processor idle. Will go back to running state when debug module issues a wakeup command (on a pending interrupt or wakeup command from other CPU).
ErrorMode	10	Processor in error mode due to trap in trap condition. Debug accesses allowed. To resume from this state, the pipeline must be either reset or forced into stopped state by the debug module.

97.9.5 Processor reset operation

The following table indicates the reset values of a subset of the registers which are affected by the reset. Since the processor resets into a stopped state, the registers may in some cases be modified via the debug port before starting execution.

*Table 1949.*Processor reset values

Register	Reset value, memmap=0	Reset value, memmap=1
Trap Base Register	0x0	0xC0000000
PC (program counter)	0x0	0xC0000000
nPC (next program counter)	0x4	0xC0000004
PSR (processor status register)	ET=0, S=1	ET=0, S=1

97.9.6 CPU-to-CPU interface

The CPU to CPU interface allows a processor to control and monitor other processors. This interface is accessed from software over ASI 0x22, and is implemented using signals between the debug module and cache controllers.

A permission matrix tracks which processors are allowed to control which, and any illegal commands will be ignored. By default CPU0 is allowed to control all remaining CPUs and the other CPUs are not allowed to control any processor.

GRIP
Apr 2024, Version 2024.1

1652

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

For monitoring, the processor can read out the user-visible state (as described in section 97.9.4) of each of the processors it has permission to control. For controlling, it may send start, break and wakeup commands to the other processors by writing to specific registers. A custom "boot word" can be set by the controlling processor, that the processors can read out.

There is in addition a reboot command that will make the debug module reset the processor pipeline and start up at a specified address. The reset is done in a controlled way that guarantees there is no currently ongoing access to the AMBA bus by the processor that is restarted.

Through a delegation register, permissions can be handed over to a group of processors, for example CPU0 may hand over control over CPU5-7 to CPU5. Each processor has read only access to its segment of the permissions matrix to see how many other CPUs it has control over at the current time. This allows partitioning of processors where the software dynamically adapts to the number of processors it's been assigned.

97.10 Debug support

97.10.1 Overview

Debug support is implemented by a combination of features in the various parts of the LEON5 subsystem.

The processor pipeline provides debug signals that allows the execution to be stopped at any time, and also to make it stop automatically at certain conditions. When stopped, the software visible state of the pipeline can be accessed through the debug signals. Also, loads and stores to arbitrary addresses and ASIs can be performed through the debug port, allowing access to any other software-visible registers and spaces.

The L1 caches, MMU, and FPU implement diagnostic features that can be accessed from the processor, either functionally from software or through the debug interface while debugging. These features are accessed through alternative address spaces.

The subsystem includes a central debug and control module that connects to the debug ports of all CPUs. The module handles resetting the processors and starting them up after reset, unless configured to break the execution instantly for debugging.

The debug module provides ports for external AHB debug masters. The debug masters can access the processors debug ports, read from the trace buffers, access internal registers of the debug module itself, and perform accesses directly on the processor AHB bus.

97.10.2 Command bus

Each processor has a command bus that is used for execution control (starting, stopping, etc). The commands are used both for functional (inter-processor control, waking up on interrupt) and debugging purposes. The command bus is driven by the debug module which acts as a control hub also for the functional start/stop control.

The commands into the pipeline from the debug module are listed in table 1950. When the processor is in Running state, the command needs to be given continuously on the command bus until the externally visible state changes. In the Stopped, Sleeping and ErrorMode states, commands only need to be

GRIP
Apr 2024, Version 2024.1
1653
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

given for one cycle to have effect. Commands may not be given at the same time as a debug register access is taken place.

Table 1950.

Command	Encoding	
None	000	No command.
Start	001	Moves the pipeline from stopped to running state so that it starts executing. This is given automatically by the debug module after reset for processor 0.
Wakeup	010	Moves the pipeline from sleeping to running state.
Break	011	Moves the pipeline to stopped state if it is in Running or Sleeping states.
ForceStop	100	Moves the pipeline to stopped state from any state. Used typically by debugger to get processor back to initial state.
ForceRun	101	Moves the pipeline to running state from any state. Included for completeness, not used normally.
ForceErr	110	Moves the pipelne to ErrMode state from any state. Included for completeness, not used normally.
ForceSleep	111	Moves the pipeline to Sleeping state from any state. Typically used by debugger to resume execution for processors that were sleeping at the time of breaking.

While debugging, commands can be sent to each processor through the debug module's register interface.

97.10.3 Current and previous state tracking

The debug module contains status registers that track which state each processor is currently in. Refer to section 97.9.4 for a description of the state model.

The debug module looks for changes of processor state and keeps a register tracking the previous state each processor was in before entering the current one. In addition, there is a bit set indicating when a processor has been stopped if this was caused by a user level command (i.e one processor stopping another through the CPU-to-CPU interface) or by a stop command entered via the debug register interface. This information is needed by the debugger after breaking execution to resolve whether the processors actually stopped by the debugger or if they were already in stopped state anyway, and then to determine whether they should be resumed when continuing execution.

97.10.4 Start-up handling

After reset, the debug module will start up CPU0 to boot from its default reset address. This can be suppressed by asserting the dsubreak signal during reset, if this is set then the processor will be left in stopped state and no instructions will be executed until the user connects with a debugger and starts the processor.

97.10.5 Wake-up handling

The functionality to wake up the processor from sleep mode (i.e while waiting for an interrupt) is managed by a combination of the processor, interrupt controller and debug module. Each processor sends an interrupt pending signal up to the debug module, that then responds by issuing a wakeup command on the command bus to that processor.

CPU-to-CPU command handling

Processors starting and stopping each other, either via the CPU-to-CPU interface described in section 97.9.6 or via the legacy IRQMP status register interface, are handled through the debug module. The

GRIP

Apr 2024, Version 2024.1

1654

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

start/stop commands are stored in "pending" bits that are the forwarded to the command bus of the accessed CPUs.

A block user commands bit (blockusr) can be set in the debug module to block any of these commands to be delivered to the CPU. The commands are left pending until the blockusr bit is cleared. This is to allow for debugging of a single CPU even if other CPUs are still running that may be trying to start and stop it. The debug module interface has been designed to allow atomically setting the blockusr bit at the same time as sending the stop command to the processors.

97.10.6 Processor break conditions

Control signals into the pipeline from the debug module can configure it to automatically break execution into stopped state (and set the usrblock bit) when certain traps occur.

• BA - any traps

• BE - any traps except window over/underflow, floating point disabled, interrupts, or software traps

• BS - software trap 1 (software breakpoint)

• BW - watchpoint exception (hardware breakpoint)

These signals are tied to register bits in the debug module.

97.10.7 Break matrix

To allow breaking multiple cores at once for debugging, the debug module contains a (NCPU x NCPU) bit matrix to control what should happen when one CPU stops. When a CPU transitions into Stopped or ErrorMode state, that CPUs row in the break matrix is evaluated and any CPUs that have their break bit set to 1 will be sent the break command and have it's usrblock bit set.

97.10.8 Debug access

An interface is implemented between the debug module and the LEON5 pipeline to allow the debug module access the registers of the integer pipeline. The pipeline must be in Stopped or ErrorMode state while the register access is performed. This interface also allows provides indirect access to the cache and all registers that can be accessed from software via alternate address space identifiers.

97.10.9 Debug master access

The debug module provides a set of ports for AHB masters to connect to for debug access. Standard debug masters from the GRLIB library can be connected to these debug ports.

From the debug master's point of view, the behavior is as if the master was directly connected to the processor bus, with the addition of an extra AHB slave area representing the debug module. The debug masters will see the AMBA plug and play information on the processor bus, however in addition the debug module overlays additional plug and play records. One slave record is added for the debug register interface, and master records are added for each debug master connected to the debug module.

The debug module implements a transparent bridge between each debug master and the processor AHB bus, that provides pipeline registers so that there are no direct combinatorial paths between the debug masters and the processor bus, or between the debug masters.

The debug masters can be blocked from accessing the system using the dsuen signal.

97.10.10 Register area

The debug module provides a register area for debugging and control that can be accessed only by the debug AHB masters. Depending on which address is accessed, the access may be handled directly

inside the debug module, or it may lead to an internal access into the LEON5 pipeline. The register map and descriptions are in section 97.16.

97.10.11 Debug sessions

The debug module provides support for a concept called debug sessions. The purpose of this is to allow debug scenarios where multiple debuggers are active on the system in parallel, debugging different subsets of the system without interfering with each other. The debug module provides 4 sessions if the number of CPUs are greater than four, or a number of sessions is equal to the number of CPUs if less than or equal to four.

Each debugger has to claim a unique session ID when connecting, and the debug module provides a simple protocol to achieve this. When a session has been claimed, by default it gets all resources that are not currently in use. The debugger should check that it got all needed resources and then free up the ones it does not intend to use for the next session.

Each session provides a poll register where the processors and other resources allocated to the session can be polled for events using a single register read. The session also provides commands to sample the state of all allocated CPUs atomically or to send a command to all allocated CPUs atomically. A per-session buffer is provided to hold the read/write data for these action.

97.10.12 Debug session allocation protocol

The debug session IDs are arbitrated using the following protocol that must be followed by all debuggers in order for the sessions to work (and debuggers not supporting multiple debug sessions are recommended to follow it for forward compatibility):

1. Read the global debug status register to get the number of sessions Nsess supported

2. Try each possible session ID between 0 and Nsess-1:

2.1 Write to the session's claim register with the pending bit set to 1

2.2 Read back the session's claim register.

2.3 If both the pending and claimed bit are high in the read back value from 2.2 then we are the owners of this session and can proceed to step 3. If getting some other values on the two bits, then go back to 2.1 and try the next ID. If all session IDs failed then all sessions are already in use, stop or retry from step 1.

3. Read the resource masks from the acquired session's register area

4. If the resource masks do not have the needed bits set, the targeted CPUs are already being debugged. Go to step 7 to deallocate the session, then stop or retry from step 1.

5. Clear the bits of the resources we do not need and write back to the session resource masks.

6. The session is now set up and can be used for debugging. When done, proceed to step 7.

7. Free the session ID by writing 1 to the claimed register

97.10.13 UART interception

The debug module contains a UART debug function that works transparently to the system being debugged. It can capture the outgoing data over the transmit lane for reading out via the debug modules register area. Optionally the characters can still also go out to the external UART.

An overrun bit indicates if characters were lost in the debug interface due to not reading fast enough. Optionally the flow control signals into the UART can be asserted when the debug interface FIFO is full in order to avoid overruns, flow control must be enabled in the UART for this to have effect.

The data capture is integrated with the debug sessions so that the UART capture and the processors can be polled using a single register read.

GRIP
Apr 2024, Version 2024.1
1656
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

UART reception can also be intercepted by the debug module to inject input characters. The debug module supports optionally using flow control (to avoid overrun inside the UART) and optional blocking of external input.

97.10.14 Internal deadlock detection

A debug access deadlock detection feature is implemented in the debug module, to detect if a debug access into the pipeline does not return with data within a reasonable time. This will normally only trigger due to an hardware fault (corrupted state of the pipeline) but could also happen due to incorrectly accessing the debug interface of the pipeline without stopping the processor first. The feature is intended to allow for some investigation into the cause of an unexpected stall, but note that a full reset is still required after a deadlock to recover from the error.

If a debug register access leading into the LEON5 pipeline times out and the deadlock detection triggers, the debug module will finish the access towards to the debug master (release the HREADY signal) and set a number of internal registers to indicate that a deadlock occurred and capture which address was accessed. Note that the data returned to the master for the access that failed will be unpredictable.

In order to see that a deadlock triggered, the processor status register can be checked. The event poll register will also indicate the deadlock detection status, so this can be checked as part of the regular event polling without any extra access.

Note that the deadlock detection is only activated on debug accesses over parts of the DSU5 memory area, regular accesses towards memory or peripherals that go into the processor AHB bus may have any number of wait states and if they stall indefinitely the debug master will be correspondingly locked up until the design is reset.

97.10.15 Low level debug register

In order to debug AHB bus lockup situations, the debug module has a low level debug register that can be accessed by the other debug masters even if one master is stuck waiting for an access to complete. In systems with more than one debug link, this allows going in via another debug link and getting some basic information.

The debug register contains the current HREADY status of the bus and whether the deadlock detection hit. It also allows to read-out a set of design-specific signals fed in on the sysstat input of the subsystem.

The low level debug register can be written in order to request a soft reset of the system. If the debug register is written with the value 0x99, then the rstreqn signal of the subsystem will be asserted. Whether or not this actually triggers a reset depends on if the signal is connected externally.

97.11 Memory map

97.11.1 Physical memory map

The subsystem allows two different memory maps depending on the memmap generic. Memory map 0 provides the most compatibility and similarity with existing LEON3 systems, while memory map 1 provides a larger address space for memory and has peripheral registers aligned on 4 KiB page boundaries.

+46 31 7758650 | frontgrade.com/gaisler

The subsystem implements the following memory map as seen from the processor (using physical addresses) or from other masters on the processor bus, or from masters on the debug ports:

*Table 1951.*Physical bus memory map, memmap=0

Range	Function	Comment
0x00000000 - 0x7FFFFFFF	For use by external AHB slaves (main memory)	Typically, boot ROM at 0x00000000, RAM at 0x40000000
0x80000000 - 0x8000000FF	For use by external APB slave	Typically used by memory controller
0x80000100 - 0x800001FF	Console UART registers	See APBUART documentation
0x80000200 - 0x800002FF	IRQ controller registers	See IRQMP documentation
0x80000300 - 0x800003FF	Timer registers	See GPTIMER documentation
0x80000400 - 0x800FFFFF	For use by external APB slaves	
0x80100000 - 0x8FFFFFFF	For use by external AHB slaves	
0x90000000 - 0x9FFFFFFF	Debug access	Only accessible from debug ports
0xA0000000 - 0xFFFFEFFF	For use by external AHB slaves	
0xFFFFF000 - 0xFFFFFFFF	AMBA Plug'n'play information	Read only. Different information when seen from debug port or via processor bus.

*Table 1952.*Physical bus memory map, memmap=1

Range	Function	Comment
0x00000000 - 0xDFFFFFFF	For use by external AHB slaves (main memory)	Typically, RAM at 0x00000000, RAM/IO/ROM at 0x80000000, boot ROM at 0xC0000000
0xE0000000 - 0xEFFFFFFF	Debug access	Only accessible from debug ports
0xF0000000 - 0xFF8FFFFF	For use by external AHB slaves	
0xFF900000 - 0xFF900FFF	Console UART registers	See APBUART documentation
0xFF901000 - 0xFF903FFF	For use by external APB slave	
0xFF904000 - 0xFF904FFF	IRQ controller registers	See IRQMP documentation
0xFF905000 - 0xFF907FFF	For use by external APB slave	
0xFF908000 - 0xFF908FFF	Timer registers	See GPTIMER documentation
0xFF909000 - 0xFF9FFFFF	For use by external APB slaves	
0xFFA00000 - 0xFFFFEFFF	For use by external AHB slaves	
0xFFFFF000 - 0xFFFFFFFF	AMBA Plug'n'play information	Read only. Different information when seen from debug port or via processor bus.

97.11.2 Alternative address spaces

The alternative address spaces (ASIs) are implemented inside the LEON5 cache controller and only accessible from inside the processor or indirectly through the debug module. The table shows the ASI usage for LEON5.

Table 1953. ASI usage

ASI	Address	Usage	Ref
0x01	virtual	Forced cache miss. Address is virtual address as for regular load.	
0x02	System control registers		
	0x00000000	Cache control register	97.12.6
	0x00000008	Instruction cache configuration register	97.12.7
	0x0000000C	Data cache configuration register	97.12.7
	0x00000010	LEON5 configuration register 2	97.12.3
	0x00000014	LEON5 FT configuration register (FT only)	97.13.2
	0x00000018	Region flush mask register	97.12.8
	0x0000001C	Region flush address register	97.12.9
	0x00000020	AHB error register	97.12.10
	0x00000024	AHB error address register	97.12.11
	0x0000002C	Trap register	
	0x00000030	Cache error injection register (FT configurations only)	97.13.4
	0x00000034	Scrubber position register (FT configuration only)	97.13.5
	0x00000038	Error counter register (FT configuration only)	97.13.6
	0x0000003C	Boot word register read-out	97.12.13
	0x00000040	TCM configuration register (TCM configuration only)	97.12.14
	0x00000044	TCM FT configuration register (TCM+FT configuration only)	97.13.3
	0x00000048	Instruction TCM control register	97.12.15
	0x0000004C	Data TCM control register	97.12.16
	0x00000060	Block redundancy config register (BR configuration only)	97.14.2
	0x00000064	Block redundancy error state (BR configuration only)	97.14.3
	0x00000068	Block redundancy trap configuration (BR configuration only)	97.14.4
0x08, 0x09	-	Not supported	
0x0A	virtual	Access memory as if in user mode. Note: for backward compatibility with LEON3/LEON4, a special case is made for the CASA instruction. CASA with ASI 0xA will access memory in user or supervisor mode depending on current status in the PSR register.	
0x0B	virtual	Access memory as if in supervisor mode.	
0x0C	cache-index	Instruction cache tags diagnostic access	
0x0D	cache-index	Instruction cache data diagnostic access	
0x0E	cache-index	Data cache tags diagnostic access	
0x0F	cache-index	Data cache data diagnostic access	
0x10, 0x13	(ignored)	Flush instruction and data cache	
0x11	(ignored)	Flush data cache	
0x18, 0x03	(ignored)	Flush TLB and I/D cache	
0x19, 0x04	MMU control registers		
	0x00000000	MMU control register	97.12.19
	0x00000100	Context pointer register	97.12.20
	0x00000200	Context register	97.12.20
	0x00000300	Fault status register	97.12.21
	0x00000400	Fault address register	97.12.22

97.12.2 ASR17, LEON5 configuration register 1

The ancillary state register 17 (%asr17) provides information on how various configuration options were set during synthesis. This can be used to enhance the performance of software, or to support enumeration in multi-processor systems. There are also a few bits that are writable to configure certain aspects of the processor. The layout of this register has been preserved to keep compatibility with LEON3/LEON4 code, new fields specific to LEON5 have been added to a separate register.

Table 1958. LEON5 configuration register 1 (%asr17)

31	30	29	28	27	26	25	24	23	22	21		18	17	16
INDEX				DBP	RES	DBPM	REXV		REXM		RESERVED		CS	CF[1]
*				0	0	0	00		00		0		*	*
r				rw	r	rw	r		r		r		r	r

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
CF[0]	DWT	SVT	LD	FPU		M	V8		NWP				NWIN		
*	*	0	0	01		0	1		*				*		
r	rw	r	r	r		r	r		r				r		

31:28	Processor index (INDEX) - In multi-processor systems, each LEON core gets a unique index to support enumeration.
27	Disable Branch Prediction (DBP) - Disables branch prediction when set to '1'. Default value is '0'.
26	Reserved for future implementations
25	Disable Branch Prediction on instruction cache misses (DBPM) - When set to '1' this avoids instruction cache fetches (and possible MMU table walk) for predicted instructions that may be annulled. This feature is on by default (reset value '1').
24:21	Always reads 0000 to indicate REX not supported on LEON5
20:18	Reserved for future implementations
17:15	Always reads 000 to indicate that clock switching is not supported on LEON5
14	Disable write error trap (DWT). When set, a write error trap (tt = 0x2b) will be ignored. Set to zero after reset.
13	Always reads 0 to indicate that single vector trapping is unsupported on LEON5.
12	Always reads 0 to indicate a load-delay of 1
11:10	FPU option. Always "01" on LEON5 (GRFPU5 or NanoFPU)
9	Always reads 0 to indicate that the optional multiply-accumulate (MAC) instruction is unavailable on LEON5
8	Always reads 1 to indicate that the SPARC V8 multiply and divide instructions are available
7:5	Number of implemented watchpoints (NWP) (0 - 4)
4:0	Number of implemented registers windows corresponds to NWIN+1.

97.12.4 ASR22-23 - Up-counter

The ancillary state registers 22 and 23 (%asr22-23) contain an internal up-counter that can be read by software without causing any access on the on-chip AMBA bus. The number of available bits in the counter is implementation dependent and is decided by the number of counter bits in the DSU time tag counter. %ASR23 contains the least significant part of the counter value and %ASR22 contains the most significant part. In case the implementation does not contain a debug support unit connected to the processor then the up-counter is not available (value is always zero).

The time tag value accessible in these registers is the same time tag value used for the system's trace buffers (if implemented) and for all processors connected to the same debug support unit. The time tag counter will increment when any of the trace buffers is enabled, or when the time tag counter is forced to be enabled via the DSU register interface, or when any processor has its %ASR22 Disable Up-counter (DUCNT) field set to zero.

The up-counter value will increment even if all processors have entered power-down mode.

Table 1960. LEON5 up-counter MSbs (%ASR22)

31	30	0
DUCNT	UPCNT(62:32)	

31	Disable Up-counter (DUCNT) - Disable upcounter. When set to '1' the up-counter may be disabled. When cleared, the counter will increment each processor clock cycle. Default (reset) value is '1'.
30:0	Counter value (UPCNT(62:32)) - Most significant bits of internal up-counter. Read-only.

Table 1961. LEON5 up-counter LSbs (%ASR23)

31	0
UPCNT(31:0)	

| 31:0 | Counter value (UPCNT(31:0)) - Least significant bits of internal up-counter. Read-only. |

97.12.5 ASR24-31, Hardware watchpoint/breakpoint registers

Each breakpoint consists of a pair of ancillary state registers (%asr24/25, %asr26/27, %asr28/29 and %asr30/31) registers; one with the break address and one with a mask:

%asr24, %asr26
%asr28, %asr30

31	2	1	0
WADDR[31:2]			IF
NR		0	0
rw		r	rw

%asr25, %asr27
%asr29, %asr31

31	2	0
WMASK[31:2]	DL	DS
NR	0	0
rw	rw	rw

Figure 262. Watch-point registers

WADDR - Address to compare against

WMASK - Bit mask controlling which bits to check (1) or ignore (0) for match

IF - break on instruction fetch from the specified address/mask combination

DL - break on data load from the specified address/mask combination

DS - break on data store to the specified address/mask combination

Note: Setting IF=DL=DS=0 disables the breakpoint

When there is a hardware watchpoint match and DL or DS is set then trap 0x0B will be generated.

31	Reserved
30	Snoop Tag Flag (STE) - Used on LEON3FT/LEON4FT to indicate that a parity error was detected in the data physical (snoop) tags. Always reads zero on LEON5, for error counters refer to the separate FT error counter register.
29	Reserved
28	Parity Select (PS) - Used on LEON3FT/LEON4FT to modify the diagnostic ASI so that it will return 4 check bits in the lsb bits. Always reads zero on LEON5.
27:24	Test Bits (TB) -Used on LEON3FT/LEON4FT for bits to be xored during diagnostic write. Not used on LEON5 and always reads zero. Refer to error injection register for error injection support.
23	Data cache snoop enable (DS) - if set, will enable data cache snooping.
22	Flush data cache (FD). If set, will flush the data cache. Always reads as zero.
21	Flush Instruction cache (FI). If set, will flush the instruction cache. Always reads as zero.
20:19	FT scheme (FT) - "00" = no FT, "01" = generic RTL-based ECC implemented, "10" - Technology-specific protection implemented.
18	Reserved for future implementations
17	Separate snoop tags (ST). This bit is always set to 1 on LEON5 for LEON3/LEON4 compatibility, to indicate that ASI 0x1E is available.
16	Reserved
15	Instruction cache flush pending (IP). This bit is set when an instruction cache flush operation is in progress
14	Data cache flush pending (DP). This bit is set when an data cache flush operation is in progress.
13:12	Instruction Tag Errors (ITE) - Used on LEON3FT/LEON4FT to indicate number of detected parity errors in the instruction tag cache. Always reads zero on LEON5, for error counters refer to the separate FT error counter register.
11:10	Instruction Data Errors (IDE) - Used on LEON3FT/LEON4FT to indicate number of detected parity errors in the instruction data cache. Always reads zero on LEON5, for error counters refer to the separate FT error counter register.
9:8	Data Tag Errors (DTE) - Used on LEON3FT/LEON4FT to indicate number of detected parity errors in the data tag cache.Always reads zero on LEON5, for error counters refer to the separate FT error counter register.
7:6	Data Data Errors (DDE) - Used on LEON3FT/LEON4FT to indicate number of detected parity errors in the data data cache. Always reads zero on LEON5, for error counters refer to the separate FT error counter register.
5	Data Cache Freeze on Interrupt (DF) - If set, the data cache will automatically be frozen when an asynchronous interrupt is taken.
4	Instruction Cache Freeze on Interrupt (IF) - If set, the instruction cache will automatically be frozen when an asynchronous interrupt is taken.
3:2	Data Cache state (DCS) - Indicates the current data cache state according to the following: X0= disabled, 01 = frozen, 11 = enabled.
1:0	Instruction Cache state (ICS) - Indicates the current data cache state according to the following: X0= disabled, 01 = frozen, 11 = enabled.

97.12.7 I-cache and D-cache configuration registers

The configuration of the two caches if defined in two read-only registers: the instruction and data configuration registers. They are located under ASI 2 at offset 8 and 12.

*Table 1963.*LEON5 Cache configuration register

31	30	28	27	26	24	23		20	19	18	16
CL	REPL		SN	WAYS		WSIZE			LR	LSIZE	
0	001		*	*		*			0	*

15					4	3	2	1	0
RESERVED						M	SO	RESERVED	
0						1	0	0	
r						r	r	r	

31	Cache locking (CL). Set if cache locking is implemented (always zero on LEON5)
30:28	Cache replacement policy (REPL). Always reads "01" (least recently used) on LEON5.
27	Cache snooping (SN). Set if snooping is implemented.
26:24	Cache associativity (WAYS). Number of ways in the cache: 000 - direct mapped, 001 - 2-way associative, 010 - 3-way associative, 011 - 4-way associative
23:20	Way size (WSIZE). Indicates the size (KiB) of each cache way. Size = 2^{SIZE}
19	Local ram (LR). Used on LEON3 to indicate that local scratch pad ram is implemented, always reads 0 for LEON5. For TCM availability on LEON5, refer to LEON5 configuration register 2.
18:16	Line size (LSIZE). Indicated the size (words) of each cache line. Line size = 2^{LSZ}
15:4	RESERVED
3	MMU present (M). This bit is set to '1' if an MMU is present. Always reads 1 on LEON5
2	SO (supervisor only access) bit is present. Always reads 0 on LEON5
1:0	Reserved for future implementations

97.12.8 Region flush mask register

The region flush mask register is located at ASI 0x2 address 0x18. It controls which address bits are compared for the region flush function.

*Table 1964.*LEON5 Region flush mask register

21 : 18	Cache state error trap pending. Bit mask indicating which cache state errors have occurred but where the trap has not yet been delivered. Bit positions matching the cache state error source field.
17 :16	Cache state error source. This field is set after a cache error trap to indicate the cause of the trap.
	00: Duplicated tag in instruction cache
	01: Duplicated tag in data cache
	10: Uncorrectable error occurred and configured to trap when this happens (FT only).
	11: Unrecoverable late error detected (FT only)
15 : 13	Reserved
12 : 11	Data store error lost. Bit mask indicating data store errors that did not cause a trap depending on store error mode configuration.
10 : 9	Data store error pending: Bit mask indicating data store error traps that have not yet been delivered. Bit positions matching the data store error source field.
8	Data store error source. This field is set after a data_store_error trap to indicate the cause of the trap.
	0: AHB error on write of data from store instruction
	1: AHB error during MMU PTE writeback operation
7 : 5	Instruction access exception lost traps. Bit mask indicating instruction access exceptions that did not cause a trap. Bit positions matching the instruction access exception source field
4 : 2	Instruction access exception pending. Bit mask indicating instruction access exceptions that have not yet caused a trap. Bit positions matching the instruction access exception source field
1 : 0	Instruction access exception source. The field is set after an instruction_access_exception trap to indicate the source of the trap.
	00: AHB error during instruction featch
	01: MMU lookup error
	10: TCM permission error
	11: Reserved

97.12.13 Boot word register

The boot word register is located at ASI 0x2 address 0x3C. It contains a 32-bit word that can be set by the monitoring processor through the CPU-to-CPU interface. The interpretation of the word is to be defined by software.

97.12.14 TCM configuration register

The TCM configuration register is at ASI 0x2 address 0x40. It is only implemented if the ITCME or DTCME bits in the LEON5 configuration register 2 is set, and should not be accessed unless these bits have been checked.

Table 1968. LEON5 TCM configuration register

31	30					24	23		21	20			16

31:28	MMU Implementation ID. Hardcoded to "0000"

*Table 1973.*LEON5 MMU control register

27:24	MMU Version ID. Hardcoded to "0001".
23:21	Number of ITLB entries. The number of ITLB entries is calculated as 2^{ITLB}. If the TLB is shared between instructions and data, this field indicates to total number of TLBs.
20:18	Number of DTLB entries. The number of DTLB entries is calculated as 2^{DTLB}. If the TLB is shared between instructions and data, this field is zero.
17:16	Page size. The size of the smallest MMU page. 0 = 4 Kib; 1 = 8 Kib; 2 = 16 Kib; 3 = 32 Kib. If the page size is programmable, this field is writable, otherwise it is read-only.
15	TLB disable. When set to 1, the TLB will be disabled and each data access will generate an MMU page table walk.
14	Separate TLB. This bit is set to 1 if separate instruction and data TLBs are implemented
13	This bit only exists if *mmuen* generic is set to 2. This bit is written to the SO (supervisor only access) part of the TAG during diagnostic writes.
13:2	Reserved for future implementations
1	No Fault. When NF= 0, any fault detected by the MMU causes FSR and FAR to be updated and causes a fault to be generated to the processor. When NF= 1, a fault on an access to ASI 9 is handled as when NF= 0; a fault on an access to any other ASI causes FSR and FAR to be updated but no fault is generated to the processor.
0	Enable MMU. 0 = MMU disabled, 1 = MMU enabled.

97.12.20MMU context pointer and context registers

The MMU context pointer register is located in ASI 0x19 offset 0x100 and the MMU context register is located in ASI 0x19 offset 0x200. They together determine the location of the root page table descriptor for the current context. Their definition follows the SRMMU specification in the SPARC V8 manual with layouts shown below..

*Table 1974.*LEON5 MMU context pointer register

31	2	1	0
CONTEXT TABLE POINTER		RES	
NR		0	
rw		r	

31:2	Context table pointer, physical address bits 35:6 (note address is shifted 4 bits)
1:0	Reserved, always 0

*Table 1975.*LEON5 MMU context register

31	8	7	0
RESERVED		CONTEXT	
0		0	
r		rw	

31:8	Reserved
7:0	Current context ID

In the LEON5, the context bits are OR:ed with the lower MMU context pointer bits when calculating the address, so one can use less context bits to reduce the size/alignment requirements for the context table.

97.12.21MMU fault status register

The MMU fault status register is located in ASI 0x19 offset 0x300, and the definition is based on the SRMMU specification in the SPARC V8 manual. The SPARC V8 specifies that the fault status regis-

97.13 Fault tolerance registers

97.13.1 Overview

In fault tolerant configuration, some additional configuration and status registers become available in ASI 0x2. These registers are only defined if the FTEN bit is set to 1 in the L5CFG2 register (see section 97.12.3). Note that also for FT releases, these registers are only inplemented if ECC features are actually enabled in the processor at build time via either the cmemconf or rfconf generic.

97.14 Block redundancy registers

97.14.1 Overview

In block redundant configuration, some additional configuration and status registers become available in the cache controller plus some registers are added to the debug module. These registers are only defined if the BREN bit is set to 1 in the L5CFG2 register (see section 97.12.3). Note that also for FT releases, these registers are only inplemented if block-redundancy features are actually enabled in the processor at build time via the redconf generic.

97.14.2 Block redundancy configuration register

The block redundancy configuration register is located at ASI 0x2, address 0x60. The layout of this register mirrors the structure of the redconf generic.

97.14.3 Block redundancy error state register

The block redundancy error state register is located at ASI 0x2, address 0x64. The register contains status bits indicating which errors have been detected, and a status bit used for trap handling. Note that the terms uncorrectable and correctable errors in this register refers to miscompares at the block boundaries and should not be confused with uncorrectable and correctable ECC errors.

2	Enable trap on block-redundancy correctable error for integer register file
1	Enable trap on block-redundancy uncorrectable error for pipeline
0	Enable trap on block-redundancy correctable error for pipeline

97.14.5 Pipeline reboot data stash

When the pipeline is build block-redundant (the PLRED field in the block-redundancy configuration register is non-zero), the debug module adds a 64-bit stash area per CPU core that can be accessed via ASI 0x22, addresses 0xF8 and 0xFC. The stash area can hold any data to be preserved across a pipeline self-reboot, and can be accessed either with 32-bit or with 64-bit load/store alternate instructions.

97.15 CPU-to-CPU interface registers

97.15.1 Overview

The CPU to CPU interface provides a set of registers shared between the processors. Each processor gets a unique view into the interface through loads and stores to ASI 0x22.

Note that all processor indexes in the CPU to CPU interface are relative, so CPU0 refers to the processor that is accessing the interface, CPU1 to the processor with the next higher index, and so on. The purpose of this is to allow making software that does not have to know the absolute processor IDs it is running on.

The layout of the register interface has been designed to allow systems with potentially up to 64 processors, therefore many functions are covered with multiple 32-bit registers. Only the first of each register needs to be accessed for systems with 16 or less CPUs (or where each CPU only needs to control at most 15 other processors).

97.15.2 Effective control bitmap

The read-only registers at offsets 0x0 (for CPU 0-31) and 0x4 (for CPU 32-63) provide the part of the effective control matrix, showing which CPUs the reading processor can control and monitor. The effective control matrix takes into account both the direct permissions matrix and any delegation of control currently enabled through the delegation matrix.

GRIP
Apr 2024, Version 2024.1

1684

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

97.15.3 Delegation bitmap

Registers at offsets 0x8 (for CPU 0-31) and 0xC (for CPU 32-63) allow the accessing processor to configure it's part of the delegation matrix. By setting the delegation setting to 1 for CPU #n and 0 for CPUs #(n+1) up to #(n+k), CPU #n will be allowed to control CPU (n+1)..(n+k).

97.15.4 CPU state read-out

Read-only registers at offsets 0x10 (CPU 0-15), 0x14 (CPU16-31), 0x18 (CPU32-47), 0x1C (CPU48-63) provide access to the current two-bit CPU state according to the model in section 97.9.4.

Processors that the reading processor does not have permission to access will report a state of 00 regardless of actual current state.

97.15.5 Reboot request reset address

The reboot request reset address at offset 0x20 holds the address to be used for the next reboot command issued by this processor.

97.15.6 Reboot request control and status

The reboot request control and status register at offset 0x24 is used to command a reboot of another CPU, and to monitor the progress of the reboot request.

97.15.7 Legacy interface control register

The legacy interface control register at offset 0x28 is only available for CPU0. It contains one bit to disable the legacy, IRQ controller based, boot interface.

The bit can only be set through the CPU-to-CPU interface, clearing it requires a reset or access through the debug port.

97.15.8 SMP broadcast group register

The SMP broadcast group register at offset 0x30 and 0x34 allows the processor to define an SMP broadcast group. The group may include the processor itself and any of the processors it has permissions to control. Any SMP broadcast made by any of the processors in the group will reach the other processors in the same group.

97.15.9 SMP broadcast configuration

The SMP broadcast configuration register at offset 0x38 allows the processor to mask any incoming SMP broadcast from other members of the SMP group.

97.15.10 SMP broadcast request

The SMP broadcast request register at offset 0x3C allows the processor to broadcast commands to the other processors of the same SMP group.

97.15.11 Processor control commands

The set of registers at 0x40 up to 0x6C allows the processor to send start, stop and wakeup commands to the other processors.

97.15.12 Boot word access

The set of registers at 0x100 (for CPU relative index 0, the processor itself) up to 0x1FC (CPU relative index 63) allows the processor to read and write the "boot word" registers of other processors.

GRIP
Apr 2024, Version 2024.1

1685

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The processor allowed to access its own boot register as well as those of the processors that it is allowed to control.

97.16 Debug module registers

97.16.1 Overview

The debug module's register interface is only accessible from debug masters.

Note that backward compatibility is not guaranteed for this interface. Compatibility breaking changes are indicated by incrementing the version number of the DSU5 entry in the AHB plug'n'play information that is visible for the debug masters.

97.16.2 Memory map

Registers in the debug module are either global, per CPU, or per session.

*Table 1986.*Debug module registers address overview

[27:22]	[21:19]	[18:9]	[8]	[7]	[6]	[5:2]	Description

cpu index	110	zero					Pipeline debug register 3
cpu index	111	address					Cache controller ASI access

97.17 Software considerations

97.17.1 Register file initialization on power up

It is recommended that the boot code for the processor writes all registers in the IU and FPU register files before launching the main application. This allows software to be portable to both FT and non-FT versions of the LEON3, LEON4 and LEON5 processors.

97.17.2 LEON3 and LEON4 compatibility

The LEON5 subsystem has been designed to provide a high degree of binary compatibility with existing LEON3 and LEON4 software:

•   Backward compatible layout of registers and feature detection bits

•   Compatible assignments of ASIs and ASRs'

•   Support for V9 CASA instruction as for LEON3/LEON4

GRIP
Apr 2024, Version 2024.1

1686

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Similar memory map and peripherals as LEON3/LEON4 systems

- Support for the standard total store order model

Potential areas where compatibility problems may arise:

- Some software may depend on explicit checking of the PSR.VER field and not work as intended when it detect the value 5 rather than 3.

- Any code written that assumes every instruction takes at least of one cycle, for example using NOP instructions to create a certain number of cycles delay, may not work as expected due to the dual issue capability of LEON5.

- Code that is accessing the diagnostic ASIs to read cache tags have to be adjusted to account for that the cache lines are physically tagged on LEON5.

97.18 Vendor and device identifiers

The core has vendor identifiers 0x01 (Frontgrade Gaisler) and device identifiers 0x0BA for the LEON5 AHB master interface on the processor bus, and 0xBB for the LEON5 debug support unit (register area) on the debug ports. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

97.19 Implementation

97.19.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

97.19.2 Technology mapping

LEON5 has two technology mapping VHDL generics, *fabtech* and *memtech*. The *fabtech* generic controls the implementation of some pipeline features, while *memtech* selects which memory blocks will be used to implement cache memories and the IU/FPU register file. *Fabtech* can be set to any of the provided technologies (0 - NTECH) as defined in the TECHMAP.GENCOMP package. See the GRLIB Users's Manual for available settings for *memtech*.

The LEON5 core maps all usage of RAM memory on the *syncram*, *syncram_2p* and *syncram_dp* components from the technology mapping library (TECHMAP).

97.19.3 Register file implementation

The LEON5 requires an integer register file with 4 read ports and 2 write ports. The register file can be configured to use either a flip-flop based implementation or an implementation based on two-port RAMs. The two-port RAM configuration will use a total of 16 syncram_2p instances.

The floating-point register file always uses a flip flop based implementation.

97.19.4 RAM usage

The instruction cache will use only single-port syncram instances for both tags and data.

The data cache tags can be configured into three different modes depending on the cmemconf generic. Depending on configuration it will use either syncram, syncram_2p or syncram_dp instantiations and

GRIP
Apr 2024, Version 2024.1

1687

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

valid bits will be either included in the tag or held separately in flip flops. The different modes are functionally equivalent.

The data cache data memory is always implemented using single-port memories. It can be configured to use memories with individual byte-write stobes if such are available in the technology. When byte strobes are not available, byte/half-word updates are handled by forwarding back read data from the same memory which may impact timing on some technologies.

The LEON5 makes use of the "read-hold" feature of the RAM techmap and assumes the memory keeps its current data output when disabled in order to save power and reduce logic. If this is not the case, emulation logic inside the techmap will be added to provide the equivalent functionality.

97.19.5 Clock gating

If the cgen generic is set to 1, the processors will support block-level clock gating of the processors while in power-down mode. The clock for each CPU is supplied separately on the gclk input of the subsystem, and a gclken signal indicates when the clock should be enabled. The gclken may be pipe-lined externally if needed.

97.19.6 Block redundancy concerns

When block redundancy is used, care needs to be taken to ensure that redandant copies are not optimized out by the synthesis tools.

Some attributes specific to Synplify have been set in the source code when block-redundancy is enabled to achieve this:

syn_keep is set to true on signals between the different sub-parts of the processor core.

syn_hier is set to "hard" on the top of each sub-part to prevent logic optimization across the block boundary.

syn_radhardstyle attribute is set to "none" on the top of the entities holding dual- and triple-redundant copies. This is done to override any global radhardstyle setting, to allow a mix of block-TMR and local TMR.

97.20 Configuration options

Table 1987 shows the configuration options of the core (VHDL generics).

*Table 1987.*Configuration options

Generic	Function	Allowed range	Default
fabtech	Target technology	0 - NTECH	0 (inferred)
memtech	Vendor library for regfile and cache RAMs. Bits 17 and 18 of this generic can be used to for the IU register file and FP register file to inferred technology: + 2**17: Force inferred technology for IU register file + 2**18: Force inferred technology for FP register file	0 - 16#FFFFFFFF#	0 (inferred)
ncpu	Number of processors instantiated in subsystem	1 - 16	1
nextmst	Number of external masters connected to processor AHB bus Note due to limitations of VHDL, this generic must be at least 1. If no external AHB masters are implemented, select one master and use the ahbm_none constant.	1 - NAHBMST	1
nextslv	Number of external slaves connected to processor AHB bus	1 - NAHBSLV	1
nextapb	Number of external slaves connected to APB bus	0 - NAPBSLV	0

98   LOGAN - On-chip Logic Analyzer

98.1   Introduction

The LOGAN core implements an on-chip logic analyzer for tracing and displaying of on-chip signals. LOGAN consists of a circular trace buffer and a triggering module. When armed, the logic analyzers stores the traced signals in the circular buffer until a trigger condition occurs. A trigger condition will freeze the buffer, and the traced data can then be read out via an APB interface.

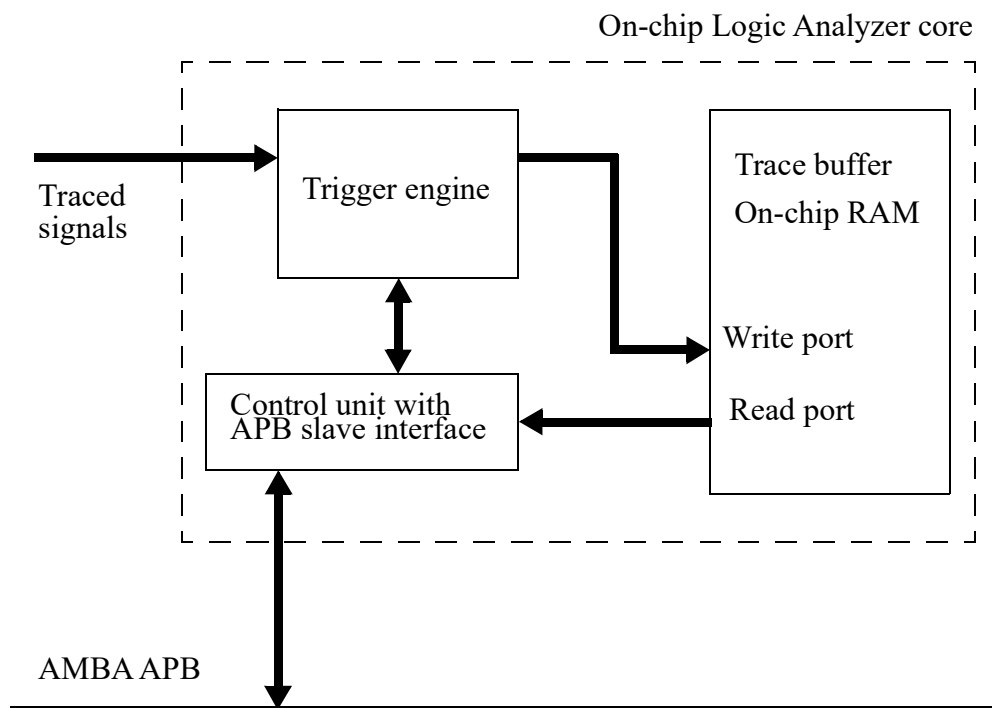
The depth and width of the trace buffer is configurable through VHDL generics, as well as the number of trigger levels.


Figure 263. On-chip Logic Analyzer block diagram

98.2   Operation

98.2.1   Trace buffer

When the logic analyzer is armed, the traced signals are sampled and stored to the trace buffer on the rising edge of the sample clock (TCLK). The trace buffer consists of a circular buffer with an index register pointing to the next address in the buffer to be written. The index register is automatically incremented after each store operation to the buffer.

98.2.2   Clocking

LOGAN uses two clocks: TCLK and the APB clock. The trace signals are sampled on the rising edge of the sample clock (TCLK), while the control unit and the APB interface use the APB clock. TCLK and the APB clock does not need to be synchronized or have the same frequency.

                                                                                +46 31 7758650 | frontgrade.com/gaisler

98.2.3 Triggering

The logic analyzer contains a configurable number of trig levels. Each trig level is associated with a pattern and a mask. The traced signals are compared with the pattern, only comparing the bits set in the mask. This allows for triggering on any specific value or range. Furthermore each level has a match counter and a boolean equality flag. The equality flag specifies whether a match means that the pattern should equal the traced signals or that it should not be equal. It is possible to configure the trigger engine to stay at a certain level while the traced signals have a certain value using this flag. The match counter is a 6 bit counter which can be used to specify how many times a level should match before proceeding to the next. This is all run-time configurable through registers described in the register section.

To specify post-, center- or pre-triggering mode, the user can set a counter register that controls when the sampling stops relative to the triggering event. It can be set to any value in the range 0 to *depth*-1 thus giving total control of the trace buffer content.

To support the tracing of slowly changing signals, the logic analyzer has a 16-bit sample frequency divider register that controls how often the signals are sampled. The default divider value of 1 will sample the signals every clock cycle.

The *usequal* configuration option has a similar purpose as the sample frequency divider. The user can define one of the traced signals as a qualifier bit that has to have a specified value for the current signals to be stored in the trace buffer. This makes sampling of larger time periods possible if only some easily distinguished samples are interesting. This option has to be enabled with the *usequal* generic and the qualifier bit and value are written to a register.

98.2.4 Arming

To start operation, the logic analyzer needs to be armed. This is done by writing to the status register with bit 0 set to 1. A reset can be performed anytime by writing zero to the status register. After the final triggering event, the trigged flag will be raised and can be read out from the status register. The logic analyzer remains armed and trigged until the trigger counter reaches zero. When this happens the index of the oldest sample can be read from the trace buffer index register.

98.3 Registers

Both trace data and all registers are accessed through an APB interface. The LOGAN core will allocate a 64 kbyte block in the APB address space.

Table 1990. APB address mapping

APB address offset	Registers
0x0000	Status register
0x0004	Trace buffer index
0x0008	Page register
0x000C	Trig counter
0x0010	Sample freq. divider
0x0014	Storage qualifier setting
0x2000 - 0x20FF	Trig control settings
0x6000 - 0x6FFF	Pattern/mask configuration
0x8000 - 0xFFFF	Trace data

GRIP

98.3.1 Status register

Table 1991. 0x0000 - STAT - Status register

31	30	29	28	27	20	19	6	5	0
usereg	qualifier	armed	trigged	dbits		depth		trig levels	
*	*	0	0	*		*		*	
r	r	rw	rw	r		r		r	

31: 28	These bits indicate whether an input register and/or storage qualifier is used and if the Logic Analyzer is armed and/or trigged.
27: 20	Number of traced signals (Read Only).
19: 6	Last index of trace buffer. Depth-1 (Read Only).
5: 0	Number of trig levels (Read Only).

98.3.2 Trace buffer index

Table 1992. 0x0004 - INDEX - Trace buffer index register

31	abits	abits-1	0
RESERVED		the index of the oldest sample	
0		0	
r		r	

31: *abits*	Reserved.
abits-1:0	The index of the oldest sample in the buffer. The trace buffer index simply points to where a new sample will be written , in a circular buffer it is the oldest sample if it was previously written. *abits* is the number of bits needed to represent the configured depth.

Note that this register is written by the trigger engine clock domain and thus needs to be known stable when read out. Only when the 'armed' bit in the status register is zero is the content of this register reliable.

98.3.3 Page register

Table 1993. 0x0008 - PAGE - Trace buffer index register

31	4	3	0
RESERVED		current page	
0		0	
r		rw	

31: 4	Reserved.
3: 0	This register selects what page that will be used when reading from the trace buffer.

The trace buffer is organized into pages of 1024 samples. Each sample can be between 1 and 256 bits. If the depth of the buffer is more than 1024 the page register has to be used to access the other pages. To access the i:th page the register should be set i (where i=0..15).

98.3.4 Trig counter

Table 1994. 0x000C - TRIGC - Trig counter register

31	abits	abits-1	0
RESERVED		trig counter value	
0		0	
r		rw	

31:abits	Reserved.
nbits-1:0	Trig counter value. A counter is incremented by one for each stored sample after the final triggering event and when it reaches the value stored in this register the sampling stops. 0 means posttrig and *depth-1* is pretrig. Any value in between can be used.

98.3.5 Sample frequency divider

Table 1995. 0x0010 - CLKDIV - Sample freq. divider register

31	16	15	0
RESERVED		divider value	
0		0x0001	
r		rw	

31: 16	Reserved.
15: 0	A sample is stored on every i:th clock cycle where i is specified through this register. This resets to 1 thus sampling occurs every cycle if not changed.

98.3.6 Storage qualifier

Table 1996. 0x0014 - SQUAL - Storage qualifier register

31	9	8	7	0
RESERVED		val	qualifier	
0		0	0	
r		rw	rw	

31: 9	Reserved.
8:	Qualify storage if bit is 1/0.
7: 0	Which bit to use as qualifier.

98.3.7 Trig control registers

This memory area contains the registers that control when the trigger engine shall proceed to the next level, i.e the match counter and a one bit field that specifies if it should trig on equality or inequality. There are *trigl* words where each word is used like in the figure below.

Table 1997. 0x2000-0x20FF - TCTRL - Trigger control register

31	7	6	1	0
RESERVED		match counter		eq
0		NR		nr
r		rw		rw

31: 7	Reserved.
6: 1	Match counter. A counter is increased with one on each match on the current level and when it reaches the value stored in this register the trigger engine proceeds to the next level or if it is the last level it raises the trigged flag and starts the count of the trigger counter.
0:	Specifies if a match is that the pattern/mask combination is equal or inequal compared to the traced signals. 1 - equal

0- inequal.

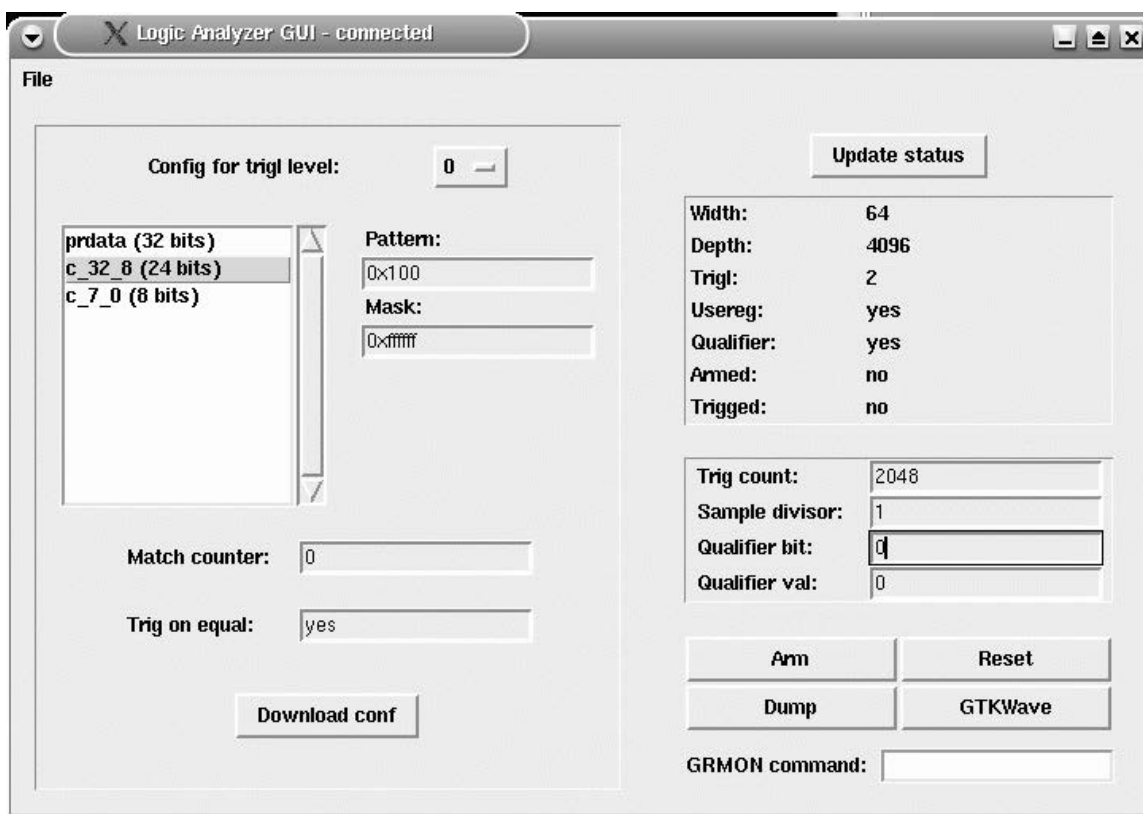
98.3.8 Pattern/mask configuration

In these registers the pattern and mask for each trig level is configured. The pattern and mask can contain up to 8 words (256 bits) each so a number of writes can be necessary to specify just one pattern. They are stored with the LSB at the lowest address. The pattern of the first trig level is at 0x6000 and the mask is located 8 words later at 0x6020. Then the next trig levels starts at address 0x6040 and so on.

98.3.9 Trace data

It is placed in the upper half of the allocated APB address range. If the configuration needs more than the allocated 32 kB of the APB range the page register is used to page into the trace buffer. Each stored word is *dbits* wide but 8 words of the memory range is always allocated so the entries in the trace buffer are found at multiples of 0x20, i.e. 0x8000, 0x8020 and so on.

98.4 Graphical interface

The logic analyzer is normally controlled by the LOGAN debug driver in GRMON. It is also possible to control the LOGAN operation using a graphical user interface (GUI) written in Tcl/Tk. The GUI is provided with GRMON, refer to the GRMON manual for more details.


98.5 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x062. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

98.6 Implementation

98.6.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

98.7 Configuration options

Table 1998 shows the configuration options of the core (VHDL generics).

Table 1998. Configuration options

Generic	Function	Allowed range	Default
dbits	Number of traced signals	1 - 255	32
depth	Number of stored samples	256 - 16384	1024
trigl	Number of trigger levels	1 - 63	1
usereg	Use input register	0 - 1	1
usequal	Use storage qualifier	0 - 1	0
pindex	APB slave index	0 - NAPBSLV - 1	0
paddr	The 12-bit MSB APB address	0 -16#FFF#	0
pmask	The APB address mask	16#000 - 16#F00#	F00
memtech	Memory technology	0 - NTECH	0

The usereg VHDL generic specifies whether to use an input register to synchronize the traced signals and to minimize their fan out. If usereg=1 then all signals will be clocked into a register on the positive edge of the supplied clock signal, otherwise they are sent directly to the RAM.

98.8 Signal descriptions

Table 1999 shows the interface signals of the core (VHDL ports).

Table 1999. Signal descriptions

Signal name	Field	Type	Function	Active
RSTN	N/A	Input	Reset	Low
CLK	N/A	Input	System clock	-
TCLK	N/A	Input	Sample clock	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
SIGNALS	N/A	Input	Vector of traced signals	-

* See GRLIB IP Library users manual

```

99 MCTRL - Combined PROM/IO/SRAM/SDRAM Memory Controller

99.1 Overview

The memory controller handles a memory bus hosting PROM, memory mapped I/O devices, asynchronous static ram (SRAM) and synchronous dynamic ram (SDRAM). The controller acts as a slave on the AHB bus. The function of the memory controller is programmed through memory configuration registers 1, 2 & 3 (MCFG1, MCFG2 & MCFG3) through the APB bus. The memory bus supports four types of devices: PROM, SRAM, SDRAM and local I/O. The memory bus can also be configured in 8- or 16-bit mode for applications with low memory and performance demands.

Chip-select decoding is done for two PROM banks, one I/O bank, five SRAM banks and two SDRAM banks.

The controller decodes three address spaces (PROM, I/O and RAM) whose mapping is determined through VHDL-generics.

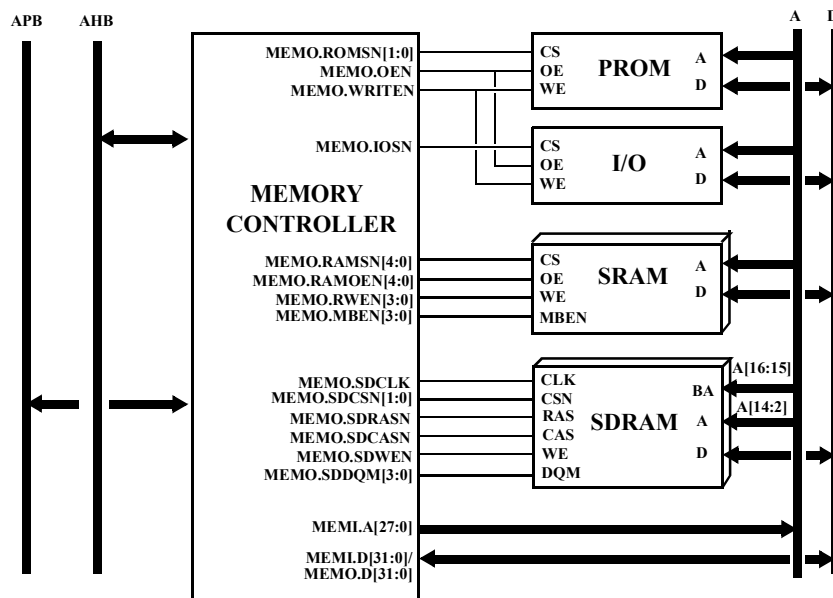
Figure 264 shows how the connection to the different device types is made.


Figure 264. Memory controller conected to AMBA bus and different types of 32-bit memory devices

99.2 PROM access

Accesses to prom have the same timing as RAM accesses, the differences being that PROM cycles can have up to 15 waitstates.

Two PROM chip-select signals are provided, MEMO.ROMSN[1:0]. MEMO.ROMSN[0] is asserted when the lower half of the PROM area as addressed while MEMO.ROMSN[1] is asserted for the upper half.

99.3 Memory mapped I/O

Accesses to I/O have similar timing to ROM/RAM accesses, the differences being that a additional waitstates can be inserted by de-asserting the MEMI.BRDYN signal. The I/O select signal (MEMO.IOSN) is delayed one clock to provide stable address before MEMO.IOSN is asserted.

99.4 SRAM access

The SRAM area can be up to 1 Gbyte, divided on up to five RAM banks. The size of banks 1-4 (MEMO.RAMSN[3:0]is programmed in the RAM bank-size field (MCFG2[12:9]) and can be set in binary steps from 8 Kbyte to 256 Mbyte. The fifth bank (RAMSN[4]) decodes the upper 512 Mbyte (controlled by means of the *sdrasel* VHDL generic) and cannot be used simultaneously with SDRAM memory. A read access to SRAM consists of two data cycles and between zero and three waitstates. Accesses to MEMO.RAMSN[4] can further be stretched by de-asserting MEMI.BRDYN until the data is available. On non-consecutive accesses, a lead-out cycle is added after a read cycle to prevent bus contention due to slow turn-off time of memories or I/O devices. Figure 272 shows the basic read cycle waveform (zero waitstate).

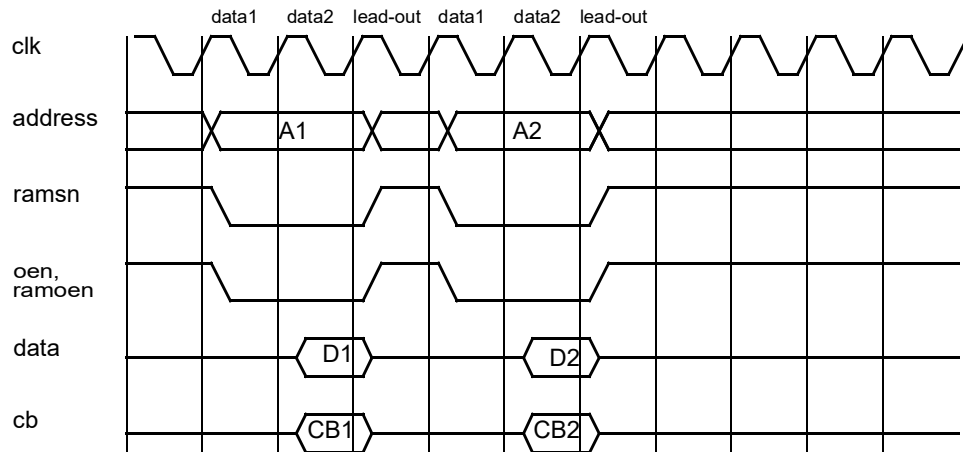

Figure 272. **SRAM non-consecutive read cyclecs.**

For read accesses to MEMO.RAMSN[4:0], a separate output enable signal (MEMO.RAMOEN[n]) is provided for each RAM bank and only asserted when that bank is selected. A write access is similar to the read access but takes a minimum of three cycles:

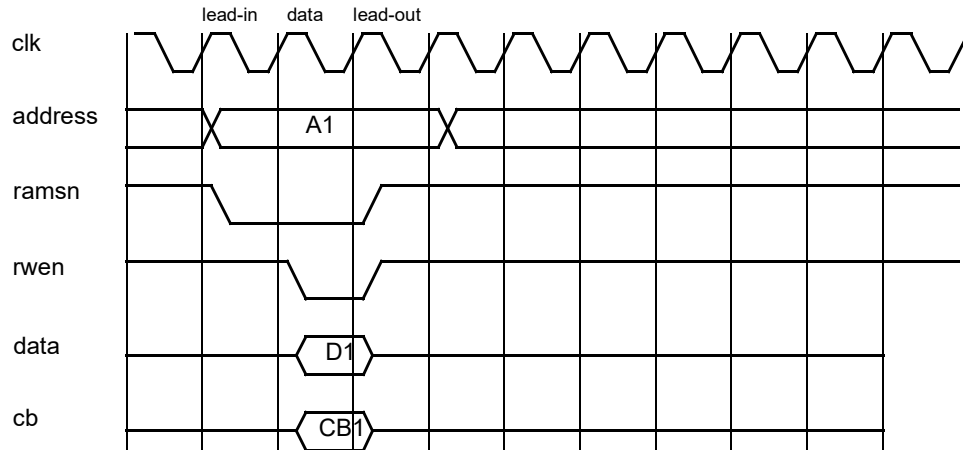
Through an (optional) feed-back loop from the write strobes, the data bus is guaranteed to be driven until the write strobes are de-asserted. Each byte lane has an individual write strobe to allow efficient byte and half-word writes. If the memory uses a common write strobe for the full 16- or 32-bit data, the read-modify-write bit in the MCFG2 register should be set to enable read-modify-write cycles for sub-word writes.


Figure 273. **Sram write cycle (0-waitstates)**

A drive signal vector for the data I/O-pads is provided which has one drive signal for each data bit. It can be used if the synthesis tool does not generate separate registers automatically for the current technology. This can remove timing problems with output delay.

99.5   8-bit and 16-bit PROM and SRAM access

To support applications with low memory and performance requirements efficiently, it is not necessary to always have full 32-bit memory banks. The SRAM and PROM areas can be individually configured for 8- or 16-bit operation by programming the ROM and RAM size fields in the memory configuration registers. Since read access to memory is always done on 32-bit word basis, read access to 8-bit memory will be transformed in a burst of four read cycles while access to 16-bit memory will

generate a burst of two 16-bits reads. During writes, only the necessary bytes will be writen. Figure 274 shows an interface example with 8-bit PROM and 8-bit SRAM. Figure 275 shows an example of a 16-bit memory interface.

99.6   Burst cycles

To improve the bandwidth of the memory bus, accesses to consecutive addresses can be performed in burst mode. Burst transfers will be generated when the memory controller is accessed using an AHB burst request. These includes instruction cache-line fills, double loads and double stores. The timing of a burst cycle is identical to the programmed basic cycle with the exception that during read cycles, the lead-out cycle will only occurs after the last transfer. Burst cycles will not be generated to the IO area.

Only word (HSIZE = "010") bursts of incremental type (HBURST=INCR, INCR4, INCR8 or INCR16) are supported.

99.7   8- and 16-bit I/O access

Similar to the PROM/RAM areas, the I/O area can also be configured to 8- or 16-bit mode. However, the I/O device will NOT be accessed by multiple 8/16 bit accesses as the memory areas, but only with one single access just as in 32-bit mode. To access an I/O device on a 16-bit bus, LDUH/STH instructions should be used while LDUB/STB should be used with an 8-bit bus.

99.8   SDRAM access

99.8.1   General

Synchronous dynamic RAM (SDRAM) access is supported to two banks of PC100/PC133 compatible devices. This is implemented by a special version of the SDCTRL SDRAM controller core from Frontgrade Gaisler, which is optionally instantiated as a sub-block. The SDRAM controller supports 64M, 256M and 512M devices with 8 - 12 column-address bits, and up to 13 row-address bits. The size of the two banks can be programmed in binary steps between 4 Mbyte and 512 Mbyte. The operation of the SDRAM controller is controlled through MCFG2 and MCFG3 (see below). Both 32- and 64-bit data bus width is supported, allowing the interface of 64-bit DIMM modules. The memory controller can be configured to use either a shared or separate bus connecting the controller and SDRAM devices. When the VHDL generic **mobile** is set to a value not equal to 0, the controller supports mobile SDRAM.

99.8.2   Address mapping

The two SDRAM chip-select signals are decoded. SDRAM area is mapped into the upper half of the RAM area defined by BAR2 register. When the SDRAM enable bit is set in MCFG2, the controller is enabled and mapped into upper half of the RAM area as long as the SRAM disable bit is not set. If the SRAM disable bit is set, all access to SRAM is disabled and the SDRAM banks are mapped into the lower half of the RAM area.

99.8.3   Initialisation

When the SDRAM controller is enabled, it automatically performs the SDRAM initialisation sequence of PRECHARGE, 2x AUTO-REFRESH and LOAD-MODE-REG on both banks simultaneously. When mobile SDRAM functionality is enabled the initialization sequence is appended by a LOAD-EXTMODE-REG command. The controller programs the SDRAM to use page burst on read and single location access on write.

99.8.4 Configurable SDRAM timing parameters

To provide optimum access cycles for different SDRAM devices (and at different frequencies), some SDRAM parameters can be programmed through memory configuration register 2 (MCFG2) The programmable SDRAM parameters can be seen in tabel 2001.

*Table 2001.*SDRAM programmable timing parameters

Function	Parameter	Range	Unit
CAS latency, RAS/CAS delay	t_{CAS}, t_{RCD}	2 - 3	clocks
Precharge to activate	t_{RP}	2 - 3	clocks
Auto-refresh command period	t_{RFC}	3 - 11	clocks
Auto-refresh interval		10 - 32768	clocks

Remaining SDRAM timing parameters are according the PC100/PC133 specification.

When mobile SDRAM support is enabled, one additional timing parameter (TXSR) can be programmed though the Power-Saving configuration register.

*Table 2002.*Mobile SDRAM programmable minimum timing parameters

SDRAM timing parameter	Minimum timing (clocks)
Exit Self Refresh mode to first valid command (t_{XSR})	tXSR

99.9 Refresh
