GRLIB IP Core User's Manual

Apr 2024, Version 2024.1

GRLIB IP Core

Table of contents

1 Introduction

1.1 Scope

This document describes specific IP cores provided with the GRLIB IP library. When applicable, the cores use the GRLIP plug&play configuration method as described in the 'GRLIB User's Manual'.

1.2 Other resources

There are several documents that together describe the GRLIB IP Library and Frontgrade Gaisler's IP cores:

- GRLIB IP Library User's Manual (grlib.pdf) - Main GRLIB document that describes the library infrastructure, organization, tool support and on-chip bus.

- GRLIB-FT User's Manual (grlib-ft.pdf) - Describes the FT and FT-FPGA versions of the GRLIB IP library. The document is an addendum to the GRLIB IP Library User's Manual. This document is only available in the FT and FT-FPGA distributions of GRLIB.

- GRLIB FT-FPGA Xilinx Add-on User's Manual (grlib-ft-fpga-xilinx.pdf) - Describes functionality of the Virtex5-QV and Xilinx TMRTool add-on package to the FT-FPGA version of the GRLIP IP library. The document should be read as an addendum to the 'GRLIB IP Library User's Manual' and to the GRLIB FT-FPGA User's Manual. This document is only available as part of the add-on package for FT-FPGA.

- LEON/GRLIB Configuration and Development Guide (guide.pdf) - This configuration and development guide is intended to aid designers when developing systems based on LEON/GRLIB. The guide complements the GRLIB IP Library User's Manual and the GRLIB IP Core User's Manual. While the IP Library user's manual is suited for RTL designs and the IP Core user's manual is suited for instantiation and usage of specific cores, this guide aims to help designers make decisions in the specification stage.

1.4 Processor license overview

The table below lists different processor IP core license types. A license covers a specific processor from either the LEON SPARC family (LEON3, LEON4, or LEON5) or the NOEL RISC-V family (NOEL-V).

The LEON5 and NOEL-V processor models are available in several different configurations, and the license type determines what configurations that the licensee can instantiate in a design.

For LEON5 and NOEL-V:

- The Advanced license also allows instantiate the processor configuration in the version covered by the General, Entry, and Controller licenses.

- The General license also allows to instantiate Entry and Controller configurations.

- The Entry license allows to instantiate Controller configurations (NOEL-V only)

The LEON3 and LEON4 processors are only available in Entry and Controller license types, respectively.

Licenses for the processors, and GRLIB IP library, are also available with and without fault-tolerance features (FT and COM) and can be licensed either for ASIC or FPGA implementations. An ASIC license allows for FPGA prototyping.

The processor license type (Controller, Entry, General, Advanced) affects included peripherals in terms of floating-point unit and Level-2 cache core. Single-bus Level-2 caches and floating-point units not included in a particular license are available as add-ons as separate licenses.

The Advanced license includes multi-bus support for Level-2 caches and IOMMU, allowing for higher performance of the on-chip interconnect.

Table 1. Processor licenses

License	Architecture	Processor	FPU Included	L2C	L2C-Lite	Striped bus
Controller	SPARC	LEON3 single issue	No	No	No	No
	RISC-V	NOEL-V single issue				
Entry	SPARC	LEON4 single issue	No	No	Yes	No
		LEON5 single issue	NanoFPU			
	RISC-V	NOEL-V single issue	NanoFPUnv			
General	SPARC	LEON5 dual issue	NanoFPU	Yes	Yes	No
	RISC-V	NOEL-V dual issue	NanoFPUnv			
Advanced	SPARC	LEON5 dual issue	GRFPU5 +NanoFPU	Yes	Yes	Yes
	RISC-V	NOEL-V dual issue	GRFPUnv +NanoFPUnv			

Table 2 and table 3 provides detailed information about the cores differing between the processor licenses. In addition to the cores listed below, a GRLIB IP library license includes additional cores depending on the type of release (GPL, COM or FT). These are further described in section 1.5.

Note: A LEON license includes either LEON4/LEON4FT or LEON5/LEON5FT, not both.

Note: FT licenses includes the fault-tolerant version of the respective processor core.

Table 2. LEON license cores

Name	Function	Controller	Entry	General	Advanced
LEON3/LEON3FT	SPARC V8 32-bit processor	Yes	No	No	No
DSU3	Multi-processor Debug support unit (LEON3)	Yes	No	No	No
L3STAT	LEON3 statistics unit	Yes	No	No	No
LEON4/LEON4FT	SPARC V8 32-bit processor	No	Yes	No	No
L4STAT	LEON4 statistics unit	No	Yes	No	No

GRLIB IP Core

Table 2. LEON license cores

Name	Function	Controller	Entry	General	Advanced
DSU4	Multi-processor Debug support unit (LEON4)	No	Yes	No	No
LEON3 CLK2x	LEON processor double clocking (includes special LEON entity, interrupt controller and qualifier unit)	Yes	No	No	No
LEON4 CLK2x	LEON processor double clocking (includes special LEON entity, interrupt controller and qualifier unit)	No	Yes	No	No
LEON5/LEON5FT	High-performance SPARC V8 32-bit Processor	No	Yes	Yes	Yes
DSU5	Multi-processor Debug support unit (LEON5)	No	Yes	Yes	Yes
LEON5SYS	High-performance SPARC V8 32-bit Processor Subsystem	No	Yes	Yes	Yes
GRFPU / GRFPC	High-performance IEEE-754 Floating-point unit with floating-point controller to interface LEON3/4	No	No	No	No
GRFPU-Lite / GRFPC-lite	Low-area IEEE-754 Floating-point unit with floating point controller to interface LEON3/4	No	No	No	No
GRFPU5/GRFPC5	High-performance IEEE-754 Floating-point unit with floating-point controller to interface LEON5	No	No	No	Yes
NANOFPU	Low-area combined Floating-point unit and floating point controller for LEON5	No	Yes	Yes	Yes
L2CACHE	Level-2 cache controller	No	No	Yes	Yes
L2C-LITE	Level-2 cache controller - Lite	No	Yes	Yes	Yes
GRIOMMU	I/O Memory management unit	No	Yes	Yes	Yes
GRIOMMU2	RISC-V I/O memory management unit	No	No	No	No

Table 3. NOEL license cores

Name	Function	Controller	Entry	General	Advanced
NOEL-V/NOEL-VFT	High-performance RISC-V RV64GC Processor	Yes	Yes	Yes	Yes
RVDM	RISC-V debug module	Yes	Yes	Yes	Yes
NOELVSYS	High-performance RISC-V RV64GC Processor Subsystem	Yes	Yes	Yes	Yes
GRFPUNV	High-performance RISC-V Floating-point unit for NOEL-V	No	No	No	Yes
NANOFPUNV	Low-area combined Floating-point unit and floating point controller for NOEL-V	No	Yes	Yes	Yes
L2CACHE	Level-2 cache controller	No	No	Yes	Yes
L2C-LITE	Level-2 cache controller - Lite	No	Yes	Yes	Yes
GRIOMMU	I/O Memory management unit	No	No	No	No
GRIOMMU2	RISC-V I/O memory management unit	No	Yes	Yes	Yes

1.5   IP core overview

The tables below lists the provided IP cores and their AMBA plug&play device ID. The columns on the right indicate in which GRLIB distributions a core is available. Note that there are cores that are only included in some processor licenses. These are listed in section 1.4. Spacecraft data handling IP cores are available as a separate license and can be found in section 1.6.

The release columns corresponds to the main licensing and distributions of the GRLIB IP library: GPL, COM, and FT. GPL is the GRLIB GNU GPL (free) distribution; COM is the commercial distribution, which can be licensed either for ASIC or for FPGA; FT the full fault-tolerant distribution, which can be licensed for either ASIC or radiation-tolerant FPGAs.

Each commercial distribution (COM or FT) is based on a processor licensing model (cf. section 1.4). The lists marks which distribution each core is included in with "Yes" or "No". Cores marked with "Yes" are included in the corresponding distribution, irrespectively of the processor model; cores marked with "No" are not included in the corresponding distribution, irrespectively of the processor licensing model. Cores that are affected by the processor licensing model are marked with a note.

Some cores can only be licensed separately or as additions to existing releases, this is marked in the *Notes* column. Contact Frontgrade Gaisler for licensing details.

Note: The open-source version of GRLIB includes only cores marked with "Yes" in the GPL column.

Note: IP core FT features are only supported in FT or FT-FPGA distributions. This includes protection of Level-1 cache and register files for the LEON3, LEON4, LEON5 and NOEL-V processors and fault-tolerance features for other IP cores such as the PCI, Ethernet and SpaceWire controllers.

Note: For encrypted RTL, contact Frontgrade Gaisler to ensure that your EDA tool is supported by GRLIB for encrypted RTL. Supported tools are listed in the GRLIB IP Library user's manual.

Table 4 lists the processors and supporting cores that differ between processor license type and indicates which cores are included in the GPL release GRLIB. For details on which cores are included in each processor license, refer to section 1.4.

Table 4. Processor license functions

Name	Function	Vendor:Device	GPL	Note
LEON3	SPARC V8 32-bit processor	0x01 : 0x003	Yes	3)
LEON3FT	Fault-tolerant SPARC V8 32-bit Processor	0x01 : 0x053	No	2) 3)
DSU3	Multi-processor Debug support unit (LEON3)	0x01 : 0x004	Yes	
L3STAT	LEON3 statistics unit	0x01 : 0x098	Yes	
LEON4	SPARC V8 32-bit processor	0x01 : 0x048	No	3)
LEON4FT	Fault-tolerant SPARC V8 32-bit Processor	0x01 : 0x048	No	2) 3)
L4STAT	LEON4 statistics unit	0x01 : 0x047	No	
DSU4	Multi-processor Debug support unit (LEON4)	0x01 : 0x049	No	
LEON3/4 CLK2x	LEON processor double clocking (includes special LEON entity, interrupt controller and qualifier unit)	-	No	
LEON5	High-performance SPARC V8 32-bit Processor	0x01 : 0x0BA	Yes	3)
LEON5FT	Fault-tolerant high-performance SPARC V8 32-bit Processor	0x01 : 0x0BA	No	2) 3)
DSU5	Multi-processor Debug support unit (LEON5)	0x01 : 0x0BB	Yes	
LEON5SYS	High-performance SPARC V8 32-bit Processor Subsystem	-	Yes	
NOEL-V	High-performance RISC-V RV64GC Processor	0x01 : 0x0BD	Yes	3)
NOEL-VFT	Fault-tolerant high-performance RISC-V RV64GC Processor	0x01 : 0x0BD	No	2) 3)

Table 4. Processor license functions

Name	Function	Vendor:Device	GPL	Note
RVDM	RISC-V debug module	0x01 : 0x0BE	Yes	
NOELVSYS	High-performance RISC-V RV64GC Processor Subsystem	-	Yes	
GRFPU / GRFPC	High-performance IEEE-754 Floating-point unit with floating-point controller to interface LEON3/4	-	No	1) 2)
GRFPU-Lite / GRFPC-lite	Low-area IEEE-754 Floating-point unit with floating point controller to interface LEON3/4	-	No	1) 2)
GRFPU5/GRFPC5	High-performance IEEE-754 Floating-point unit with floating-point controller to interface LEON5	-	No	1) 2)
NANOFPU	Low-area combined Floating-point unit and floating point controller for LEON5	-	Yes	1)
GRFPUNV	High-performance RISC-V Floating-point unit for NOEL-V	-	No	1) 2)
NANOFPUNV	Low-area combined Floating-point unit and floating point controller for NOEL-V	-	Yes	1)
L2CACHE	Level-2 cache controller	0x01 : 0x04B	No	1) 2)
L2C-LITE	Level-2 cache controller - Lite	0x01 : 0x0D0	Yes	1)
GRIOMMU	I/O Memory management unit	0x01 : 0x04F	No	1)
GRIOMMU2	RISC-V I/O memory management unit	0x01 : 0x0D3	No	1)

1) Available as separate package or as addition to existing releases.
2) Delivered as encrypted RTL or in netlist format.
3) The non-FT and FT processor cores are functionally equivalent except that fault-tolerance features can be enabled for the FT versions.

Table 5. Processor support functions

Name	Function	Vendor:Device	GPL	COM	FT	Notes
CLKGEN	Clock generation	-	Yes	Yes	Yes	
DIV32	Divider module	-	Yes	Yes	Yes	
GPTIMER	General purpose timer unit	0x01 : 0x011	Yes	Yes	Yes	
GRCLKGATE	Clock gate unit	0x01 : 0x02C	No	Yes	Yes	
GRDMAC	DMA controller with AHB/APB bridge (deprecated)	0x01 : 0x095	No	No	No	
GRDMAC2	DMA controller	0x01 : 0x0C0	Yes	Yes	Yes	
GRTIMER	General purpose timer unit (deprecated)	0x01 : 0x038	No	Yes	Yes	
GRWATCHDOG	Watchdog module with separate clock domain	0x01 : 0x0C9	No	Yes	Yes	
IRQMP	Multi-processor Interrupt controller	0x01 : 0x00D	Yes	Yes	Yes	
IRQ(A)MP	Multi-processor Interrupt controller	0x01 : 0x00D	Yes	Yes	Yes	
MUL32	32x32 multiplier module	-	Yes	Yes	Yes	
MULTLIB	High-performance multipliers	-	Yes	Yes	Yes	

Table 6. Memory controllers and supporting cores

Name	Function	Vendor:Device	GPL	COM	FT	Note
DDRSPA	Single-port 16/32/64 bit DDR controller	0x01 : 0x025	Yes	Yes	Yes	3)
DDR2SPA	Single-port 16/32/64-bit DDR2 controller	0x01 : 0x02E	Yes	Yes	Yes	3)
MCTRL	8/16/32-bit PROM/SRAM/SDRAM controller	0x04 : 0x00F	Yes	Yes	Yes	
SDCTRL	32-bit PC133 SDRAM controller	0x01 : 0x009	Yes	Yes	Yes	
SRCTRL	8/32-bit PROM/SRAM controller	0x01 : 0x008	Yes	Yes	Yes	

Table 6. Memory controllers and supporting cores

Name	Function	Vendor:Device	GPL	COM	FT	Note
SSRCTRL	32-bit Synchronous SRAM (SSRAM) controller	0x01 : 0x00A	No	Yes	Yes	
FTADDR	Autonomous DDR2/DDR3 Controller with EDAC	0x01 : 0x0AE	No	No	No	1) 2)
FTMCTRL	8//32-bit PROM/SRAM/SDRAM Controller w. RS/BCH EDAC	0x01 : 0x054	No	No	Yes	
FTSDCTRL	32/64-bit PC133 SDRAM Controller with EDAC	0x01 : 0x055	No	No	Yes	
FTSDCTRL64	64-bit PC133 SDRAM Controller with EDAC (deprecated)	0x01 : 0x058	No	No	No	4)
FTSRCTRL	8/32-bit PROM/SRAM/IO Controller w. BCH EDAC	0x01 : 0x051	No	No	Yes	
FTSRCTRL8	8-bit SRAM / 16-bit IO Memory Controller with EDAC	0x01 : 0x056	No	No	Yes	
NANDFCTRL	NAND Flash Memory Controller	0x01 : 0x059	No	Yes	Yes	
NANDFCTRL2	NAND Flash Memory Controller with DMA	0x01 : 0x0C5	No	No	No	1) 2)
SPIMCTRL	SPI Memory controller	0x01 : 0x045	Yes	Yes	Yes	
AHBSTAT	AHB status register	0x01 : 0x052	Yes	Yes	Yes	
MEMSCRUB	Memory scrubber	0x01 : 0x057	No	No	Yes	

1) Available as separate package or as addition to existing releases.
2) Delivered as encrypted RTL or in netlist format.
3) Requires PHY for selected target technology. Please see IP core documentation for supported technologies.
4) Deprecated

Table 7. AMBA Bus control

Name	Function	Vendor:Device	GPL	COM	FT	Note
AHB2AHB	Uni-directional AHB/AHB Bridge	0x01 : 0x020	No	Yes	Yes	
AHB2AVLA	Asynchronous AHB to Avalon Bridge	0x01 : 0x096	Yes	Yes	Yes	
AHB2AXIB	AHB to AXI bridge	0x01 : 0x09F	Yes	Yes	Yes	
AHBBRIDGE	Bi-directional AHB/AHB Bridge	0x01 : 0x020	No	Yes	Yes	
AHBCTRL	AMBA AHB bus controller with plug&play	-	Yes	Yes	Yes	
APBCTRL	AMBA APB Bridge with plug&play	0x01 : 0x006	Yes	Yes	Yes	
AHBLITM2AHBM	AHB-LITE to AHB MASTER	-	Yes	Yes	Yes	
AHBM2AXI	AHB Master to AXI Adapter	-	Yes	Yes	Yes	
AHBTRACE	AMBA AHB Trace buffer	0x01 : 0x017	Yes	Yes	Yes	
MMA	Memory Mapped AMBA bridge	0x01 : 0x07F	No	Yes	Yes	

Table 8. PCI interface

Name	Function	Vendor:Device	GPL	COM	FT	Note
GRPCI2	Advanced 32-bit PCI bridge	0x01 : 0x07C	Yes	Yes	Yes	1)
PCITARGET	32-bit target-only PCI interface (deprecated)	0x01 : 0x012	No	No	No	

Table 8. PCI interface

Name	Function	Vendor:Device	GPL	COM	FT	Note
PCIMTF/GRPCI	32-bit PCI master/target interface with FIFO (deprecated)	0x01 : 0x014	No	No	No	
PCITRACE	32-bit PCI trace buffer (deprecated)	0x01 : 0x015	No	No	No	
PCIDMA	DMA controller for PCIMTF (deprecated)	0x01 : 0x016	No	No	No	
PCIARB	PCI Bus arbiter	0x04 : 0x010	Yes	Yes	Yes	

1) Available as separate package or as addition to existing releases.

Table 9. On-chip memory functions

Name	Function	Vendor:Device	GPL	COM	FT	Note
AHBRAM	Single-port RAM with AHB interface	0x01 : 0x00E	Yes	Yes	Yes	
AHBDPRAM	Dual-port RAM with AHB and user back-end interface	0x01 : 0x00F	Yes	Yes	Yes	
AHBROM	ROM generator with AHB interface	0x01 : 0x01B	Yes	Yes	Yes	
FTAHBRAM	RAM with AHB interface and EDAC protection	0x01 : 0x050	No	No	Yes	
REGFILE_3P	Parametrizable 3-port register file	-	Yes	Yes	Yes	
SYNCRAM	Parametrizable 1-port RAM	-	Yes	Yes	Yes	
SYNCRAM_2P	Parametrizable 2-port RAM	-	Yes	Yes	Yes	
SYNCRAM_DP	Parametrizable dual-port RAM	-	Yes	Yes	Yes	

Table 10. Serial communication

Name	Function	Vendor:Device	GPL	COM	FT	Note
AHBUART	Serial/AHB debug interface	0x01 : 0x007	Yes	Yes	Yes	
AHBJTAG	JTAG/AHB debug interface	0x01 : 0x01C	Yes	Yes	Yes	
APBPS2	PS/2 host controller with APB interface	0x01 : 0x060	Yes	Yes	Yes	
APBUART	Programmable UART with APB interface	0x01 : 0x00C	Yes	Yes	Yes	
CAN_OC	Opencores CAN 2.0 MAC with AHB interface	0x01 : 0x019	Yes	Yes	Yes	
GRCAN	CAN 2.0 Controller with DMA	0x01 : 0x03D	No	Yes	Yes	
GRCANFD	CAN Flexible Data Rate Controller	0x01 : 0x0B5	No	No	No	1)
GRHSSL	SpaceFibre and WizardLink controller with DMA engine	0x01 : 0x0C8	No	No	No	1) 2) 5) 7)
GRSPFI_CODEC	SpaceFibre Codec	N/A	No	No	No	1) 2) 5)
GRSPFI	SpaceFibre Codec with DMA Engine and Bus Master Interface	0x01 : 0x0BC	No	No	No	1) 2) 5)
GRSPW2	SpaceWire link with RMAP and AHB interface	0x01 : 0x029	No	No	No	1) 2) 4)
GRSPW_CODEC	SpaceWire Codec	N/A	No	No	No	1) 2) 4)
GRSPW_PHY	Receiver Physical layer for GRSPW (deprecated)	N/A	No	No	No	
GRSPW2_PHY	Receiver Physical layer	N/A	No	No	No	
GRSPWROUTER	SpaceWire routing switch	0x01 : 0x03E	No	No	No	1) 2) 4)
GRSPWTDP	SpaceWire - Time Distribution Protocol	0x01 : 0x097	No	No	No	1)
GRSRIO	Serial Rapid IO (deprecated)	0x01 : 0x0A8	No	No	No	

Table 10. Serial communication

Name	Function	Vendor:Device	GPL	COM	FT	Note
GRWIZL	WizardLink codec with DMA engine and Bus Master Interface	0x01 : 0x0C7	No	No	No	1) 2) 7)
I2C2AHB	I2C (slave) to AHB bridge	0x01 : 0x00B	Yes	Yes	Yes	
I2CMST	I2C Master with APB interface	0x01 : 0x028	Yes	Yes	Yes	
I2CSLV	I2C Slave with APB interface	0x01 : 0x03E	Yes	Yes	Yes	
SOCBRIDGE	AHB to AHB interface through byte stream	0x01 : 0x0C4	No	Yes	Yes	
SPI2AHB	SPI (slave) to AHB bridge	0x01 : 0x05C	Yes	Yes	Yes	
SPICTRL	SPI Controller with APB interface	0x01 : 0x02D	Yes	Yes	Yes	
SPIMASTER	SPI master device	0x01 : 0x0A6	No	No	No	1) 6)
SPISLAVE	Dual port SPI slave with space protocol	0x01 : 0x0A7	No	No	No	1) 6)
TAP	JTAG TAP controller	-	No	Yes	Yes	

1) Available as separate package or as addition to existing releases.

2) Delivered as encrypted RTL or in netlist format.

3) Deprecated

4) Delivered together with GRSPW2_PHY.

5) GRSPFI_CODEC, GRSPFI and GRHSSL are delivered together under the same license.

6) SPIMASTER and SPISLAVE are delivered together under the same license.

7) GRWIZL and GRHSSL are delivered together with GRHSSL under the same license.

Table 11. Ethernet interface

Name	Function	Vendor:Device	GPL	COM	FT	Note
GRETH	Frontgrade Gaisler 10/100 Mbit Ethernet MAC with AHB I/F	0x01 : 0x01D	Yes	Yes	Yes

1.6 Spacecraft data handling IP cores

The Spacecraft Data Handling IP cores represent a collection of cores that have been developed specifically for the space sector.

These IP cores implement functions commonly used in spacecraft data handling and management systems. They implement international standards from organizations such as Consultative Committee for Space Data Systems (CCSDS), European Cooperation on Space Standardization (ECSS), and the former Procedures, Standards and Specifications (PSS) from the European Space Agency (ESA).

The table below lists the existing CCSDS/ECSS IP cores and AMBA plug&play device identifiers.

The Spacecraft Data Handling IP cores can not be licensed separately.

Table 21. Spacecraft data handling functions

Name	Function	Vendor : Device	GPL	COM	FT	TMTC	Note

1.7   Supported technologies

Technology support and instructions for extending GRLIB with support for additional technologies is documented in the 'GRLIB User's Manual'. The table below shows the technology maps available from Frontgrade Gaisler for GRLIB and in which GRLIB distributions these technology maps are included.

Vendor	Technology	GPL	COM	FT	FT-FPGA	Comment
Actel / Microsemi	ProASIC3, ProASIC3e, ProASIC3l, Axcelerator, Axcelerator DSP, Fusion, IGLOO2, PolarFire	No	Yes	Yes	Yes	
Actel / Microsemi	RTG4	No	No	Yes	Yes	
Altera	Cyclone2 - 4, Stratix - StratixV	Yes	Yes	Yes	Yes	Note that several parts of the FT and FT-FPGA versions are distributed as encrypted RTL. Encrypted RTL is not provided for the Quartus II tool.
Lattice	Certus-NX, CertusPro-NX, CrossLink-NX	No	Yes	Yes	Yes	
Lattice	-	Yes	Yes	Yes	Yes	
Xilinx	Unisim (Virtex2 - UltraScale)+	Yes	Yes	Yes	Yes	
Xilinx	Hi-rel support (Virtex5-QV and UltraScale)	No	No	Yes	Yes	Support for built-in ECC protection in addition to Xilinx Sirf and TMR-Tool support
NanoXplore	BRAVE (NG-Medium, NG-Large, NG-Ultra)	No	No	Yes	Yes	
Other ASIC	-	No	-	-	No	Contact Frontgrade Gaisler for details. See also *GRLIB IP Library User's Manual*.

1.8   Implementation characteristics

Implementation characteristics are available in the GRLIB area spreadsheet:

> http://www.gaisler.com/products/grlib/grlib_area.xls

The spreadsheet is also included in GRLIB packages together with this document.

1.9   Definitions

This section and the following subsections define the typographic and naming conventions used throughout this document.

1.9.1   Bit numbering

The following conventions are used for bit numbering:

- The most significant bit (MSb) of a data type has the leftmost position
- The least significant bit of a data type has the rightmost position
- Unless otherwise indicated, the MSb of a data type has the highest bit number and the LSb the lowest bit number

1.9.2   Radix

The following conventions is used for writing numbers:

- Binary numbers are indicated by the prefix "0b", e.g. 0b1010.
- Hexadecimal numbers are indicated by the prefix "0x", e.g. 0xF00F
- Unless a radix is explicitly declared, the number should be considered a decimal.

1.9.3   Data types

Byte (BYTE)	8 bits of data
Halfword (HWORD)	16 bits of data
Word (WORD)	32 bits of data
Double word (DWORD)	64 bits of data
Quad word (4WORD)	128-bits of data

1.10   Register descriptions

An example register, showing the register layout used throughout this document, can be seen in table 22. The values used for the reset value fields are described in table 23, and the values used for the field type fields are described in table 24. Fields that are named RESERVED, RES, or R are read-only fields. These fields can be written with zero or with the value read from the same register field.

Table 22. <Address> - <Register acronym> - <Register name>

31 24	23 16	15 8	7 0
EF3	EF2	EF1	EF0
<Reset value for EF3>	<Reset value for EF2>	<Reset value for EF1>	<Reset value for EF0>
<Field type for EF3>	<Field type for EF2>	<Field type for EF1>	<Field type for EF0>

31: 24	Example field 3 (EF3) - <Field description>
23: 16	Example field 2 (EF2) - <Field description>
15: 8	Example field 1 (EF1) - <Field description>
7: 0	Example field 0 (EF0) - <Field description>

Table 23. Reset value definitions

Value	Description
0	Reset value 0.
1	Reset value 1. Used for single-bit fields.
0xNN	Hexadecimal representation of reset value. Used for multi-bit fields.
0bNN	Binary representation of reset value. Used for multi-bit fields.
NR	Field not reset. Fields marked with NR will be reset to 0 if full reset of all registers have been enabled in the global GRLIB configuration options (see GRLIB user manual for more information).
*	Special reset condition, described in textual description of the field. Used for example when reset value is taken from a pin.
-	Don't care / Not applicable

Table 24. Field type definitions

Value	Description
r	Read-only. Writes have no effect.
w	Write-only. Used for a writable field in a register where the field's read-value has no meaning.
rw	Readable and writable.
rw*	Readable and writable. Special condition for write, described in textual description of field.
wc	Write-clear. Readable, and cleared when written with a 1
cas	Readable, and writable through compare-and-swap. Only applies to SpaceWire Plug-and-Play registers.

Memory mapped registers may be mapped at several locations within an address space assigned to a peripheral (register set may wrap due to decoding a subset of the address bits). Because of this, memory accesses should only be performed to memory locations where registers are documented to be present.

2 AHB2AHB - Uni-directional AHB/AHB bridge

2.1 Overview

The uni-directional AHB/AHB bridge is used to connect two AMBA AHB buses clocked by synchronous clocks with any frequency ratio. The bridge is connected through a pair consisting of an AHB slave and an AHB master interface. AHB transfer forwarding is performed in one direction, where AHB transfers to the slave interface are forwarded to the master interface. Applications of the uni-directional bridge include system partitioning, clock domain partitioning and system expansion.

Features offered by the uni-directional AHB to AHB bridge are:

• Single and burst AHB transfers

• Data buffering in internal FIFOs

• Efficient bus utilization through (optional) use of SPLIT response and data prefetching. **NOTE:** SPLIT responses require an AHB arbiter that allows assertion of HSPLIT during second cycle of SPLIT response. This is supported by GRLIB's AHBCTRL IP core.

• Posted writes

• Read and write combining, improves bus utilization and allows connecting cores with differing AMBA access size restrictions.

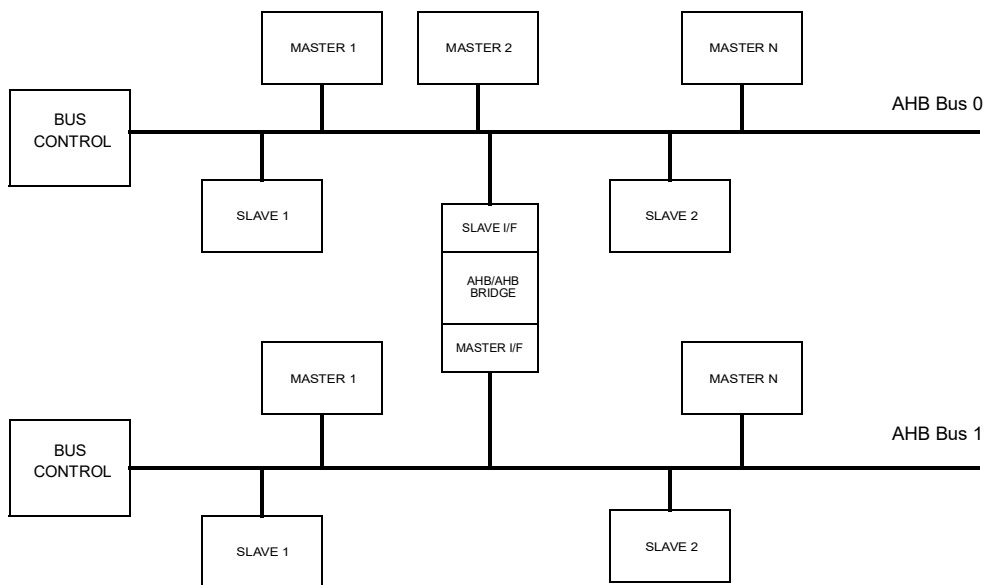
• Deadlock detection logic enables use of two uni-directional bridges to build a bi-directional bridge (one example is the bi-directional AHB/AHB bridge core (AHBBRIDGE))


Figure 1. Two AHB buses connected with (uni-directional) AHB/AHB bridge

2.2 Operation

2.2.1 General

The address space occupied by the AHB/AHB bridge on the slave bus is configurable and determined by Bank Address Registers in the slave interface's AHB Plug&Play configuration record.

The bridge is capable of handling single and burst transfers of all burst types. Supported transfer sizes (HSIZE) are BYTE, HALF-WORD, WORD, DWORD, 4WORD and 8WORD.

For AHB write transfers write data is always buffered in an internal FIFO implementing posted writes. For AHB read transfers the bridge uses GRLIB's AMBA Plug&Play information to determine whether the read data will be prefetched and buffered in an internal FIFO. If the target address for an AHB read burst transfer is a prefetchable location the read data will be prefetched and buffered.

The bridge can be implemented to use SPLIT responses or to insert wait states when handling an access. With SPLIT responses enabled, an AHB master initiating a read transfer to the bridge is always splitted on the first transfer attempt to allow other masters to use the slave bus while the bridge performs read transfer on the master bus.The descriptions of operation in the sections below assume that the bridge has been implemented with support for AMBA SPLIT responses. The effects of disabling support for AMBA SPLIT responses are described in section 2.2.11.

If interrupt forwarding is enabled the interrupts on the slave bus interrupt lines will be forwarded to the master bus and vice versa.

2.2.2   AHB read transfers

When a read transfer is registered on the slave interface the bridge gives a SPLIT response. The master that initiated the transfer will be de-granted allowing other bus masters to use the slave bus while the bridge performs a read transfer on the master side. The master interface then requests the bus and starts the read transfer on the master side. Single transfers on the slave side are normally translated to single transfers with the same AHB address and control signals on the master side, however read combining can translate one access into several smaller accesses. Translation of burst transfers from the slave to the master side depends on the burst type, burst length, access size and the AHB/AHB bridge configuration.

If the read FIFO is enabled and the transfer is a burst transfer to a prefetchable location, the master interface will prefetch data in the internal read FIFO. If the splitted burst on the slave side was an incremental burst of unspecified length (INCR), the length of the burst is unknown. In this case the master interface performs an incremental burst up to a specified address boundary (determined by the VHDL generic *rburst)*. The bridge can be configured to recognize an INCR read burst marked as instruction fetch (indicated on HPROT signal). In this case the prefetching on the master side is completed at the end of a cache line (the cache line size is configurable through the VHDL generic *iburst*). When the burst transfer is completed on the master side, the splitted master that initiated the transfer (on the slave side) is allowed in bus arbitration by asserting the appropriate HSPLIT signal to the AHB controller. The splitted master re-attempts the transfer and the bridge will return data with zero wait states.

If the read FIFO is disabled, or the burst is to non-prefetchable area, the burst transfer on the master side is performed using sequence of NONSEQ, BUSY and SEQ transfers. The first access in the burst on the master side is of NONSEQ type. Since the master interface can not decide whether the splitted burst will continue on the slave side or not, the master bus is held by performing BUSY transfers. On the slave side the splitted master that initiated the transfer is allowed in bus arbitration by asserting the HSPLIT signal to the AHB controller. The first access in the transfer is completed by returning read data. The next access in the transfer on the slave side is extended by asserting HREADY low. On the master side the next access is started by performing a SEQ transfer (and then holding the bus using BUSY transfers). This sequence is repeated until the transfer is ended on the slave side.

In case of an ERROR response on the master side the ERROR response will be given for the same access (address) on the slave side. SPLIT and RETRY responses on the master side are re-attempted until an OKAY or ERROR response is received.

2.2.3   AHB write transfers

The AHB/AHB bridge implements posted writes. During the AHB write transfer on the slave side the data is buffered in the internal write FIFO and the transfer is completed on the slave side by always giving an OKAY response. The master interface requests the bus and performs the write transfer when the master bus is granted. If the burst transfer crosses the write burst boundary (defined by VHDL

generic *wburst*), a SPLIT response is given. When the bridge has written the contents of the FIFO out on the master side, the bridge will allow the master on the slave side to perform the remaining accesses of the write burst transfer.

Writes are accepted with zero wait states if the bridge is idle and the incoming access is not locked. If the incoming access is locked, each access will have one wait state. If write combining is disabled a non-locked BUSY cycle will lead to a flush of the write FIFO. If write combining is enabled or if the incoming access is locked, the bridge will not flush the write FIFO during the BUSY cycle.

2.2.4   Deadlock conditions

When two bridges are used to form a bi-drectional bridge, a deadlock situation can occur if the bridges are simultaneously accessed from both buses. The bridge that has been configured as a slave contains deadlock detection logic which will resolve a deadlock condition by giving a RETRY response, or by issuing SPLIT complete followed by a new SPLIT response. When the core resolves a deadlock while prefetching data, any data in the prefetch buffer will be dropped when the core's slave interface issues the AMBA RETRY response. When the access is retried it may lead to the same memory locations being read twice.

Deadlock detection logic for bi-directional configurations may lead to deadlocks in other parts of the system. Consider the case where a processor on bus A on one side of the bidirectional bridge needs to perform an instruction fetch over the bridge before it can release a semaphore located in memory on bus A. Another processor on bus B, on the other side of the bridge, may spin on the semaphore wating for its release. In this scenario, the accesses from the processor on bus B could, depending on system configuration, continuously trigger a deadlock condition where the core will drop data in, or be prevented from initiating, the instruction fetch for the processor on bus A. Due to scenarios of this kind the bridge should not be used in bi-directional configurations where dependencies as the one described above exist between the buses connected by the bridge.

Other deadlock conditions exist with locked transfers, see section 2.2.5.

2.2.5   Locked transfers

The AHB/AHB bridge supports locked transfers. The master bus will be locked when the bus is granted and remain locked until the transfer completes on the slave side. Locked transfers can lead to deadlock conditions, the core's VHDL generic *lckdac* determines if and how the deadlock conditions are resolved.

With the VHDL generic *lckdac* set to 0, locked transfers may *not* be made after another read access which received SPLIT until the first read access has received split complete. This is because the bridge will return split complete for the first access first and wait for the first master to return. This will cause deadlock since the arbiter is not allowed to change master until a locked transfer has been completed. The AMBA specification requires that the locked transfer is handled before the previous transfer, which received a SPLIT response, is completed.

With *lckdac* set to 1, the core will respond with an AMBA ERROR response to locked access that is made while an ongoing read access has received a SPLIT response. With *lckdac* set to 2 the bridge will save state for the read access that received a SPLIT response, allow the locked access to complete, and then complete the first access. All non-locked accesses from other masters will receive SPLIT responses until the saved data has been read out.

If the core is used to create a bi-directional bridge there is one more deadlock condition that may arise when locked accesses are made simultaneously in both directions. If the VHDL generic *lckdac* is set to 0 the core will deadlock. If *lckdac* is set to a non-zero value the slave bridge will resolve the deadlock condition by issuing an AMBA ERROR response to the incoming locked access.

2.2.6 Read and write combining

Read and write combining allows the bridge to assemble or split AMBA accesses on the bridge's slave interface into one or several accesses on the master interface. This functionality can improve bus utilization and also allows cores that have differing AMBA access size restrictions to communicate with each other. The functionality attained by read and write combining depends on the VHDL generics *rdcomb* (defines type of read combining), *wrcomb* (defines type of write combining), *slvmstaccsz* (defines maximum AHB access size supported by the bridge's slave interface) and *mstmaccsz* (defines maximum AHB access size that can be used by bridge's master interface). These VHDL generics are described in section 2.5.4. The table below shows the effect of different settings. BYTE and HALF-WORD accesses are special cases. The table does not list illegal combinations, for instance *mstmaccsz* /= *slvmaccsz* requires that *wrcomb* /= 0 and *rdcomb* /= 0.

Table 25. Read and write combining

Access on slave interface	Access size	wrcomb	rdcomb	Resulting access(es) on master interface
BYTE or HALF-WORD single read access to any area	-	-	-	Single access of same size
BYTE or HALF-WORD read burst to prefetchable area	-	-	-	Incremental read burst of same access size as on slave interface, the length is the same as the number of 32-bit words in the read buffer, but will not cross the read burst boundary.
BYTE or HALF-WORD read burst to non-prefetchable area	-	-	-	Incremental read burst of same access size as on slave interface, the length is the same as the length of the incoming burst. The master interface will insert BUSY cycles between the sequential accesses.
BYTE or HALF-WORD single write	-	-	-	Single access of same size
BYTE or HALF-WORD write burst	-	-	-	Incremental write burst of same size and length, the maximum length is the number of 32-bit words in the write FIFO.
Single read access to any area	Access size <= mstmaccsz	-	-	Single access of same size
Single read access to any area	Access size > mstmaccsz	-	1	Sequence of single accesses of mstmaccsz. Number of accesses: (access size)/mstmaccsz
Single read access to any area	Access size > mstmaccsz	-	2	Burst of accesses of size mstmaccsz. Length of burst: (access size)/mstmaccsz
Read burst to prefetchable area	-	-	0	Burst of accesses of incoming access size up to address boundary defined by rburst.
Read burst to prefetchable area	-	-	1 or 2	Burst of accesses of size mstmaccsz up to address boundary defined by rburst.
Read burst to non-prefetchable area	Access size <= mstmaccsz	-	-	Incremental read burst of same access size as on slave interface, the length is the same as the length of the incoming burst. The master interface will insert BUSY cycles between the sequential accesses.
Read burst to non-prefetchable area	Access size > mstmaccsz	-	1 or 2	Burst of accesses of size mstmaccsz. Length of burst: (incoming burst length)*(access size)/mstmaccsz
Single write	Access size <= mstmaccsz	-	-	Single write access of same size
Single write	Access size > mstmaccsz	1	-	Sequence of single access of mstmaccsz. Number of accesses: (access size)/mstmaccsz.
Single write	Access size > mstmaccsz	2	-	Burst of accesses of mstmaccsz. Length of burst: (access size)/mstmaccsz.

Table 25. Read and write combining

Access on slave interface	Access size	wrcomb	rdcomb	Resulting access(es) on master interface
Write burst	-	0	-	Burst of same size as incoming burst, up to address boundary defined by VHDL generic wburst.
Write burst	-	1 or 2	-	Burst write of maximum possible size. The bridge will use the maximum size (up to mst-maccsz) that it can use to empty the writebuffer.

Read and write combining prevents the bridge from propagating fixed length bursts and wrapping bursts. See section 2.2.7 for a discussion on burst operation.

Read and write combining with VHDL generics *wrcomb/rdcomb* set to 1 cause the bridge to use single accesses when divding an incoming access into several smaller accesses. This means that another master on the bus may write or read parts of the memory area to be accessed by the bridge before the bridge has read or written all the data. In bi-directional configurations, an incoming access on the master bridge may cause a collision that aborts the operation on the slave bridge. This may cause the bridge to read the same memory locations twice. This is normally not a problem when accessing memory areas. The same issues apply when using an AHB arbiter that performs early burst termination. The standard GRLIB AHBCTRL core does not perform early burst termination.

To ensure that the bridge does not re-read an address, and that all data in an access from the bridge's slave interface is propagated out on the master interface without interruption the VHDL generics *rdcomb* and *wrcomb* should both be set to 0 or 2. In addition to this, the AHB arbiter may not perform early burst termination (early burst termination is not performed by the GRLIB AHBCTRL arbiter).

Read and write combining can be limited to specified address ranges. See description of the *comb-mask* VHDL generic for more information. Note that if the core is implemented with support for prefetch and read combining, it will not obey combmask for prefetch operations (burst read to prefetchable areas). Prefetch operations will always be performed with the maximum allowed size on the master interface.

2.2.7   Burst operation

The core can be configured to support all AMBA 2.0 burst types (single access, incrementing burst of unspecified length, fixed length incrementing bursts and wrapping bursts). Single accesses and incrementing bursts of unspecified length have previously been discussed in this document. An incoming single access will lead to one access, or multiple accesses for some cases with read/write combining, on the other side of the bridge. An incoming incrementing burst of unspecified length to a prefetchable area will lead to the prefetch buffer (if available) being filled using the same access size, or the maximum allowed access size if read/write combining is enabled, on the master interface.

If the core is used in a system where no fixed length bursts or incremental bursts will be used in accesses to the bridge, then set the *allbrst* generic to 0 and skip the remainder of this section.

The VHDL generic *allbrst* controls if the core will support fixed length and wrapping burst accesses. If *allbrst* is set to 0, the core will treat all burst accesses as incrementing of unspecified length. For fixed length and wrapping bursts this can lead to performance penalties and malfunctions. Support for fixed length and wrapping bursts is enabled by setting *allbrst* to 1 or 2. Table 26 describes how the core will handle different burst types depending on the setting of *allbrst*.

Table 26. Burst handling

Value of allbrst generic	Access type*	Undefined length incrementing burst INCR	Fixed length incrementing burst INCR{4,8,16}	Wrapping burst WRAP{4,8,16}
0	Reads to non-prefetchable area	Incrementing burst with BUSY cycles inserted. Same behaviour with read and write combining.	Fixed length burst with BUSY cycles inserted. If the burst is short then the burst may end with a BUSY cycle. If access combining is used the HBURST signal will get incorrect values.	Malfunction. Not supported
	Reads to prefetchable area	Incrementing burst of maximum allowed size, filling prefetch buffer, starting at address boundary defined by prefetch buffer.		Malfunction. Not supported
	Write burst	Incrementing burst	Incrementing burst, if write combining is enabled, and triggered, the burst will be translated to an incrementing burst of undefined length. VHDL generic *wrcomb* should not be set to 1 (but to 0 or 2) in this case	Write combining is not supported. Same access size will be used on both sides of the bridge.
1	Reads to non-prefetchable area	Incrementing burst with BUSY cycles inserted. Same behaviour with read and write combining.	Same burst type with BUSY cycles inserted. If read combining is enabled, and triggered by the incoming access size, an incremental burst of unspecified length will be used. If the burst is short then the burst may end with a BUSY cycle.	Same burst type with BUSY cycles inserted. If read combining is enabled, and triggered by the incoming access size, an incremental burst of unspecified length will be used. This will cause AMBA violations if the wrapping burst does not start from offset 0.
	Reads to prefetchable area	Incrementing burst of maximum allowed size, filling prefetch buffer.	For reads, the core will perform full (or part that fits in prefetch buffer) fixed/wrapping burst on master interface and then respond with data. No BUSY cycles are inserted. If the access made to the slave interface is larger than the maximum supported access size on the master interface then a incrementing burst of unspecified length will be used to fill the prefetch buffer. This (read combining) is not supported for wrapping bursts.	
	Write burst	Same as for allbrst = 0		
2	Reads to non-prefetchable area	Incrementing burst with BUSY cycles inserted. Same behaviour with read and write combining.	Reads are treated as a prefetchable burst. See below.	
	Reads to prefetchable area	Incrementing burst of maximum allowed size, filling prefetch buffer, starting at address boundary defined by prefetch buffer.	Core will perform full (or part that fits in prefetch buffer) fixed/wrapping burst on master interface and then respond with data. No BUSY cycles are inserted. If the access made to the slave interface is larger than the maximum supported access size on the master interface then a incrementing burst of unspecified length will be used to fill the prefetch buffer. This (read combining) is not supported for wrapping bursts.	
	Write burst	Same as for allbrst = 0		

* Access to prefetchable area where the core's prefetch buffer is ised (VHDL generic pfen /= 0).

2.2.8   Transaction ordering, starvation and AMBA arbitration schemes

The bridge is configured at implementation to use one of two available schemes to handle incoming accesses. The bridge will issue SPLIT responses when it is busy and on incoming read accesses. If the bridge has been configured to use first-come, first-served ordering it will keep track of the order of incoming accesses and serve the requests in the same order. If first-come, first-served ordering is disabled the bridge will give some advantage to the master it has a response for and then allow all masters in to arbitration simultaneously, moving the decision on which master that should be allowed to access the bridge to the bus arbitration.

When designing a system containing a bridge the expected traffic patterns should be analyzed. The designer must be aware how SPLIT responses affect arbitration and how the selected transaction ordering in the bridge will affect the system. The two different schemes are further described in sections 2.2.9 and 2.2.10.

2.2.9   First-come, first-served ordering

First-come, first served ordering is used when the VHDL generic *fcfs* is non-zero.

With first-come, first-served ordering the bridge will keep track of the order of incoming accesses. The accesses will then be served in the same order. For instance, if master 0 initiates an access to the bridge, followed by master 3 and then master 5, the bridge will propagate the access from master 0 (and respond with SPLIT on a read access) and then respond with SPLIT to the other masters. When the bridge has a response for master 0, this master will be allowed in arbitration again by the bridge asserting HSPLIT. When the bridge has finished serving master 0 it will allow the next queued master in arbitration, in this case master 3. Other incoming masters will receive SPLIT responses and will not be allowed in arbitration until all previous masters have been served.

An incoming locked access will always be given precedence over any other masters in the queue.

A burst that has initiated a pre-fetch operation will receive SPLIT and be inserted last in the master queue if the burst is longer than the maximum burst length that the bridge has been configured for.

It should be noted that first-come, first-served ordering may not work well in systems where an AHB master needs to have higher priority compared to the other masters. The bridge will not prioritize any master, except for masters performing locked accesses.

2.2.10   Bus arbiter ordering

Bus arbiter ordering is used when VHDL generic *fcfs* is set to zero.

When several masters have received SPLIT and the bridge has a response for one of these masters, the master with the queued response will be allowed in to bus arbitration by the bridge asserting the corresponding HSPLIT signal. In the following clock cycle, all other masters that have received SPLIT responses will also be allowed in bus arbitration as the bridge asserts their HSPLIT signals simultaneously. By doing this the bridge defers the decision on the master to be granted next to the AHB arbiter. The bridge does not show any preference based on the order in which it issued SPLIT responses to masters, except to the master that initially started a read or write operation. Care has been taken so that the bridge shows a consistent behavior when issuing SPLIT responses. For instance, the bridge could be simplified if it could issue a SPLIT response just to be able to change state, and not initiate a new operation, to an access coming after an access that read out prefetched data. When the bridge entered its idle state it could then allow all masters in bus arbitration and resume normal operation. That solution could lead to starvation issues such as:

T0: Master 1 and Master 2 have received SPLIT responses, the bridge is prefetching data for Master 1

T1: Master 1 is allowed in bus arbitration by setting the corresponding HSPLIT

T2: Master 1 reads out prefetch data, Master 2 HSPLIT is asserted to let Master 2 in to bus arbitration

T3: Master 2 performs an access, receives SPLIT, however the bridge does not initiate an access, it just stalls in order to enter its idle state.

T4: Master 2 is allowed in to bus arbitration, Master 1 initiates an access that leads to a prefetch and Master 1 receives a SPLIT response

T5: Master 2 performs an access, receives SPLIT since the bridge is prefetching data for master 1

T6: Go back to T0

This pattern will repeat until Master 1 backs away from the bus and Master 2 is able to make an access that starts an operation over the bridge. In most systems it is unlikely that this behavior would introduce a bus lock. However, the case above could lead to an unexpectedly long time for Master 2 to complete its access. Please note that the example above is illustrative and the problem does not exist in the core as the core does not issue SPLIT responses to (non-locked) accesses in order to just change state but a similar pattern could appear as a result of decisions taken by the AHB arbiter if Master 1 is given higher priority than Master 2.

In the case of write operations the scenario is slightly different. The bridge will accept a write immediately and will not issue a SPLIT response. While the bridge is busy performing the write on the master side it will issue SPLIT responses to all incoming accesses. When the bridge has completed the write operation on the master side it will continue to issue SPLIT responses to any incoming access until there is a cycle where the bridge does not receive an access. In this cycle the bridge will assert HSPLIT for all masters that have received a SPLIT response and return to its idle state. The first master to access the bridge in the idle state will be able to start a new operation. This can lead to the following behavior:

T0: Master 1 performs a write operation, does NOT receive a SPLIT response

T1: Master 2 accesses the bridge and receives a SPLIT response

T2: The bridge now switches state to idle since the write completed and asserts HSPLIT for Master 2.

T3: Master 1 is before Master 2 in the arbitration order and we are back at T0.

In order to avoid this last pattern the bridge would have to keep track of the order in which it has issued SPLIT responses and then assert HSPLIT in the same order. This is done with first-come, first-served ordering described in section 2.2.9.

2.2.11   AMBA SPLIT support

Support for AMBA SPLIT responses is enabled/disabled through the VHDL generic *split*. SPLIT support should be enabled in most systems. The benefits of using SPLIT responses is that the bus on the bridge's slave interface side can be free while the bridge is performing an operation on the master side. This will allow other masters to access the bus and generally improve system performance. The use of SPLIT responses also allows First-come, first-served transaction ordering.

For configurations where the bridge is the only slave interface on a bus, it can be beneficial to implement the bridge without support for AMBA SPLIT responses. Removing support for SPLIT responses reduces the area used by the bridge and may also reduce the time required to perform accesses that traverse the bridge. It should be noted that building a bi-directional bridge without support for SPLIT responses will increase the risk of access collisions.

If SPLIT support is disabled the bridge will insert wait states where it would otherwise issue a SPLIT response to a master initiating an access. This means that the arbitration ordering will be left to the bus arbiter and the bridge cannot be implemented with the First-come, first-served transaction ordering scheme. The bridge will still issue RETRY responses to resolve dead lock conditions, to split up long burst and also when the bridge is busy emptying it's write buffer on the master side.

2.2.12 Core latency

The delay incurred when performing an access over the core depends on several parameters such as core configuration, the operating frequency of the AMBA buses, AMBA bus widths and memory access patterns. Table 27 below shows core behavior in a system where both AMBA buses are running at the same frequency and the core has been configured to use AMBA SPLIT responses. Table 28 further down shows core behavior in the same system without support for SPLIT responses.

Table 27. Example of single read with FFACT = 1, and SPLIT support

Clock cycle	Core slave side activity	Core master side activity
0	Discovers access and transitions from idle state	Idle
1	Slave side waits for master side, SPLIT response is given to incoming access, any new incoming accesses also receive SPLIT responses.	Discovers slave side transition. Master interface output signals are assigned.
2		If bus access is granted, perform address phase. Otherwise wait for bus grant.
3		Register read data and transition to data ready state.
4	Discovers that read data is ready, assign read data output and assign SPLIT complete	Idle
5	SPLIT complete output is HIGH	
6	Typically a wait cycle for the SPLIT:ed master to be allowed into arbitration. Core waits for master to return. Other masters receive SPLIT responses.	
7	Master has been allowed into arbitration and performs address phase. Core keeps HREADY high	
8	Access data phase. Core has returned to idle state.	

Table 28. Example of single read with FFACT = 1, without SPLIT support

Clock cycle	Core slave side activity	Core master side activity
0	Discovers access and transitions from idle state	Idle
1	Slave side waits for master side, wait states are inserted on the AMBA bus.	Discovers slave side transition. Master interface output signals are assigned.
2		Bus access is granted, perform address phase.
3		Register read data and transition to data ready state.
4	Discovers that read data is ready, assign HREADY output register and data output register.	Idle
5	HREADY is driven on AMBA bus. Core has returned to idle state	

While the transitions shown in tables 27 and 28 are simplified they give an accurate view of the core delay. If the master interface needs to wait for a bus grant or if the read operation receives wait states, these cycles must be added to to the cycle count in the tables. The behavior of the core with a fre-

quency factor of two between the buses is shown in tables 29 and 30 (best case, delay may be larger depending on on which slave clock cycle an access is made to the core).

Table 29. Example of single read with FFACT = 2, Master freq. > Slave freq, without SPLIT support

Slave side clock cycle	Core slave side activity	Master side clock cycle	Core master side activity
0	Discovers access and transitions from idle state	0	Discovers slave side transition. Master interface output signals are assigned.
1	Slave side waits for master side, wait states are inserted on the AMBA bus.		
2		1	Bus access is granted, perform address phase.
3			
4		2	Register read data and transition to data ready state.
5			
6	Discovers that read data is ready, assign HREADY output register and data output register.	3	Idle
7	HREADY is driven on AMBA bus. Core has returned to idle state		

Table 30. Example of single read with FFACT = 2, Master freq. > Slave freq, without SPLIT support

Slave side clock cycle	Core slave side activity	Master side clock cycle	Core master side activity
0	Discovers access and transitions from idle state	0	Idle
		1	
1	Slave side waits for master side, wait states are inserted on the AMBA bus.	2	Discovers slave side transition. Master interface output signals are assigned.
		3	Bus access is granted, perform address phase.
2	Discovers that read data is ready, assign HREADY output register and data output register.	4	Register read data and transition to data ready state.
		5	Idle
3	HREADY is driven on AMBA bus. Core has returned to idle state	6	
		7	

Table 31 below lists the delays incurred for single operations that traverse the bridge while the bridge is in its idle state. The second column shows the number of cycles it takes the master side to perform the requested access, this column assumes that the master slave gets access to the bus immediately and that each access is completed with zero wait states. The table only includes the delay incurred by traversing the core. For instance, when the access initiating master reads the core's prefetch buffer, each additional read will consume one clock cycle. However, this delay would also have been present if the master accessed any other slave.

Write accesses are accepted with zero wait states if the bridge is idle, this means that performing a write to the idle core does not incur any extra latency. However, the core must complete the write operation on the master side before it can handle a new access on the slave side. If the core has not transitioned into its idle state, pending the completion of an earlier access, the delay suffered by an access be longer than what is shown in the tables in this section. Accesses may also suffer increased delays during collisions when the core has been instantiated to form a bi-directional bridge. Locked accesses that abort on-going read operations will also mean additional delays.

If the core has been implemented to use AMBA SPLIT responses there will be an additional delay where, typically, one cycle is required for the arbiter to react to the assertion of HSPLIT and one clock cycle for the repetition of the address phase.

Note that if the core has support for read and/or write combining, the number of cycles required for the master will change depending on the access size and length of the incoming burst access. For instance, in a system where the bus in the core's master side is wider than the bus on the slave side, write combining will allow the core to accept writes with zero wait states and then combine several accesses into one or several larger access. Depending on memory controller implementation this could reduce the time required to move data to external memory, and will reduce the load on the master side bus.

Table 31. Access latencies

Access	Master acc. cycles	Slave cycles	Delay incurred by performing access over core
Single read	3	1	$1 * clk_{slv} + 3 * clk_{mst}$
Burst read with prefetch	2 + (burst length)[x]	2	$2 * clk_{slv} + (2 + burst\ length) * clk_{mst}$
Single write[xx]	(2)	0	0
Burst write[xx]	(2 + (burst length))	0	0

[x] A prefetch operation ends at the address boundary defined by the prefetch buffer's size

[xx] The core implements posted writes, the number of cycles taken by the master side can only affect the next access.

2.2.13 Endianness

The core is designed for big-endian systems.

2.3 Registers

The core does not implement any registers.

2.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x020. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

2.5 Implementation

2.5.1 Technology mapping

The uni-directional AHB to AHB bridge has two technology mapping generics *memtech* and fcfsmtech. *memtech* selects which memory technology that will be used to implement the FIFO memories. *fcfsmtech* selects the memory technology to be used to implement the First-come, first-served buffer, if FCFS is enaled.

2.5.2 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

2.5.3 RAM usage

The uni-directional AHB to AHB bridge instantiates one or several *syncram_2p* blocks from the technology mapping library (TECHMAP). If prefetching is enabled max(*mstmaccsz*, *slvaccsz*)/32 *syncram_2p* block(s) with organization (max(*rburst,iburst*)-max(*mstmaccsz*, *slvaccsz*)/32) x 32 is used to implement read FIFO (max(*rburst,iburst*) is the size of the read FIFO in 32-bit words). max(*mstmaccsz*, *slvaccsz*)/32 *syncram_2p* block(s) with organization *(wburst* - max(*mstmaccsz*, *slvaccsz*)/32) x 32, is always used to implement the write FIFO (where *wburst* is the size of the write FIFO in 32-bit words).

If the core has support for first-come, first-served ordering then one *fcfs* x 4 *syncram_2p* block will be instantiated, using the technology specified by the VHDL generic *fcfsmtech*.

2.5.4 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

2.6 Configuration options

Table 32 shows the configuration options of the core (VHDL generics).

Table 32. Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
memtech	Memory technology		
hsindex	Slave I/F AHB index	0 to NAHBMAX-1	0
hmindex	Master I/F AHB index	0 to NAHBMAX-1	0
dir	0 - clock frequency on the master bus is lower than or equal to the frequency on the slave bus 1 - clock frequency on the master bus is higher than or equal to the frequency on the slave bus (for VHDL generic *ffact* = 1 the value of dir does not matter)	0 - 1	0
ffact	Frequency scaling factor between AHB clocks on master and slave buses.	1 - 15	2
slv	Slave bridge. Used in bi-directional bridge configuration where *slv* is set to 0 for master bridge and 1 for slave bridge. When a deadlock condition is detected slave bridge (*slv*=1) will give RETRY response to current access, effectively resolving the deadlock situation. This generic must only be set to 1 for a bridge where the frequency of the bus connecting the master interface is higher or equal to the frequency of the AHB bus connecting to the bridge's slave interface. Otherwise a race condition during access collisions may cause the bridge to deadlock.	0 - 1	0
pfen	Prefetch enable. Enables read FIFO.	0 - 1	0
irqsync	Interrupt forwarding. Forward interrupts from slave interface to master interface and vice versa. 0 - no interrupt forwarding, 1 - forward interrupts 1 - 15, 2 - forward interrupts 0 - 31. 3 - forward interrupts 0 - 63 (should only be used if GRLIB has been configured to support 64 interrupt lines). Since interrupts are forwarded in both directions, interrupt forwarding should be enabled for one bridge only in a bi-directional AHB/AHB bridge.	0 - 3	0

Table 32. Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
wburst	Length of write bursts in 32-bit words. Determines write FIFO size and write burst address boundary. If the wburst generic is set to 2 the bridge will not perform write bursts over a 2x4=8 byte boundary. This generic must be set so that the buffer can contain two of the maximum sized accesses that the bridge can handle.	2 - 32	8
iburst	Instruction fetch burst length. This value is only used if the generic *ibrsten* is set to 1. Determines the length of prefetching instruction read bursts on the master side. The maximum of (iburst,rburst) determines the size of the core's read buffer FIFO.	4 - 8	8
rburst	Incremental read burst length. Determines the maximum length of incremental read burst of unspecified length (INCR) on the master interface. The maximum of *rburst* and *iburst* determine the read burst boundary. As an example, if the maximum value of these generics is 8 the bridge will not perform read bursts over a 8x4=32 byte boundary. This generic must be set so that the buffer can contain two of the maximum sized accesses that the bridge can handle. For systems where AHB masters perform fixed length burst (INCRx , WRAPx) *rburst* should not be less than the length of the longest fixed length burst.	4 - 32	8
bar0	Address area 0 decoded by the bridge's slave interface. Appears as memory address register (BAR0) on the slave interface. The generic has the same bit layout as bank address registers with bits [19:18] suppressed (use functions ahb2ahb_membar and ahb2ahb_iobar in gaisler.misc package to generate this generic).	0 - 1073741823	0
bar1	Address area 1 (BAR1)	0 - 1073741823	0
bar2	Address area 2 (BAR2)	0 - 1073741823	0
bar3	Address area 3 (BAR2)	0 - 1073741823	0
sbus	The number of the AHB bus to which the slave interface is connected. The value appears in bits [1:0] of the user-defined register 0 in the slave interface configuration record and master configuration record.	0-3	0
mbus	The number of the AHB bus to which the master interface is connected. The value appears in bits [3:2] of the user-defined register 0 in the slave interface configuration record and master configuration record.	0-3	0
ioarea	Address of the I/O area containing the configuration area for AHB bus connected to the bridge's master interface. This address appears in the bridge's slave interface user-defined register 1. In order for a master on the slave interface's bus to access the configuration area on the bus connected to the bridge's master interface, the I/O area must be mapped on one of the bridge's BARs. If this generic is set to 0, some tools, such as Frontgrade Gaisler's GRMON debug monitor, will not perform Plug'n'Play scanning over the bridge.	0 - 16#FFF#	0
ibrsten	Instruction fetch burst enable. If set, the bridge will perform bursts of *iburst* length for opcode access (HPROT[0] = '0'), otherwise bursts of *rburst* length will be used for both data and opcode accesses.	0 - 1	0

Table 32. Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
lckdac	Locked access error detection and correction. Locked accesses may lead to deadlock if a locked access is made while an ongoing read access has received a SPLIT response. The value of *lckdac* determines how the core handles this scenario: 0: Core will deadlock 1: Core will issue an AMBA ERROR response to the locked access 2: Core will allow both accesses to complete. If the core is used to create a bidirectional bridge, a deadlock condition may arise when locked accesses are made simultaneously in both directions. With *lckdac* set to 0 the core will deadlock. With *lckdac* set to a non-zero value the slave bridge will issue an ERROR response to the incoming locked access.	0 - 2	0
slvmaccsz	The maximum size of accesses that will be made to the bridge's slave interface. This value must equal *mstmaccsz* unless *rdcomb* /= 0 and *wrcomb* /= 0.	32 - 256	32
mstmaccsz	The maximum size of accesses that will be performed by the bridge's master interface. This value must equal *mstmaccsz* unless *rdcomb* /= 0 and *wrcomb* /= 0.	32 - 256	32
rdcomb	Read combining. If this generic is set to a non-zero value the core will use the master interface's maximum AHB access size when prefetching data and allow data to be read out using any other access size supported by the slave interface. If slvmaccsz > 32 and mstmaccsz > 32 and an incoming single access, or access to a non-prefetchable area, is larger than the size supported by the master interface the bridge will perform a series of small accesses in order to fetch all the data. If this generic is set to 2 the core will use a burst of small fetches. If this generic is set to 1 the bridge will not use a burst unless the incoming access was a burst. Read combining is only supported for single accesses and incremental bursts of unspecified length.	0 - 2	0
wrcomb	Write combining. If this generic is set to a non-zero value the core may assemble several small write accesses (that are part of a burst) into one or more larger accesses or assemble one or more accesses into several smaller accesses. The settings are as follows: 0: No write combining 1: Combine if burst can be preserved 2: Combine if burst can be preserved and allow single accesses to be converted to bursts (only applicable if slvmaccsz > 32) Only supported for single accesses and incremental bursts of unspecified length	0 - 2	0

Table 32. Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
combmask	Read/write combining mask. This generic determines which ranges that the core can perform read/write combining to (only available when rdcomb respectively wrcomb are non-zero). The value given for combmask is treated as a 16-bit vector with LSB bit (right-most) indicating address 0x0 - 0x10000000. Making an access to an address in an area marked as '0' in combmask is equivalent to making an access over a bridge with rdcomb = 0 and wrcomb = 0. However, combmask is not taken into account when the core performs a prefetch operation (see pfen generic). When a prefetch operation is initiated, the core will always use the maximum supported access size (when rdcomb /= 0).	0 - 16#FFFF#	16#FFFF#
allbrst	Support all burst types 2: Support all types of burst and always prefetch for wrapping and fixed length bursts. 1: Support all types of bursts 0: Only support incremental bursts of unspecified length See section 2.2.7 for more information. When allbrst is enabled, the core's read buffer (size set via rburst/iburst generics) must have at least 16 slots.	0 - 2	0
ifctrlen	Interface control enable. When this generic is set to 1 the input signals *ifctrl.mstifen* and *ifctrl.slvifen* can be used to force the AMBA slave respectively master interface into an idle state. This functionality is intended to be used when the clock of one interface has been gated-off and any stimuli on one side of the bridge should not be propagated to the interface on the other side of the bridge. When this generic is set to 0, the ifctrl.* input signals are unused.	0 - 1	0
fcfs	First-come, first-served operation. When this generic is set to a non-zero value, the core will keep track of the order of incoming accesses and handle the requests in the same order. If this generic is set to zero the bridge will not preserve the order and leave this up to bus arbitration. If FCFS is enabled the value of this generic must be higher or equal to the number of masters that may perform accesses over the bridge.	0 - NAHBMST	0
fcfsmtech	Memory technology to use for FCFS buffer. When VHDL generic *fcfs* is set to a non-zero value, the core will instantiate a 4 bit x *fcfs* buffer to keep track of the incoming master indexes. This generic decides the memory technology to use for the buffer.	0 - NTECH	0 (inferred)
scantest	Enable scan support	0 - 1	0
split	Use AMBA SPLIT responses. When this generic is set to 1 the core will issue AMBA SPLIT responses. When this generic is set to 0 the core will insert waitstates instead and may also issue AMBA RETRY responses. If this generic is set to 0, the *fcfs* generic must also be set to 0, otherwise a simulation failure will be asserted.	0 - 1	1

Table 32. Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
pipe	This setting controls the insertion of pipeline registers between the master and slave side of the bridge. *pipe* set to 0 does not include any extra pipeline registers and the incurred delays for accesses over the bridge is as described in this documentation. *pipe* set to 1 includes extra registers on all signals between the master and slave side. *pipe* set to 2 includes pipeline registers on all signals going from the slave interface to the master interface and does NOT insert extra registers on signals going from the master interface to the slave interface. *pipe* set to 3 includes pipeline registers on all signals going from the master interface to the slave interface and does NOT insert extra registers on signals going from the slave interface to the master interface. *pipe* set to 128 includes signals on a subset of the signals to prevent direct paths from the slave clock to the master side bus and from the master clock to the slave side bus.	0, 1, 128	

2.7 Signal descriptions

Table 33 shows the interface signals of the core (VHDL ports).

Table 33. Signal descriptions (VHDL ports)

Signal name	Field	Type	Function	Active
RST		Input	Reset	Low
HCLKM		Input	AHB master bus clock	-
HCLKS		Input	AHB slave bus clock	-
AHBSI	*	Input	AHB slave input signals	-
AHBSO	*	Output	AHB slave output signals	-
AHBMI	*	Input	AHB master input signals	-
AHBMO	*	Output	AHB master output signals	-
AHBSO2	*	Input	AHB slave input vector signals (on master i/f side). Used to decode cachability and prefetchability Plug&Play information on bus connected to the bridge's master interface.	-
LCKI	slck blck mlck	Input	Used in systems with multiple AHB/AHB bridges (e.g. bi-directional AHB/AHB bridge) to detect deadlock conditions. Tie to "000" in systems with only uni-directional AHB/AHB bus.	High
LCKO	slck blck mlck	Output	Indicates possible deadlock condition	High
IFCTRL	mstifen	Input	Enable master interface. This input signal is unused if the VHDL generic *ifctrlen* is 0. If VHDL generic *ifctrlen* is 1 this signal must be set to '1' in order to enable the core's AMBA master interface, otherwise the master interface will always be idle and will not respond to stimuli on the core's AMBA slave interface. This signal is intended to be used to keep the core's master interface in a good state when the core's slave interface clock has been gated off. Care should be taken to ensure that the bridge is idle when the master interface is disabled.	High
	slvifen	Input	Enable slave interface. This input signal is unused if the VHDL generic *ifctrlen* is 0. If VHDL generic *ifctrlen* is 1 this signal must be set to '1' in order to enable the core's AMBA slave interface, otherwise the interface will always be ready and the bridge will not propagate stimuli on the core's AMBA slave interface to the core's AMBA master interface. This signal is intended to be used to keep the slave interface in a good state when the core's master interface clock has been gated off. Care should be taken to ensure that the bridge is idle when the slave interface is disabled.	High

* see GRLIB IP Library User's Manual

2.8 Library dependencies

Table 34 shows the libraries used when instantiating the core (VHDL libraries).

Table 34. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions
GAISLER	MISC	Component	Component declaration

2.9 Instantiation

GRLIB contains an example design with AHB2AHB and LEON processors: *designs/leon3-ahb2ahb* (only available in commercial distributions). The LEON/GRLIB Configuration and Development Guide contains more information on how to use the bridge to create multi-bus systems.

3 AHB2AXIB - AHB to AXI Bridge

3.1 Overview

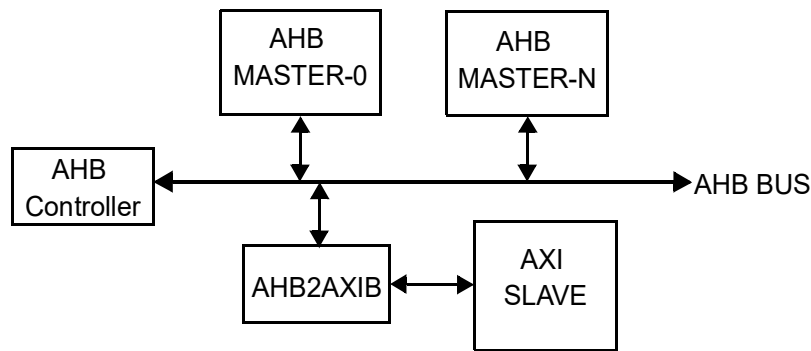
The AHB2AXIB bridge allows to access an AXI3 or AXI4 slave from an AHB bus through an AHB slave interface (see Fig. 2). It can also be used to connect a standalone AHB master to an AXI slave (see Fig. 3). The bridge has an AHB slave interface on the AHB side and AXI3 or AXI4 master interface on the AXI side. The bridge has optional read prefetching and write buffering features in order to improve the latency of burst operations. The AHB2AXIB bridge is not compatible with the AHB2AHB bridge which is a part of GRLIB IP library.


Figure 2. An AXI slave connected to the AHB bus through AHB2AXIB bridge
Figure 3. A standalone AHB master is connected to an AXI slave through AHB2AXIB bridge

3.1.1 AHB support

The AHB2AXIB bridge currently supports the following features of the AHB protocol:

Transfer Type: IDLE, NONSEQ, SEQ

Burst Operation: SINGLE, INCR, INCR4, INCR8, INCR16

Data-width: 32-bit, 64-bit, 128-bit, 256-bit

Transfer Size: All possible transfer sizes up to the selected data-width are supported.

Response: AXI read error response is translated to AHB read error.

Unsupported AHB Features:

The following features of AHB protocol are not supported by the AHB2AXIB bridge.

- BUSY transfer type : Behavior of the AHB2AXIB bridge is unpredictable when a BUSY transaction is received hence the AHB2AXIB bridge can not be used with the AHB2AHB bridge which is a part of GRLIB IP library.

- Locked transfers : Locked transfers are ignored by the AHB2AXIB bridge.

Unused AHB Features:

- RETRY and SPLIT responses ; AHB2AXIB bridge does not generate these response types.

- Write error response : Due to the difference between the write error handling of AXI and AHB protocol the write errors received from the AXI side is not propagated.

3.2 Operation

3.2.1 Read Prefetching and Write Buffering and Postponed Writes

The bridge has the feature of read prefetching and write buffering for the AHB bursts in which the transfer size (HSIZE) is equal to the selected data-width. For the transfer sizes that are narrower than the data-width it can still support read prefetching and write buffering if byte invariant big endian mode is used. Otherwise each beat in the burst treated as a single transaction on the AXI side. Read prefetching and write buffering reduces the latency of undefined length burst operations since otherwise each beat in an undefined length burst has to be treated as an independent AXI transaction with a length of one.

3.2.2 Read Prefetching

Read prefetch number that is set through *rprefetch_num* generic determines the length of the AXI transaction(s) that is generated when an undefined length AHB read burst is encountered. When an undefined length AHB read burst is encountered, an AXI transaction is generated with a length of *rprefetch_num*. If the AHB read burst has less beats than *rprefetch_num* then dummy reads are generated on the AXI side to complete the AXI transaction. If the AHB read burst has more beats than *rprefetch_num* then a new AXI transaction is generated with a number of beats equal to *rprefetch_num* and this scheme continuous until the AHB burst ends. If the start address of a burst is not aligned to the prefetch boundary then the initial prefetch has less number of beats in order to align the upcoming prefetches. For example given a 32-bit (4 Byte) data-width and a *rprefetch_num* of 16 (16*4=64 Bytes) if the least significant bits of the initial burst address corresponds to byte 48, then the initial prefetch length is 4 ((64-48)/4). This way the upcoming prefetches are always aligned to 64 Byte boundary. If a new AHB burst is encountered during dummy read operations on the AXI side, the AHB burst is stalled until the current AXI transaction ends.

The maximum read prefetch number depends on the AXI protocol. For AXI3 the maximum number is 16, and for AXI4 it can be up to 256 depending on the selected data-width. Prefetch length can only be a power of two and if it is not set to be a power of two then the number is floored to the closest power of two automatically. For fixed length AHB bursts (single, INCR4, INCR8, INCR16) the length of the AXI burst is equal to the AHB burst length since in those cases the burst length is known at the beginning of the burst. The bridge will not issue a new AXI transaction while dummy cycles are inserted hence there is a trade-off for performance when selecting the read prefetch number.

3.2.3 Write Buffering

Write buffering gathers a number of consecutive beats in a AHB write burst and initiates an AXI transaction. A generic called *wbuffer_num* determines the maximum number of AHB write burst beats that will be gathered before an AXI write burst transaction is generated. If the number of beats

in the AHB write burst is less than *wbuffer_num* then the AXI write transaction starts after detecting the last beat in the burst (transition from SEQ to IDLE). If the number of beats are higher than *wbuffer_num* then the first AXI transaction is generated once *wbuffer_num* number of beats are buffered. It should be noted that once an AXI write transaction is generated and AHB write burst still continues then AXI transaction and buffering of the next write batch happens in parallel to improve the latency. This scheme continuous until the AHB burst is ended. The last data beat in the burst is always acknowledged with OKAY response immediately when it is buffered in the bridge. See section 3.2.5 for more detailed information.

Write buffer length can only be a power of two, and if it is not set to be a power of two then the number is floored to the closest power of two automatically. The maximum number has the same constraints as the read prefetch number. A synchronous memory width one read and write port is generated for write buffering. The size of the memory is determined by the write buffer length. The type of the memory can be configured with a generic also. The first AXI write transaction will not start until the buffer is filled or the AHB transaction has written the last beat in the burst. As a result there is a trade-off for performance while selecting the write buffer length which depends on the AXI slave behavior.

Write transactions which has the property of HBURST_SINGLE does not go through the buffer and has a very low latency. This is intended to improve the performance of LEON3/LEON4 since the processors are write-through and writes are done with HBURST_SINGLE property (apart from the store double in LEON3).

3.2.4   Narrow Sized Transactions

When an AHB transaction is encountered which has a narrower size (HSIZE) than the data-width of the AHB2AXIB bridge, the behavior is configurable through the generics depending on the selected endianness on the AXI side. When the endianness mode on the AXI side is set as little-endian than each beat in the narrow sized AXI transaction is treated as single transaction on the AXI side. When the endinness mode on the AXI side is set as byte invariant big-endian than the *narrow_acc_mode* generic determines the behaviour. If the *narrow_acc_mode* generic is set as zero than each beat in the narrow sized AXI transaction is treated as single transaction on the AXI side. If it is set to 1 then a corresponding narrow sized AXI burst is generated with read prefetching and write buffering. But it should be noted that the length of the narrow sized burst will be determined by *rprefetch_num* and *wbuffer_num* generics and it is same as for all access sizes. When the endianness on the AXI side is set ass little-endian then *narrow_acc_mode* generic must be set to zero. See sec. 3.2.6 for more detailed information about endianness modes.

3.2.5   Postponed Writes

Since the write response from AXI is not propagated to AHB side the last beat in the AHB write transaction is acknowledged immediately when it is buffered in the bridge. Hence the corresponding AXI write transaction will finish after the AHB write transaction is completed. The transaction order on the AHB bus side will be preserved because the bridge will block an AHB read, if there is an AXI write transaction is ongoing, until the AXI write response is received. But if a transaction order has to be preserved between the AHB side of a AHB2AXIB bridge and an independent AXI master that accesses to the same AXI slave then special considerations in software might be needed.

The bridge can have more than one outstanding writes on the AXI bus to improve the performance. The number of outstanding writes is determined by "ostand_writes" generic. As soon as outstanding write limit is not reached the bridge will continue operation after the last write in the AXI burst is acknowledged. The write acknowledgment channel is tracked in the background to confirm the overall write transaction. But if the bridge receives a READ operation when an outstanding write opera-

tion exists it will stall until all the outstanding writes are cleared. A write operation will cause a stall only if outstanding write limit is reached.

3.2.6 Endianness

The AHB side of AHB2AXIB can be either set to be little-endian or big-endian through "ahb_endianness" generic.

When AHB2AXIB is set to be little-endian then data is mapped directly to AXI since AXI is little-endian also.

When AHB2AXIB is set to be big-endian, the endianness on the AXI side is configurable through the *endianness_mode* generic.

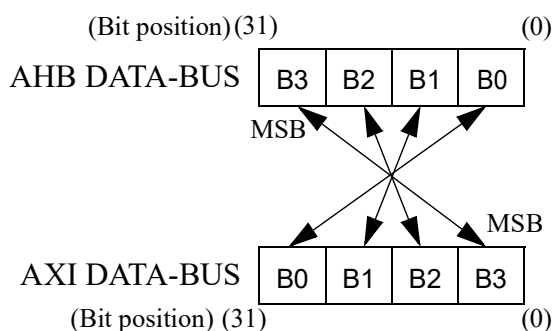
When *endianness_mode* generic is set to zero a byte-invariant big-endian endianness mode is used on the AXI side. In order to translate big-endian AHB to byte-invariant big-endian AXI the byte order is reversed (see Fig. 4). No address translation occurs inside the adapter in this mode.


Figure 4. Big-endian AHB to byte-invariant Big-endian AXI translation (32-bit data-width)

When *endianness_mode* generic is set to one then big-endian AHB is translated to little-endian AXI. In order to achieve this the byte order is preserved but the address is translated from big-endian representation to little-endian representation when a narrow sized transaction is encountered (See Fig. 5 for an example with 32-bit data-bus width.).

The address translation formula for 32-bit, 64-bit, 128-bit and 256-bit data-bus widths are following:

32-bit data bus width:

if *HSIZE* < "010" :

   axi_address(1:0) = ("100" - "1"<<"*HSIZE*" - ahb_address(1:0))(1:0)

otherwise:

   axi_address(1:0) = ahb_address(1:0)

64-bit data bus width:

if *HSIZE* < "011" :

   axi_address(2:0) = ("1000" - "1"<<"*HSIZE*" - ahb_address(2:0))(2:0)

otherwise:

   axi_address(2:0) = ahb_address(2:0)

128-bit data bus width:

if *HSIZE* < "100" :

axi_address(3:0) = ("10000" - "1"<<"*HSIZE*" - ahb_address(3:0))(3:0)

otherwise:

axi_address(3:0) = ahb_address(3:0)

256-bit data bus width:

if *HSIZE* < "101" :

axi_address(4:0) = ("100000" - "1"<<"*HSIZE*" - ahb_address(4:0))(4:0)

otherwise:

axi_address(4:0) = ahb_address(4:0)

3.3   AXI AxPROT and AxCACHE Translations

The AxPROT and AxCACHE signals are translated partly according to the HPROT signal of AHB transactions. The full list of translation can be seen from Table 35.

Table 35. AxPROT and AxCACHE translations

AXI signal	Assignment
AxCACHE[3]	always logic '0'
AxCACHE[2]	always logic '0'
AxCACHE[1]	HPROT[3]
AxCACHE[0]	HPROT[2]
AxPROT[2]	not (HPROT[0])
AxPROT[1]	See configuration options (Table. 36)
AxPROT[0]	HPROT[1]

3.4 Implementation

3.4.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). All registers are reset.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

3.4.2 Endianness

The AHB endianness can be configured with the *ahb_endianness* VHDL generic while the AXI endianness can be configured with the *endianness_mode* VHDL generic. The *ahb_endianness* VHDL generic is by default set to the value of the GRLIB configuration package (see GRLIB User's Manual).

3.5 Configuration Options

Table 36. Configuration options (both AHB2AXI3B and AHB2AXI4B)

Generic	Function	Allowed range	Default
aximid	AXI master ID used for Read and Write transactions	0 - 15	0
always_secure	When set to 1 the AxPROT[1] bit is tied to logic '0' (always secure access), when set to 0 the AxPROT[1] bit is tied to logic '1' (always unsecure access).	0-1	1
ahb_endianness	Determines the endianness of the AHB side of the bridge. 0 -> Big-endian 1 -> Little-endian The default value is taken from the endianness generic set in grlib configuration. "grlib_little_endian"	0-1	GRLIB
endianness_mode	Determines the endianness mode (see section 3.2.6 for more detail) 0 -> Big-endian AHB to byte-invariant big-endian AXI 1 -> Big-endian AHB to little-endian AXI Set it to 0 for little-endian "ahb_endianness" mode	0-1	0
narrow_acc_mode	Determines if bursts with narrow access size than the data-bus width should be directly translated to narrow access size AXI bursts or single AXI transactions with narrow access size. (see section 3.2.4 for more detail) 0-> Each beat in the narrow sized AHB burst is treated as single transaction on the AXI side. 1-> Narrow sized AHB bursts are translated to narrow sized AXI bursts. (supported only when *endianness_- mode* generic is 0) **Note:** This generic must be set to 0 if *endianness_mode* is set to 1.	0-1	0
vendor	GRLIB plug&play vendor ID		GAISLER
device	GRLIB plug&play device ID		AHB2AXI
bar0	Address area 0 decoded by the bridge's slave interface. Appears as memory address register (BAR0) on the slave interface. The generic has the same bit layout as bank address registers with bits [19:18] suppressed (use functions ahb2ahb_membar and ahb2ahb_iobar in gaisler.misc package to generate this generic).	0 - 1073741823	0
bar1	Address area 1 (BAR1)	0 - 1073741823	0
bar2	Address area 2 (BAR2)	0 - 1073741823	0
bar3	Address area 3 (BAR2)	0 - 1073741823	0

Table 37. Configuration options specific for AXI3 (AHB2AXI3B)

Generic	Function	Allowed range	Default
wbuffer_num	Write-buffer length which determines the memory size also.	1-16	8
rprefetch_num	Read prefetch length.	1-16	8

Table 38. Configuration options specific for AXI4 (AHB2AXI4B)

Generic	Function	Allowed range	Default
wbuffer_num	Write-buffer length which determines the memory size also.	1-256 for data-width of 32-bit, 1-128 for data-width of 64-bit 1-64 for data-width of 128-bit 1-32 for data-width of 256-bit	8
rprefetch_num	Read prefetch length.	1-256 for data-width of 32-bit, 1-128 for data-width of 64-bit 1-64 for data-width of 128-bit 1-32 for data-width of 256-bit	8
ostand_writes	Number of outstanding writes allowed on the AXI bus. See section 3.2.5 for more details.	1-16	4

3.6 Signal descriptions

Table 39 shows the interface signals of the core (VHDL ports).

Table 39. Signal descriptions (VHDL ports)

Signal name	Field	Type	Function	Active
RST		Input	Reset	Low
CLK		Input	AHB & AXI bus clock	-
AHBSI	*	Input	AHB slave input signals	-
AHBSO	*	Output	AHB slave output signals	-

3.7 Library dependencies

Table 40 shows the libraries used when instantiating the core (VHDL libraries).

Table 40. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA & AXI signal definitions
GAISLER	AXI	Component	Component declaration

3.8 Instantiation

The instantiation of the AHB2AXIB bridge depends on the AXI protocol type. There are two components called AHB2AXI3B which is built for AXI3 protocol and AHB2AXI4B which is built for AXI4 protocol. The difference between these two components are the AXI master output signals and the maximum values that can be set for read prefetching and write buffering.

3.8.1 AHB2AXIB bridge is used to connect an AXI slave to an AHB bus

```
library ieee;
use ieee.std_logic_1164.all;

library grlib;
use grlib.amba.all;
library gaisler;
use gaisler.axi.all;

entity ahb2axib_ex is
  port (
    rstn  : in  std_logic;
    clk   : in  std_logic;
    .
    .
    .
    aximi : in  axi_somi_type;
    aximo : out axi4_mosi_type;
);
end;

architecture rtl of ahb2axib_ex is
.
.
constant hindex_ahb2axi4b : integer := 2;

begin

.
.
ahbctrl & other components
.
.

bridge:ahb2axi4b
generic map (
 hindex => hindex_ahb2axi4b,
 aximid => 0
)
port map (
 rstn => rstn,
 clk => clk,
 ahbsi => ahbsi,
 ahbso => ahbso(hindex_ahb2axi4b),
 aximi => aximi,
 aximo => aximo);
```

3.8.2 AHB2AXIB bridge is used to connect a standalone AHB master to an AXI slave.

If AHB2AXIB bridge is intended to be used to connect a standalone AHB master to an AXI slave then the following assignments are needed for correct operations:

The *hsel* input of the AHB2AXIB must be assigned to an array of (others=>'1') so that it works regardless of the assigned *hindex* value.

The *hready* input of the AHB2AXIB must be connected to the *hready* output of the AHB2AXIB.

The *hgrant* input of the AHB master must be assigned to an array of (others=>'1') so that it works regardless of the assigned *hindex* value.

4 AHBM2AXI - AHB Master to AXI Adapter

4.1 Overview

The AHBM2AXI adapter allows a single AHB master to be used as an AXI3 or AXI4 master. The adapter has an AHB slave interface on the AHB side and AXI3 or AXI4 master interface on the AXI side (see Fig. 6). The adapter has optional read prefetching and write buffering features in order to improve the latency of burst operations. The adapter is not compatible with AHB2AHB and GRD-MAC components which is a part of GRLIB IP library.
Figure 6. A standalone AHB master is connected to an AXI slave through AHBM2AXI adapter

4.1.1 AHB support

The AHBM2AXI adapter currently supports the following features of the AHB protocol:

Transfer Type: IDLE, NONSEQ, SEQ

Burst Operation: SINGLE, INCR, INCR4, INCR8, INCR16

Data-width: 32-bit, 64-bit, 128-bit, 256-bit

Transfer Size: All possible transfer sizes up to the selected data-width are supported.

Response: AXI read and write error responses are translated to AHB read and write errors.

Unsupported AHB Features:

The following features of AHB protocol are not supported by the AHBM2AXI adapter.

- BUSY transfer type : Behavior of the AHBM2AXI adapter is unpredictable when a BUSY transaction is received hence the AHBM2AXI adapter can not be used with the AHB2AHB bridge which is a part of GRLIB IP library.

- Locked transfers : Locked transfers are ignored by the AHBM2AXI adapter.

Unused AHB Features:

- RETRY and SPLIT responses : The adapter does not generate these response types.

4.2 Special Considerations

There is a combinatorial path between the incoming HTRANS signal and outgoing HREADY signal on the AHB side of the adapter, in order to allow write-buffering and write response propagation at the same time. As a result, this component is only intended to connect to a single IP core with an AHB master interface in which HTRANS output does not depend on the incoming HREADY signal combinatorially. Propagating the write response correctly is important to make sure that the intended transaction ordering has been met, meaning the AHB master that is connected to the adapter receives the acknowledgment for the last write beat in the burst when the write response has been received on the

AXI side. Being able to propagate correct write response can also simplify the software development. The AHBM2AXI adapter can not be used with the GRDMAC IP core which is a part of GRLIB IP library.

4.3   Operation

4.3.1   Read Prefetching and Write Buffering

The adapter has the feature of read prefetching and write buffering for the AHB bursts in which the transfer size (HSIZE) is equal to the selected data-width. For the transfer sizes that are narrower than the data-width each beat in the burst treated as a single transaction on the AXI side. Read prefetching and write buffering reduces the latency of undefined length burst operations since otherwise each beat in an undefined length burst has to be treated as an independent AXI transaction with a length of one.

4.3.2   Read Prefetching

Read prefetch number that is set through *rprefetch_num* generic determines the length of the AXI transaction(s) that is generated when an undefined length AHB read burst is encountered. When an undefined length AHB read burst is encountered, an AXI transaction is generated with a length of *rprefetch_num*. If the AHB read burst has less beats than *rprefetch_num* then dummy reads are generated on the AXI side to complete the AXI transaction. If the AHB read burst has more beats than *rprefetch_num* then a new AXI transaction is generated with a number of beats equal to *rprefetch_-num* and this scheme continuous until the AHB burst ends. If the start address of a burst is not aligned to the prefetch boundary then the initial prefetch has less number of beats in order to align the upcoming prefetches. For example given a 32-bit (4 Byte) data-width and a *rprefetch_num* of 16 (16*4=64 Bytes) if the least significant bits of the initial burst address corresponds to byte 48, then the initial prefetch length is 4 ((64-48)/4). This way the upcoming prefetches are always aligned to 64 Byte boundary. If a new AHB burst is encountered during dummy read operations on the AXI side, the AHB burst is stalled until the current AXI transaction ends.

The maximum read prefetch number depends on the AXI protocol. For AXI3 the maximum number is 16, and for AXI4 it can be up to 256 depending on the selected data-width. Prefetch length can only be a power of two and if it is not set to be a power of two then the number is floored to the closest power of two automatically. For fixed length AHB bursts (single, INCR4, INCR8, INCR16) the length of the AXI burst is equal to the AHB burst length since in those cases the burst length is known at the beginning of the burst. The adapter will not issue a new AXI transaction while dummy cycles are inserted hence there is a trade-off for performance when selecting the read prefetch number.

4.3.3   Write Buffering

Write buffering gathers a number of consecutive beats in a AHB write burst and initiates an AXI transaction. A generic called *wbuffer_num* determines the maximum number of AHB write burst beats that will be gathered before an AXI write burst transaction is generated. If the number of beats in the AHB write burst is less than *wbuffer_num* then the AXI write transaction starts after detecting the last beat in the burst (transition from SEQ to IDLE). If the number of beats are higher than *wbuffer_num* then the first AXI transaction is generated once *wbuffer_num* number of beats are buffered. It should be noted that once an AXI write transaction is generated and AHB burst still continues then AXI transaction and buffering for the next write batch happens in parallel to minimize the latency. This scheme continuous until the AHB burst is ended. When the last data beat of the burst is reached the HREADY on the AHB side is asserted once the write response is received from the AXI side. The write buffering feature is used for the fixed size burst also in the same way as undefined length bursts.

Write buffer length can only be a power of two, and if it is not set to be a power of two then the number is floored to the closest power of two automatically. The maximum number has the same constraints as the read prefetch number. A synchronous memory width one read and write port is generated for write buffering. The size of the memory is determined by the write buffer length. The type of the memory can be configured with a generic also. The first AXI write transaction will not start until the buffer is filled or the AHB transaction has written the last beat in the burst. As a result there is a trade-off for performance while selecting the write buffer length which depends on the AXI slave behavior.

4.3.4 Endianness

The AHB side of AHB2AXIB can be either set to be little-endian or big-endian through "ahb_endianness" generic.

When AHB2AXIB is set to be little-endian then data is mapped directly to AXI since AXI is little-endian also.

When AHB2AXIB is set to be big-endian, the endianness on the AXI side is configurable through the *endianness_mode* generic.

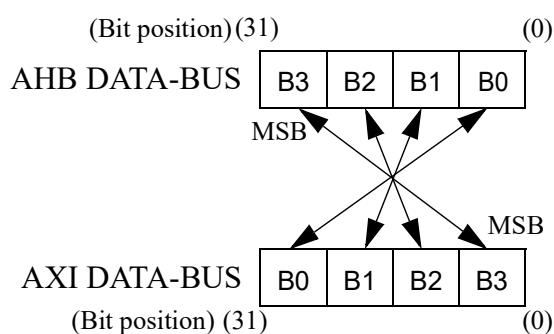
When *endianness_mode* generic is set to zero a byte-invariant big-endian endianness mode is used on the AXI side. In order to translate big-endian AHB to byte-invariant big-endian AXI the byte order is reversed (see Fig. 7). No address translation occurs inside the adapter in this mode.


Figure 7. Big-endian AHB to byte-invariant Big-endian AXI translation (32-bit data-width)

When *endianness_mode* generic is set to one then big-endian AHB is translated to little-endian AXI. In order to achieve this the byte order is preserved but the address is translated from big-endian representation to little-endian representation when a narrow sized transaction is encountered (See Fig. 8 for an example with 32-bit data-bus width.).

The address translation formula for 32-bit, 64-bit, 128-bit and 256-bit data-bus widths are following:

32-bit data bus width:

if *HSIZE* < "010" :

    axi_address(1:0) = ("100" - "1"<<"*HSIZE*" - ahb_address(1:0))(1:0)

otherwise:

    axi_address(1:0) = ahb_address(1:0)

64-bit data bus width:

if *HSIZE* < "011" :

    axi_address(2:0) = ("1000" - "1"<<"*HSIZE*" - ahb_address(2:0))(2:0)

otherwise:

   axi_address(2:0) = ahb_address(2:0)

128-bit data bus width:

if *HSIZE* < "100" :

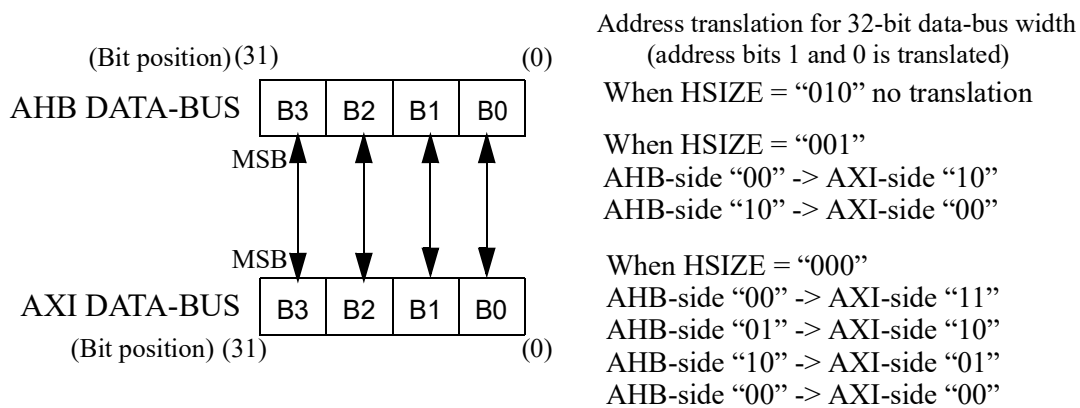
   axi_address(3:0) = ("10000" - "1"<<"*HSIZE*" - ahb_address(3:0))(3:0)

otherwise:

   axi_address(3:0) = ahb_address(3:0)

256-bit data bus width:

if *HSIZE* < "101" :

   axi_address(4:0) = ("100000" - "1"<<"*HSIZE*" - ahb_address(4:0))(4:0)


otherwise:

   axi_address(4:0) = ahb_address(4:0)

Address translation for 32-bit data-bus width
(address bits 1 and 0 is translated)

When HSIZE = "010" no translation

When HSIZE = "001"
AHB-side "00" -> AXI-side "10"
AHB-side "10" -> AXI-side "00"

When HSIZE = "000"
AHB-side "00" -> AXI-side "11"
AHB-side "01" -> AXI-side "10"
AHB-side "10" -> AXI-side "01"
AHB-side "00" -> AXI-side "00"

Figure 8. Big-endian AHB to little-endian AXI through address translation (32-bit data-width)

4.4   AXI AxPROT and AxCACHE Translations

The AxPROT and AxCACHE signals are translated partly according to the HPROT signal of AHB transactions. The full list of translation can be seen from Table 41.

Table 41. AxPROT and AxCACHE translations

AXI signal	Assignment
AxCACHE[3]	always logic '0'
AxCACHE[2]	always logic '0'
AxCACHE[1]	HPROT[3]
AxCACHE[0]	HPROT[2]
AxPROT[2]	not (HPROT[0])
AxPROT[1]	See configuration options (Table. 42)
AxPROT[0]	HPROT[1]

4.5   Implementation

4.5.1   Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). All registers are reset.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

4.5.2   Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian AHB systems while the AXI endianness can be configured with the *endianness_mode* generic.

4.6   Configuration Options

Table 42. Configuration options (both AHBM2AXI3 and AHBM2AXI4)

Generic	Function	Allowed range	Default
aximid	AXI master ID used for Read and Write transactions	0 - 15	0
always_secure	When set to 1 the AxPROT[1] bit is tied to logic '0' (always secure access), when set to 0 the AxPROT[1] bit is tied to logic '1' (always unsecure access).	0-1	1
ahb_endianness	Determines the endianness of the AHB side of the bridge. 0 -> Big-endian 1 -> Little-endian The default value is taken from the endianness generic set in grlib configuration. "grlib_little_endian"	0-1	GRLIB
endianness_mode	Determines the endianness mode (see section 4.3.4 for more detail) 0 -> Big-endian AHB to byte-invariant big-endian AXI 1 -> Big-endian AHB to little-endian AXI	0-1	0

Table 43. Configuration options specific for AXI3 (AHBM2AXI3)

Generic	Function	Allowed range	Default
wbuffer_num	Write-buffer length which determines the memory size also.	1-16	8
rprefetch_num	Read prefetch length.	1-16	8

Table 44. Configuration options specific for AXI4 (AHBM2AXI4)

Generic	Function	Allowed range	Default
wbuffer_num	Write-buffer length which determines the memory size also.	1-256 for data-width of 32-bit, 1-128 for data-width of 64-bit 1-64 for data-width of 128-bit 1-32 for data-width of 256-bit	8
rprefetch_num	Read prefetch length.	1-256 for data-width of 32-bit, 1-128 for data-width of 64-bit 1-64 for data-width of 128-bit 1-32 for data-width of 256-bit	8

4.7 Signal descriptions

4.8 Library dependencies

Table 46 shows the libraries used when instantiating the core (VHDL libraries).

Table 46. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA & AXI signal definitions
GAISLER	AXI	Component	Component declaration

4.9 Instantiation

The instantiation of the AHBM2AXI adapter depends on the AXI protocol type. There are two components called AHBM2AXI3 which is built for AXI3 protocl and AHBM2AXI4 which is built for AXI4 protocol. The difference between these two components are the AXI master output signals and the maximum values that can be set for read prefetching and write buffering.

Since AHBM2AXI adapter is intended to be used for only a single core, a transaction is sampled and evaluated directly on the rising edge of the clock, the "*hsel*" and "*hready*" inputs are ignored by the AHBM2AXI adapter. The grant signal for the AHB master that is connected to the adapter should be hardwired to logic 1.

Following is an example in which a component with an ahb master interface called "*ahbm_ex*" is connected to the AHBM2AXI4 adapter which can act as an master for AXI4 protocol.

```
library ieee;
use ieee.std_logic_1164.all;

library grlib;
use grlib.amba.all;
library gaisler;
use gaisler.axi.all;

entity ahbm2axi4_ex is
  port (
    rstn  : in  std_logic;
```

```
    clk   : in  std_logic;
    aximi : in  axi_somi_type;
    aximo : out axi4_mosi_type
  );
end;

5 AHBBRIDGE - Bi-directional AHB/AHB bridge

5.1 Overview

A pair of uni-directional bridges (AHB2AHB) can be instantiated to form a bi-directional bridge. The bi-directional AHB/AHB bridge (AHBBRIDGE) instantiates two uni-directional bridges that are configured to suit the bus architecture shown in figure 9. The bus architecture consists of two AHB buses: a high-speed AHB bus hosting LEON3 CPU(s) and an external memory controller and a low-speed AHB bus hosting communication IP-cores.

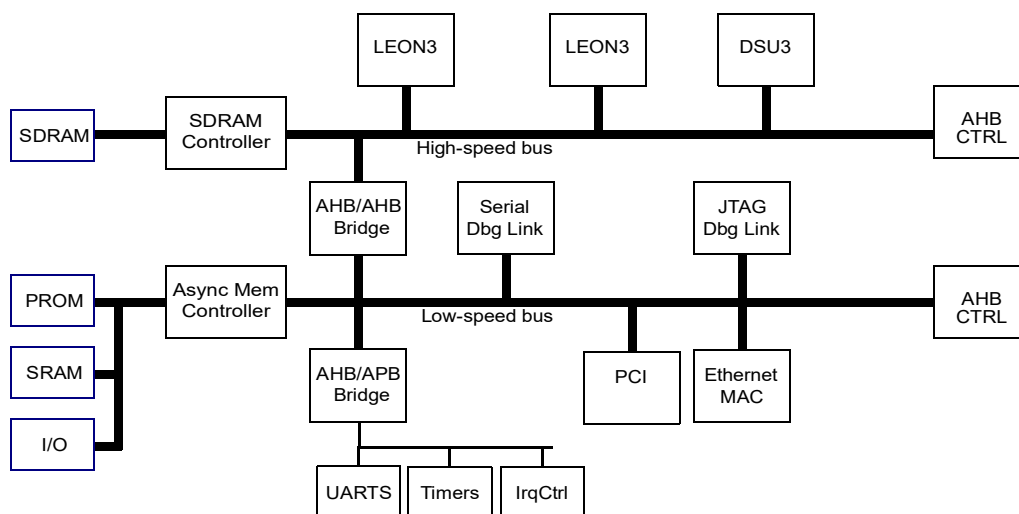
Note: For other architectures, a more general bi-directional bridge that is more suitable can be created by instantiating two uni-directional AHB to AHB bridges (see AHB2AHB core). AHBBRIDGE is not suitable for LEON4 systems and for other systems with wide AHB buses.


Figure 9. LEON3 system with a bi-directional AHB/AHB bridge

5.2 Operation

5.2.1 General

The AHB/AHB bridge is connected to each AHB bus through a pair consisting of an AHB master and an AHB slave interface. The address space occupied by the AHB/AHB bridge on each bus is determined by Bank Address Registers which are configured through VHDL generics. The bridge is capable of handling single and burst transfers in both directions. Internal FIFOs are used for data buffering. The bridge implements the AMBA SPLIT response to improve AHB bus utilization. For more information on AHB transfers please refer to the documentation for the uni-directional AHB/AHB bridge (AHB2AHB).

The requirements on the two bus clocks are that they are synchronous. The two uni-directional bridges forming the bi-directional AHB/AHB bridge are configured asymmetrically. Configuration of the bridge connecting high-speed bus with the low-speed bus (down bus) is optimized for the bus traffic generated by the LEON3 CPU since the CPU is the only master on the high-speed bus (except for the bridge itself). Read transfers generated by the CPU are single read transfers generated by single load instructions (LD), read bursts of length two generated by double load instructions (LDD) or incremental read bursts of maximal length equal to cache line size (4 or 8 words) generated during instruction cache line fill. The size of the read FIFO for the down bridge is therefore configurable to 4 or 8 entries which is the maximal read burst length. If a read burst is an instruction fetch (indicated on AHB HPROT signal) to a prefetchable area the bridge will prefetch data to the end of a instruction

cache line. If a read burst to a prefetchable area is a data access, two words will be prefetched (this transfer is generated by the LDD instruction). The write FIFO has two entries capable of buffering the longest write burst (generated by the STD instruction). The down bridge also performs interrupt forwarding, interrupt lines 1-15 on both buses are monitored and an interrupt on one bus is forwarded to the other one.

Since the low-speed bus does not host a LEON3 CPU, all AHB transfers forwarded by the uni-directional bridge connecting the low-speed bus and the high-speed bus (up bridge) are data transfers. Therefore the bridge does not make a distinction between instruction and data transfers. The size of the read and write FIFOs for this bridge is configurable and should be set by the user to suite burst transfers generated by the cores on the low-speed bus.

Note that the bridge has been optimized for a LEON3 system with a specific set of masters and a specific bus topology. Therefore the core may not be suitable for a design containing later versions of the LEON processor or other masters. In general it is not recommended instantiate the AHBBRIDGE core and instead instantiate two uni-directional AHB to AHB bridges (AHB2AHB cores) with configurations tailored for a specific design.

5.2.2 Deadlock conditions

A deadlock situation can occur if the bridge is simultaneously accessed from both buses. The bridge contains deadlock detection logic which will resolve a deadlock condition by giving a RETRY response on the low-speed bus.

There are several deadlock conditions that can occur with locked accesses. If the VHDL generic *lckdac* is 0, the bridge will deadlock if two simultaneous accesses from both buses are locked, or if a locked access is made while the bridge has issued a SPLIT response to a read access and the splitted access has not completed. If *lckdac* is greater than 0, the bridge will resolve the deadlock condition from two simultaneous locked accesses by giving an ERROR response on the low-speed bus. If *lckdac* is 1 and a locked access is made while the bridge has issued a SPLIT response to a read access, the bridge will respond with ERROR to the incoming locked access. If *lckdac* is 2 the bridge will allow both the locked access and the splitted read access to complete. Note that with *lckdac* set to 2 and two incoming locked accesses, the access on the low-speed bus will still receive an ERROR response.

5.2.3 Read and write combining

The bridge can be configured to support read and write combining so that prefetch operations and write bursts are always performed with the maximum access size possible on the master interface. Please see the documentation for the uni-directional AHB/AHB bridge (AHB2AHB) for a description of read and write combining and note that the same VHDL generics are used to specify both the maximum master and maximum slave access size on the bi-directional AHB/AHB bridge.

5.2.4 Endianness

The core is designed for big-endian systems

5.3 Registers

The core does not implement any registers.

5.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x020. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

5.5 Implementation

See documentation for AHB2AHB.

5.6 Configuration options

Table 47 shows the configuration options of the core (VHDL generics).

Table 47. Configuration options

Generic	Function	Allowed range	Default
memtech	Memory technology	-	0
ffact	Frequency ratio	1 -	2
hsb_hsindex	AHB slave index on the high-speed bus	0 to NAHBMAX-1	0
hsb_hmindex	AHB master index on the high-speed bus	0 to NAHBMAX-1	0
hsb_iclsize	Cache line size (in number of 32-bit words) for CPUs on the high-speed bus. Determines the number of the words that are prefetched by the bridge when CPU performs instruction bursts.	4, 8	8
hsb_bank0	Address area 0 mapped on the high-speed bus and decoded by the bridge's slave interface on the low-speed bus. Appears as memory address register (BAR0) on the bridge's low-speed bus slave interface. The generic has the same bit layout as bank address registers with bits [19:18] suppressed (use functions ahb2ahb_membar and ahb2ahb_iobar in gaisler.misc package to generate this generic).	0 - 1073741823	0
hsb_bank1	Address area 1 mapped on the high-speed bus	0 - 1073741823	0
hsb_bank2	Address area 2 mapped on the high-speed bus	0 - 1073741823	0
hsb_bank3	Address area 3 mapped on the high-speed bus	0 - 1073741823	0
hsb_ioarea	Address of high-speed bus I/O area that contains the high-speed bus configuration area. Will appear in the bridge's user-defined register 1 on the low-speed bus. Note that to allow low-speed bus masters to read the high-speed bus configuration area, the area must be mapped on one of the *hsb_bank* generics.	0 - 16#FFF#	0
lsb_hsindex	AHB slave index on the low-speed bus	0 to NAHBMAX-1	0
lsb_hmindex	AHB master index on the low-speed bus	0 to NAHBMAX-1	0
lsb_rburst	Size of the prefetch buffer for read transfers initiated on the low-speed-bus and crossing the bridge.	16, 32	16
lsb_wburst	Size of the write buffer for write transfers initiated on the low-speed bus and crossing the bridge.	16, 32	16
lsb_bank0	Address area 0 mapped on the low-speed bus and decoded by the bridge's slave interface on the high-speed bus. Appears as memory address register (BAR0) on the bridge's high-speed bus slave interface. The generic has the same bit layout as bank address registers with bits [19:18] suppressed (use functions ahb2ahb_membar and ahb2ahb_iobar in gaisler.misc package to generate this generic).	0 - 1073741823	0
lsb_bank1	Address area 1 mapped on the low-speed bus	0 - 1073741823	0
lsb_bank2	Address area 2 mapped on the low-speed bus	0 - 1073741823	0
lsb_bank3	Address area 3 mapped on the low-speed bus	0 - 1073741823	0

Table 47. Configuration options

Generic	Function	Allowed range	Default
lsb_ioarea	Address of low-speed bus I/O area that contains the low-speed bus configuration area. Will appear in the bridge's user-defined register 1 on the high-speed bus. Note that to allow high-speed bus masters to read the low-speed bus configuration area, the area must be mapped on one of the *lsb_bank* generics.	0 - 16#FFF#	0
lckdac	Locked access error detection and correction. This generic is mapped to the generic with the same name on the two AHB2AHB cores instantiated by AHBBRIDGE. Please see the documentation for the AHB2AHB core's VHDL generics for more information.	0 - 2	0
maccsz	This generic is propagated to the slvmaccsz and mstmaccsz VHDL generics on the two AHB2AHB cores instantiated by AHBBRIDGE. The generic determines the maximum AHB access size supported by the bridge. Please see the documentation for the AHB2AHB core's VHDL generics for more information.	32 - 256	32
rdcomb	Read combining, this generic is mapped to the generic with the same name on the two AHB2AHB cores instantiated by AHBBRIDGE. Please see the documentation for the AHB2AHB core's VHDL generics for more information.	0 - 2	0
wrcomb	Write combining, this generic is mapped to the generic with the same name on the two AHB2AHB cores instantiated by AHBBRIDGE. Please see the documentation for the AHB2AHB core's VHDL generics for more information.	0 - 2	0
combmask	Read/Write combining mask, this generic is mapped to the generic with the same name on the two AHB2AHB cores instantiated by AHBBRIDGE. Please see the documentation for the AHB2AHB core's VHDL generics for more information.	0 - 16#FFFF#	16#FFFF#
allbrst	Support all burst types, this generic is mapped to the generic with the same name on the two AHB2AHB cores instantiated by AHBBRIDGE. Please see the documentation for the AHB2AHB core's VHDL generics for more information.	0 - 2	0
fcfs	First-come, first-served operation, this generic is mapped to the generic with the same name on the two AHB2AHB cores instantiated by AHBBRIDGE. Please see the documentation for the AHB2AHB core's VHDL generics for more information.	0 - NAHBMST	0
scantest	Enable scan support	0 - 1	0

5.7 Signal descriptions

Table 48 shows the interface signals of the core (VHDL ports).

Table 48. Signal descriptions

Signal name	Type	Function	Active
RST	Input	Reset	Low
HSB_HCLK	Input	High-speed AHB clock	-
LSB_HCLK	Input	Low-speed AHB clock	-
HSB_AHBSI	Input	High-speed bus AHB slave input signals	-
HSB_AHBSO	Output	High-speed bus AHB slave output signals	-
HSB_AHBSOV	Input	High-speed bus AHB slave input signals	-
HSB_AHBMI	Input	High-speed bus AHB master input signals	-
HSB_AHBMO	Output	High-speed bus AHB master output signals	-
LSB_AHBSI	Input	Low-speed bus AHB slave input signals	-
LSB_AHBSO	Output	Low-speed bus AHB slave output signals	-
LSB_AHBSOV	Input	Low-speed bus AHB slave input signals	-
LSB_AHBMI	Input	Low-speed bus AHB master input signals	-
LSB_AHBMO	Output	Low-speed bus AHB master output signals	-

5.8 Library dependencies

GAISLER	MISC	Component	Component declaration

6 AHBCTRL - AMBA AHB controller with plug&play support

6.1 Overview

The AMBA AHB controller is a combined AHB arbiter, bus multiplexer and slave decoder according to the AMBA 2.0 standard.

The controller supports up to 16 AHB masters, and 16 AHB slaves. The maximum number of masters and slaves are defined in the GRLIB.AMBA package, in the VHDL constants NAHBSLV and NAHBMST. It can also be set with the *nahbm* and *nahbs* VHDL generics.
Figure 10. AHB controller block diagram

6.2 Operation

6.2.1 Arbitration

The AHB controller supports two arbitration algorithms: fixed-priority and round-robin. The selection is done by the VHDL generic *rrobin*. In fixed-priority mode (*rrobin* = 0), the bus request priority is equal to the master's bus index, with index 0 being the lowest priority. If no master requests the bus, the master with bus index 0 (set by the VHDL generic *defmast)* will be granted.

In round-robin mode, priority is rotated one step after each AHB transfer. If no master requests the bus, the last owner will be granted (bus parking). The VHDL generic *mprio* can be used to specify one or more masters that should be prioritized when the core is configured for round-robin mode.

Note that there are AHB slaves that implement split-like functionality by giving AHB retry responses until the access has finished and the original master tries again. All masters on the bus accessing such slaves must be round-robin arbitrated without prioritization to avoid deadlock situations. For GRLIB this applies to the GRPCI and GRPCI2 cores.

During incremental bursts, the AHB master should keep the bus request asserted until the last access as recommended in the AMBA 2.0 specification, or it might loose bus ownership. For fixed-length burst, the AHB master will be granted the bus during the full burst, and can release the bus request immediately after the first access has started. For this to work however, the VHDL generic *fixbrst* should be set to 1.

6.2.2 Decoding

Decoding (generation of HSEL) of AHB slaves is done using the plug&play method explained in the GRLIB User's Manual. A slave can occupy any binary aligned address space with a size of 1 - 4096 Mbyte. A specific I/O area is also decoded, where slaves can occupy 256 byte - 1 Mbyte. The default address of the I/O area is 0xFFF00000, but can be changed with the *ioaddr* and *iomask* VHDL generics. Access to unused addresses will cause an AHB error response.

The I/O area can be placed within a memory area occupied by a slave. The slave will not be selected when the I/O area is accessed.

6.2.3   Plug&play information

GRLIB devices contain a number of plug&play information words which are included in the AHB records they drive on the bus (see the GRLIB user's manual for more information). These records are combined into an array which is connected to the AHB controller unit.

The plug&play information is mapped on a read-only address area, defined by the *cfgaddr* and *cfgmask* VHDL generics, in combination with the *ioaddr* and *iomask* VHDL generics. By default, the area is mapped on address 0xFFFFF000 - 0xFFFFFFFF. The master information is placed on the first 2 kbyte of the block (0xFFFFF000 - 0xFFFFF800), while the slave information is placed on the second 2 kbyte block. Each unit occupies 32 bytes, which means that the area has place for 64 masters and 64 slaves. The address of the plug&play information for a certain unit is defined by its bus index. The address for masters is thus 0xFFFFF000 + $n*32$, and 0xFFFFF800 + $n*32$ for slaves.
Figure 11. AHB plug&play information record

6.3   AHB split support

AHB SPLIT functionality is supported if the *split* VHDL generic is set to 1. In this case, all slaves must drive the AHB SPLIT signal.

It is important to implement the split functionality in slaves carefully since locked splits can otherwise easily lead to deadlocks. A locked access to a slave which is currently processing (it has returned a split response but not yet split complete) an access which it returned split for to another master must be handled first. This means that the slave must either be able to return an OKAY response to the locked access immediately or it has to split it but return split complete to the master performing the locked transfer before it has finished the first access which received split.

6.4   Locked accesses

The GRLIB AHB controller treats HLOCK as coupled to a specific access. If a previous access by a master received a SPLIT/RETRY response then the arbiter will disregard the current value of HLOCK. This is done as opposed to always treating HLOCK as being valid for the next access which can result in a previously non-locked access being treated as locked when it is retried. Consider the following sequence:

T0: MSTx write 0

T1: MSTx write 1, HLOCK asserted as next access performed by master will be locked

T2: MSTx locked read

If (the non-locked) write 0 access at T0 receives a RETRY or SPLIT response (given at time T1), then the next access to be performed may be a retry of write 0. In this case the arbiter will disregard the HLOCK setting and the retried access will not have HMASTLOCK set.

6.5 AHB bus monitor

An AHB bus monitor is integrated into the core. It is enabled with the *enbusmon* generic. It has the same functionality as the AHB and arbiter parts in the AMBA monitor core (AMBAMON). For more information on which rules are checked se the AMBAMON documentation.

6.6 Registers

The core does not implement any registers.

6.7 Implementation

6.7.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers if the GRLIB config package setting *grlib_async_reset_enable* is set.

6.7.2 Endianness

The core supports both big-endian and little-endian systems. The endianness of the AHB bus controlled by the entity is selected through the generic *ahbendian*. The *ahbendian* VHDL generic is by default set to the value of the constant in *grlib_little_endian* the GRLIB configuration package (see GRLIB User's Manual).

6.8 Configuration options

Table 50 shows the configuration options of the core (VHDL generics).

Table 50. Configuration options

Generic	Function	Allowed range	Default
ioaddr	The MSB address of the I/O area. Sets the 12 most significant bits in the 32-bit AHB address (i.e. 31 downto 20)	0 - 16#FFF#	16#FFF#
iomask	The I/O area address mask. Sets the size of the I/O area and the start address together with ioaddr.	0 - 16#FFF#	16#FFF#
cfgaddr	The MSB address of the configuration area. Sets 12 bits in the 32-bit AHB address (i.e. 19 downto 8).	0 - 16#FFF#	16#FF0#
cfgmask	The address mask of the configuration area. Sets the size of the configuration area and the start address together with cfgaddr. If set to 0, the configuration will be disabled.	0 - 16#FFF#	16#FF0#
rrobin	Selects between round-robin (1) or fixed-priority (0) bus arbitration algorithm.	0 - 1	0

Table 50. Configuration options

Generic	Function	Allowed range	Default
split	Enable support for AHB SPLIT response	0 - 1	0
defmast	Default AHB master	0 - NAHBMST-1	0
ioen	AHB I/O area enable. Set to 0 to disable the I/O area	0 - 1	1
disirq	Set to 1 to disable interrupt routing	0 - 1	0
nahbm	Number of AHB masters	1 - NAHBMST	NAHBMST
nahbs	Number of AHB slaves	1 - NAHBSLV	NAHBSLV
timeout	Perform bus timeout checks (NOT IMPLEMENTED).	0 - 1	0
fixbrst	Enable support for fixed-length bursts	0 - 1	0
debug	Print configuration (0=none, 1=short, 2=all cores)	0 - 2	2
fpnpen	Enables full decoding of the PnP configuration records. When disabled the user-defined registers in the PnP configuration records are not mapped in the configuration area.	0 - 1	0
icheck	Check bus index	0 - 1	1
devid	Assign unique device identifier readable from plug and play area.	N/A	0
enbusmon	Enable AHB bus monitor	0 - 1	0
assertwarn	Enable assertions for AMBA recommendations. Violations are asserted with severity warning.	0 - 1	0
asserterr	Enable assertions for AMBA requirements. Violations are asserted with severity error.	0 - 1	0
hmstdisable	Disable AHB master rule check. To disable a master rule check a value is assigned so that the binary representation contains a one at the position corresponding to the rule number, e.g 0x80 disables rule 7.	N/A	0
hslvdisable	Disable AHB slave tests. Values are assigned as for hmstdisable.	N/A	0
arbdisable	Disable Arbiter tests. Values are assigned as for hmstdisable.	N/A	0
mprio	Master(s) with highest priority. This value is converted to a vector where each position corresponds to a master. To prioritize masters x and y set this generic to $2^x + 2^y$.	N/A	0
mcheck	Check if there are any intersections between core memory areas. If two areas intersect an assert with level failure will be triggered (in simulation). mcheck = 1 does not report intersects between AHB IO areas and AHB memory areas (as IO areas are allowed to override memory areas). mcheck = 2 triggers on all overlaps. See also documentation of VHDL generic shadow below.	0 - 2	1
ccheck	Perform sanity checks on PnP configuration records (in simulation).	0 - 1	1

Table 50. Configuration options

Generic	Function	Allowed range	Default
acdm	AMBA compliant data multiplexing (for HSIZE > word). If this generic is set to 1, and the AMBA bus data width in the system exceeds 32-bits, the core will ensure AMBA compliant data multiplexing for access sizes (HSIZE) over 32-bits. GRLIB cores have an optimization where they drive the same data on all lanes. Read data is always taken from the lowest lanes. If an AMBA compliant core from another vendor is introduced in the design, that core may not always place valid data on the low part of the bus. By setting this generic to 1, the AHBCTRL core will replicate the data, allowing the non-GRLIB cores to be instantiated without modification. Refer to [GRLIB] for more information.	0 - 1	0
index	AHB bus index optionally for trace print-out. See the *ahbtrace* generic.		0
ahbtrace	Enables AHB trace print-out to simulator console when non-zero. Some customization of prints is possible depending on the value: $ahbtrace = 1 + 2*printindex + 4*printfullword$ *printindex*: If set to 1 then each trace line is prefixed with the bus number taken from the *index* generic. *printfullword*: If set to 1 then all bits of HWDATA/HRDATA are included in the trace. Otherwise only the subword selected by HSIZE and HADDR is printed. This option is can be useful to debug endianness and data muxing on wide buses (see the *acdm* generic).	0 - 7	0
hwdebug	Enable hardware debug registers. If this generic is set to 1 the configuration area will include to diagnostic registers at offsets 0xFF4 and 0xFF8. Offset 0xFF4 will show a 32-bit register where bit *n* shows the current status of AHB master *n*'s HBUSREQ signal. Offset 0xFF8 will show a 32-bit register where bit *n* shows the current SPLIT status of AHB master *n*. The bit will be set when AHB master *n* receives a SPLIT reply and will be re-set to '0' when HSPLIT for AHB master *n* has been asserted. This functionality is not intended to be used in production systems but can provide valuable information while debugging systems with cores that have problems with AMBA SPLIT replies.	0 - 1	0
fourgslave	Allow and optimize for case with one single slave that has one 4 GiB bar	0 - 1	0

Table 50. Configuration options

Generic	Function	Allowed range	Default
shadow	Allow memory areas to shadow other memory areas. If this generic is set to 0 and two slaves map the same memory area then HSEL/HMBSEL signals will be asserted for both memory bars / slaves. This may lead to system malfunctions and causes a simulation failure if the mcheck VHDL generic is set to a non-zero value. If the shadow generic is set to 1 then memory area intersects are allowed and only the lowest HSEL and HMBSEL (HSEL has priority) will be asserted - only the slave or bar with the lowest index will be selected instead of both slaves / bars. The mcheck simulation failure will instead be asserted as a note about intersecting memory areas. Also note that intersections of cacheable and noncacheable areas will be treated as cacheable by GRLB cores that decode the plug&play information. If a non-cacheable area is placed in a cacheable area then it is recommended to use fixed cacheability.	0 - 1	0
unmapslv	If this generic is non-zero then accesses to unmapped address space (address space not occupied by any slave) will be redirected to the slave and bar selected via: 256+bar*32+slv.		0
ahbendian	Selects the endianness of the AHB bus controlled by the entity. 0: Big-endian 1: Little-endian The default value is taken from the endianness generic set in GRLIB configuration package "*grlib_little_endian*" (see GRLIB User's Manual).	0-1	GRLIB
dbgtag	If this generic is a non-empty string, it will be prefixed to each AHB trace line printed to the simulator console (see *ahbtrace* generic).	N/A	Empty string

6.9 Signal descriptions

Table 51 shows the interface signals of the core (VHDL ports).

Table 51. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	AHB reset	Low
CLK	N/A	Input	AHB clock	-
MSTI	*	Output	AMBA AHB master interface record array	-
MSTO	*	Input	AMBA AHB master interface record array	-

```

6.12 Instantiation

This example shows the core can be instantiated.

```
library ieee;
use ieee.std_logic_1164.all;

library grlib;
use grlib.amba.all;

.
.

  -- AMBA signals
  signal ahbsi : ahb_slv_in_type;
  signal ahbso : ahb_slv_out_vector := (others => ahbs_none);
  signal ahbmi : ahb_mst_in_type;
  signal ahbmo : ahb_mst_out_vector := (others => ahbm_none);

begin

-- ARBITER

ahb0 : ahbctrl -- AHB arbiter/multiplexer
  generic map (defmast => CFG_DEFMST, split => CFG_SPLIT,
rrobin => CFG_RROBIN, ioaddr => CFG_AHBIO, nahbm => 8, nahbs => 8)
  port map (rstn, clkm, ahbmi, ahbmo, ahbsi, ahbso);

-- AHB slave

sr0 : srctrl generic map (hindex => 3)
port map (rstn, clkm, ahbsi, ahbso(3), memi, memo, sdo3);

-- AHB master

e1 : eth_oc
      generic map (mstndx => 2, slvndx => 5, ioaddr => CFG_ETHIO, irq => 12, memtech =>
memtech)
      port map (rstn, clkm, ahbsi, ahbso(5), ahbmi  => ahbmi,
ahbmo => ahbmo(2), ethi1, etho1);
...
end;
```

6.13 Debug print-out

If the debug generic is set to 2, the plug&play information of all attached AHB units are printed to the console during the start of simulation. Reporting starts by scanning the master interface array from 0 to NAHBMST - 1 (defined in the grlib.amba package). It checks each entry in the array for a valid vendor-id (all nonzero ids are considered valid) and if one is found, it also retrieves the device-id. The descriptions for these ids are obtained from the GRLIB.DEVICES package, and are then printed on standard out together with the master number. If the index check is enabled (done with a VHDL generic), the report module also checks if the hindex number returned in the record matches the array number of the record currently checked (the array index). If they do not match, the simulation is aborted and an error message is printed.

This procedure is repeated for slave interfaces found in the slave interface array. It is scanned from 0 to NAHBSLV - 1 and the same information is printed and the same checks are done as for the master interfaces. In addition, the address range and memory type is checked and printed. The address information includes type, address, mask, cacheable and pre-fetchable fields. From this information, the report module calculates the start address of the device and the size of the range. The information finally printed is type, start address, size, cacheability and pre-fetchability. The address ranges currently defined are AHB memory, AHB I/O and APB I/O. APB I/O ranges are ignored by this module.

7 AHBJTAG - JTAG Debug Link with AHB Master Interface

7.1 Overview

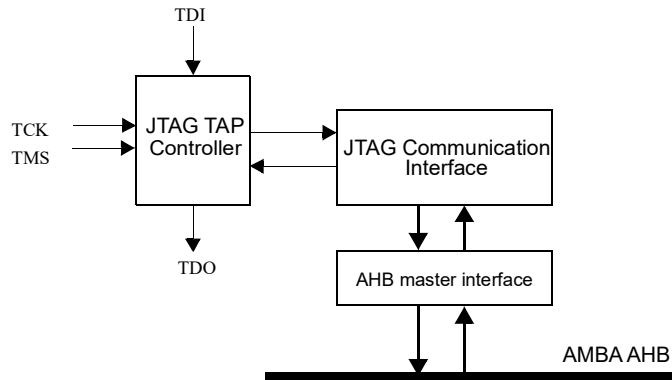
The JTAG debug interface provides access to on-chip AMBA AHB bus through JTAG. The JTAG debug interface implements a simple protocol which translates JTAG instructions to AHB transfers. Through this link, a read or write transfer can be generated to any address on the AHB bus.


Figure 12. JTAG Debug link block diagram.

7.2 Operation

7.2.1 Transmission protocol

The JTAG Debug link decodes two JTAG instructions and implements two JTAG data registers: a 35-bit Command/Address register (ADATA) and a 33-bit Data register (DDATA), see tables 53 and 54 respectively.

An AHB read access is performed by shifting a command with the read/write bit set to '0', and the desired AHB access size and AHB address fields into the ADATA register. When the AHB read access completes, the AHB response data is latched and can be retrieved by selecting the DDATA register and shifting out its contents. An AHB write access is performed by first shifting a command (with the read/write bit set to '1') into the ADATA register and later shifting the desired write data into the DDATA register.

For both reads and writes, accesses are nominally initiated when the TAP enters the Update-DR state. However, a few extra TCK cycles may be needed before this information reaches the AMBA clock domain.

The protocol also provides a means to perform *sequential transfers* where the ADATA register only needs to be accessed to set the address of the first access in a sequence. A sequential read access is made by shifting in a '1' into the SEQ bit of the DDATA register when shifting out the result of the previous read access. This causes the ADATA address field to be incremented by 4 and an AHB read access to the new address to be initiated. Similarly, if a '1' is shifted into the SEQ when shifting in data for an AHB write access into the DDATA register, then the address field in ADATA is incremented by 4 for the subsequent access. Sequential transfers should not cross a 1 kB boundary and are always word based.

Table 53. JTAG debug link Command/Address register (ADATA)

34	33 32	31 0
W	SIZE	AHB ADDRESS

34	Write (W) - '0' - read transfer, '1' - write transfer
33: 32	AHB transfer size - "00" - byte, "01" - half-word, "10" - word, "11"- reserved
31: 30	AHB address

Table 54. JTAG debug link Data register (DDATA)

32	31	0
SEQ	AHB DATA	

32	Sequential transfer (SEQ) - If '1' is shifted in this bit position when read data is shifted out or write data shifted in, the subsequent transfer will be to next word address. When read out from the device, this bit is '1' if the AHB access has completed and '0' otherwise.
31: 30	AHB Data - AHB write/read data. For byte and half-word transfers data is aligned according to big-endian order where data with address offset 0 data is placed in MSB bits.

In previous versions the debug host could not determine if an AHB accesses had finished when the read data was shifted out of the JTAG debug link data register. But as of version 1 a debug host can look at bit 32 of the received data to determine if the access was successful. If bit 32 is '1' the access completed and the data is valid. If bit 32 is '0', the AHB access was not finished when the host started to read data. In this case the host can repeat the read of the data register until bit 32 is set to '1', signaling that the data is valid and that the AMBA AHB access has completed. However, it is not possible to distinguish whether the the AHB access completed with an AHB ERROR or OKAY response.

It should be noted that while bit 32 returns '0', new data will not be latched into the data register. The debug host should therefore inspect bit 32 when shifting in data for a sequential AHB access to see if the previous command has completed. If bit 32 is '0', the read data is not valid and the command just shifted in has been dropped by the core.

Inspection of bit 32 should not be done for JTAG Debug links with version number 0.

7.2.2 Endianness

The core is designed for big-endian systems.

7.3 Registers

The core does not implement any registers mapped in the AMBA AHB or APB address space.

7.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x01C. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

7.5 Implementation

7.5.1 Clocking

Except for the TAP state machine and instruction register, the JTAG debug link operates in the AMBA clock domain. To detect when to shift the address/data register, the JTAG clock and TDI are resynchronized to the AMBA domain. The JTAG clock must be less than 1/3 of the AHB clock frequency for the debug link commands to work when nsync=2, and less than 1/2 of the AHB frequency when nsync=1.

7.5.2 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). Registers in the JTAG clock domain have asynchronous reset connected to the JTAG TRST. Registers in the system clock domain have synchronous reset.

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support the GRLIB config package setting *grlib_async_reset_enable*.

7.5.3 Endianness

The core is designed for big-endian systems and does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). Nevertheless, the core is compatible with a 32-bit AHB of any endianness because it provides direct access to the 32-bit HRDATA/HWDATA value regardless of the access size. Therefore the core is endianness-agnostic when it comes to subword accesses.

On AHB buses wider than 32 bits, the core replicates its 32-bit data across the width of the bus. This allows it to be compatible to some little-endian systems as long as all slaves also replicate data during narrow read accesses (i.e. accesses narrower then the bus width).

7.5.4 Technology mapping

When the generic technology is selected (*tech* VHDL generic set to 0) a technology agnostic customizable TAP is instantiated. It uses a 6-bit instruction register, and implements the BYPASS and IDCODE instructions in addition to the instructions for selecting the ADATA and DDATA registers.

When an FPGA technology with a supported built-in TAP is selected, the core instead instantiates a technology specific macro to access signals from the native TAP. In this case all properties of the TAP are device dependent. This includes instruction register length, IDCODE and in some cases the instruction codes that select the ADATA and DDATA registers. The GRLIB techmap layer currently includes native TAPs for Xilinx, Actel/Microsemi and Altera devices. For a complete list of supported technologies, see the *has_tap* constant in the *gencomp* package in the *techmap* library. Consult device specific documentation for details.

7.6 Configuration options

Table 55 shows the configuration options of the core (VHDL generics).

Table 55. Configuration options

Generic	Function	Allowed range	Default
tech	Target technology	0 - NTECH	0
hindex	AHB master index	0 - NAHBMST-1	0
nsync	Number of synchronization registers between clock regions	1 - 2	1
*idcode	JTAG instruction code to select IDCODE register.	0 - 255	9
*manf	Manufacturer id. Appears as bits 11-1 in TAP controller's IDCODE register. Default is Frontgrade Gaisler manufacturer ID.	0 - 2047	804
*part	Part number. Sets bits 27-12 in IDCODE register.	0 - 65535	0
*ver	Version number. Sets bits 31-28 in IDCODE register .	0 - 15	0
**ainst	JTAG instruction code to select JTAG debug link command/address (ADATA) register. Should be set to 16 for Actel/Microsemi technologies. The default value (2) can be used for all other technologies.	0 - 255	2
**dinst	JTAG instruction code to select JTAG debug link data (DDATA) register. Should be set to 17 for Actel/Microsemi TAPs. The default value (3) can be used for all other technologies.	0 - 255	3
scantest	Enable scan test support	0 - 1	0
oepol	Output enable polarity for TDOEN	0 - 1	1
*tcknen	Support externally inverted TCK.	0 - 1	0
taptecharg	Passed to TAP techmap. Used in BSCANE2_TAP to select between standard user scan chain (0: USER1/USER2, 1: USER3/USER4).		0

*) Only used with generic tech (*tech* VHDL generic set to 0).

**) Tha *ainst* and *dinst* generics are ignored in Xilinx TAPs (*tech* VHDL generic set to a Xilinx technology).

7.7 Signal descriptions

Table 56 shows the interface signals of the core (VHDL ports).

Table 56. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	System clock (AHB clock domain)	-
TCK	N/A	Input	JTAG clock*	-
TMS	N/A	Input	JTAG TMS signal*	High
TDI	N/A	Input	JTAG TDI signal*	High
TDO	N/A	Output	JTAG TDO signal*	High
AHBI	***	Input	AHB Master interface input	-
AHBO	***	Output	AHB Master interface output	-
TAPO_TCK	N/A	Output	TAP Controller User interface TCK signal**	High
TAPO_TDI	N/A	Output	TAP Controller User interface TDI signal**	High
TAPO_INST[7:0]	N/A	Output	TAP Controller User interface INSTsignal**	High
TAPO_RST	N/A	Output	TAP Controller User interface RST signal**	High
TAPO_CAPT	N/A	Output	TAP Controller User interface CAPT signal**	High
TAPO_SHFT	N/A	Output	TAP Controller User interface SHFT signal**	High
TAPO_UPD	N/A	Output	TAP Controller User interface UPD signal**	High
TAPI_TDO	N/A	Input	TAP Controller User interface TDO signal**	High
TRST	N/A	Input	JTAG TRST signal	Low
TDOEN	N/A	Output	Output-enable for TDO	See oepol
TCKN	N/A	Input	Inverted JTAG clock* (if tcknen is set)	-
TAPO_TCKN	N/A	Output	TAP Controller User interface TCKN signal**	High
TAPO_NINST	N/A	Output	TAP Controller User interface NINSTsignal**	High
TAPO_IUPD	N/A	Output	TAP Controller User interface IUPD signal**	High

*) If the target technology is Xilinx or Altera the cores JTAG signals TCK, TCKN, TMS, TDI and TDO are not used. Instead the dedicated FPGA JTAG pins are used. These pins are implicitly made visible to the core through TAP controller instantiation.

**) User interface signals from the JTAG TAP controller. These signals are used to interface additional user defined JTAG data registers such as boundary-scan register. For more information on the JTAG TAP controller user interface see JTAG TAP Controller IP-core documentation. If not used tie TAPI_TDO to ground and leave TAPO_* outputs unconnected.

***) see GRLIB IP Library User's Manual

7.8 Signal definitions and reset values

The signals and their reset values are described in table 57.

Table 57. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
dsutck	Input	JTAG clock	-	-
dsutms	Input	JTAG TMS	High	-
dsutdi	Input	JTAG TDI	High	-
dsutdo	Output	JTAG TDO	High	undefined

7.9 Timing

The timing waveforms and timing parameters are shown in figure 13 and are defined in table 58.
Figure 13. Timing waveforms

Table 58. Timing parameters

Name	Parameter	Reference edge	Min	Max	Unit
$t_{AHBJTAG0}$	clock period	-	TBD	-	ns
$t_{AHBJTAG1}$	clock low/high period	-	TBD	-	ns
$t_{AHBJTAG2}$	data input to clock setup	rising *dsutck* edge	TBD	-	ns
$t_{AHBJTAG3}$	data input from clock hold	rising *dsutck* edge	TBD	-	ns
$t_{AHBJTAG4}$	clock to data output delay	falling *dsutck* edge	-	TBD	ns

7.10 Library dependencies

Table 59 shows libraries used when instantiating the core (VHDL libraries).

Table 59. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions
GAISLER	JTAG	Signals, component	Signals and component declaration

7.11 Instantiation

This example shows how the core can be instantiated.

```
library ieee;
use ieee.std_logic_1164.all;

library grlib;
use grlib.amba.all;
library gaisler;
use gaisler.jtag.all;

entity ahbjtag_ex is
  port (
    clk : in std_ulogic;
    rstn : in std_ulogic;

    -- JTAG signals
    tck  : in std_ulogic;
    tms  : in std_ulogic;
    tdi  : in std_ulogic;
    tdo  : out std_ulogic
);
end;

architecture rtl of ahbjtag_ex is
```

```
      -- AMBA signals
      signal ahbmi : ahb_mst_in_type;
      signal ahbmo : ahb_mst_out_vector := (others => ahbm_none);
  signal gnd : std_ulogic;

  constant clkperiod : integer := 100;

  begin

      gnd <= '0';

      -- AMBA Components are instantiated here
      ...

      -- AHBJTAG debug link
      ahbjtag0 : ahbjtag generic map(tech => 0, hindex => 1)
   port map(rstn, clkm, tck, tckn, tms, tdi, tdo, ahbmi, ahbmo(1),
            open, open, open, open, open, open, open, gnd);

      jtagproc : process
      begin
        jtagcom(tdo, tck, tms, tdi, 100, 20, 16#40000000#, true);
        wait;
      end process;

  end;
```

7.12   Simulation

The *jtagtst* package in the *gaisler* library contains VHDL procedures *jread* and *jwrite* that can be used to perform read and write accesses over the JTAG debug link in simulation. The *jread* and *jwrite* procedures send, and return the results of, JTAG commands to the AHBJTAG using JTAG signals TCK, TMS, TDI and TDO. The *jread* and *jwrite* procedures have the following declarations:

```
procedure jwrite(addr, hsize, data    : in std_logic_vector;
                 signal tck, tms, tdi : out std_ulogic;
                 signal tdo           : in std_ulogic;
                 cp                   : in integer; -- 0.25 * TCK clock period
                 ainst                : in integer := 2;
                 dinst                : in integer := 3;
                 isize                : in integer := 6);

procedure jread(addr, hsize          : in  std_logic_vector;
                data                  : out std_logic_vector;
                signal tck, tms, tdi  : out std_ulogic;
                signal tdo            : in std_ulogic;
                cp                    : in integer; -- 0.25 * TCK clock period
                reread                : in boolean := false;
                assertions            : in boolean := false;
                ainst                 : in integer := 2;
                dinst                 : in integer := 3;
                isize                 : in integer := 6);
```

This JTAG test works if the generic JTAG tap controller is used (selected by setting the generic *tech* to 0) and generally does not work with built-in TAP macros common in FPGA since these macros often don't have visible JTAG pins. Though in some cases there are simulation macros available that expose JTAG pins for the built-in TAP (one example being JTAG_SIME2 providing access to BSCANE2 macros in some device families from Xilinx). In other cases the built-in TAP macro simulation models only implement a bypass register (this has been the case for the UJTAG used in some device families from Microsemi).

8   AHBLITM2AHBM - AHB-LITE to AHB MASTER

8.1   Overview

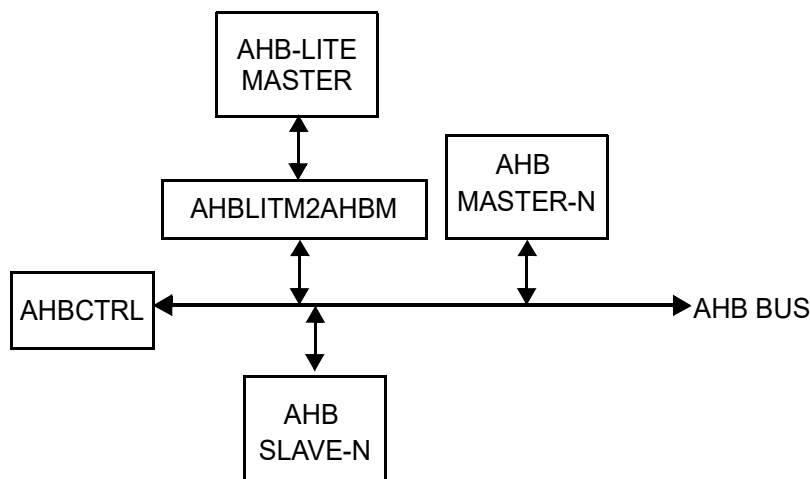
The AHBLITM2AHBM converts an AHB-LITE interface to an AHB master interface which in turns allows an AHB-LITE master to be connected to an AHB bus. This component is mainly intended to be used with the AHBCTRL of GRLIB IP library. Fig. 14 illustrates the usage of AHBLITM2AHBM.


Figure 14. An AHB-LITE master is connected to an AHB BUS through AHBLITM2AHBM

8.1.1   AHB support

The AHBLITE2AHBM component currently supports the following features of the AHB protocol:

Transfer Type: IDLE, NONSEQ, SEQ

Burst Operation: SINGLE, INCR, INCR4, INCR8, INCR16

Data-width: 32-bit, 64-bit, 128-bit, 256-bit

Transfer Size: All possible transfer sizes up to the selected data-width are supported.

Response: OK, ERROR, RETRY, SPLIT

Unsupported AHB Features:

The following features of AHB protocol are not supported by the AHBLIT2AHBM component.

*   BUSY transfer type.
*   WRAP burst operations.

8.2   Operation

8.2.1   Considerations for INCR burst type.

The AHBCTRL in GRLIB IP library changes the arbitration during an INCR burst type (undefined length burst) when busreq signal is deasserted. When an AHB-LITE master connected to the AHBLITM2AHBM starts an INCR burst the busreq signal will be asserted and it will be deasserted

when IDLE sequence is encountered. As a result if AHB-LITE master issues back-to-back INCR burst transfers without any IDLE cycles in between the busreq will be keep asserted until IDLE sequence is encountered. In order to prevent AHBLITM2AHBM to hold the bus for a long time an IDLE sequence can be inserted between back-to-back INCR burst types.

8.2.2   ERROR, RETRY and SPLIT responses

AHBLIT2AHBM will handle the RETRY and SPLIT responses from AHB bus transparently to the AHB-LITE interface. Error responses from the AHB bus will be propagated directly to the AHB-LITE interface.

8.2.3   Endianness

The AHBLIT2AHBM component does not support any endianness conversion between the two buses and requires the endianness to be the same on both sides.

8.3   Input Interface

The AHBLIT2AHBM interface uses AHB-LITE input signals in a combinatorial way in order to drive the AHB bus signals. This is needed to prevent complex buffering schemes and have zero latency. As a result it is recommended to use registered outputs on the AHB-LITE master that is connected to the AHBLIT2AHBM component.

8.4   Implementation

8.4.1   Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and reset all registers.

8.4.2   Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core supports both big-endian and little-endian systems. The core assumes the same endianness on both sides, i.e. no endianness conversion is supported.

8.5 Configuration Options

Table 60. Configuration options

9 AHBRAM - Single-port RAM with AHB interface

9.1 Overview

AHBRAM implements on-chip RAM with an AHB slave interface. Memory size is configurable in binary steps through a VHDL generic. Minimum size is 1KiB and maximum size is dependent on target technology and physical resources. Read accesses have zero or one waitstate (configured at implementation time), write access have one waitstate. The RAM supports byte- and half-word accesses, as well as all types of AHB burst accesses.

Internally, the AHBRAM instantiates a SYNCRAM block with byte writes. Depending on the target technology map, this will translate into memory with byte enables or to multiple 8-bit wide SYNCRAM blocks.

The size of the RAM implemented within AHBRAM can be read via the core's AMBA plug&play version field. The version field will display log2(number of bytes), for a 1 KiB SYNCRAM the version field will have the value 10, where $2^{10} = 1024$ bytes = 1 KiB.

9.1.1 Endianness

The core is designed for big-endian systems.

9.2 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x00E. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

9.3 Implementation

9.3.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

9.3.2 Endianness

The core support both big-endian and little-endian systems. The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The endianness can be configured through the *endianness* generic.

9.4 Configuration options

Table 63 shows the configuration options of the core (VHDL generics).

Table 63. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave bus index	0 - NAHBSLV-1	0
haddr	The MSB address of the AHB area. Sets the 12 most significant bits in the 32-bit AHB address.	0 - 16#FFF#	16#FFF#
hmask	The AHB area address mask. Sets the size of the AHB area and the start address together with *haddr*.	0 - 16#FFF#	16#FF0#
tech	Technology to implement on-chip RAM	0 - NTECH	0
kbytes	RAM size in KiB. The size of the RAM implemented will be the minumum size that will hold the size specified by *kbytes*. A value of 1 here will instantiate a 1 KiB SYNCRAM, a value of 3 will instantiate a 4 KiB SYNCRAM. The actual RAM usage on the target technology then depends on the available RAM resources and the technology map.	target-dependent	1
pipe	Add registers on data outputs. If set to 0 the AMBA data outputs will be connected directly to the core's internal RAM. If set to 1 the core will include registers on the data outputs. Settings this generic to 1 makes read accesses have one waitstate, otherwise the core will respond to read accesses with zero waitstates.	0 - 1	0
maccsz	Maximum access size supported. This generic restricts the maximum AMBA access size supported by the core and selects the width of the SYNCRAMBW RAM used internally. The default value is assigned from AHBDW, which sets the maximum bus width for the GRLIB design.	32, 64, 128, 256	AHBDW
scantest	Enable scan test support (passed on to syncram)	0 - 1	0
endianness	Select endianness. Big endian if set to 0 and little endian if set to 1.	0 - 1	0

```

10 AHBDPRAM - Dual-port RAM with AHB interface

10.1 Overview

AHBDPRAM implements a 32-bit wide on-chip RAM with one AHB slave interface port and one back-end port for a user application. The AHBDPRAM is therefore useful as a buffer memory between the AHB bus and a custom IP core with a RAM interface

The memory size is configurable in binary steps through the *abits* VHDL generic. The minimum size is 1kB while maximum size is dependent on target technology and physical resources. Read accesses are zero-waitstate, write access have one waitstate. The RAM optionally supports byte- and half-word accesses, as well as all types of AHB burst accesses. Internally, the AHBRAM instantiates one 32-bit or four 8-bit wide SYNCRAM_DP blocks. The target technology must have support for dual-port RAM cells.

The back-end port consists of separate clock, address, datain, dataout, enable and write signals. All these signals are sampled on the rising edge of the back-end clock (CLKDP), implementing a synchronous RAM interface. Read-write collisions between the AHB port and the back-end port are not handled and must be prevented by the user. If byte write is enabled, the WRITE(0:3) signal controls the writing of each byte lane in big-endian fashion. WRITE(0) controls the writing of DATAIN(31:24) and so on. If byte write is disabled, WRITE(0) controls writing to the complete 32-bit word.

10.1.1 Endianness

The core is designed for big-endian systems.

10.2 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x00F. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

10.3 Implementation

10.3.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset.

10.3.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

10.4 Configuration options

Table 66 shows the configuration options of the core (VHDL generics).

Table 66. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave bus index	0 - NAHBSLV-1	0
haddr	The MSB address of the AHB area. Sets the 12 most significant bits in the 32-bit AHB address.	0 - 16#FFF#	16#FFF#
hmask	The AHB area address mask. Sets the size of the AHB area and the start address together with *haddr*.	0 - 16#FFF#	16#FF0#
tech	Technology to implement on-chip RAM	0 - NTECH	2
abits	Address bits. The RAM size in Kbytes is equal to 2**(abits +2)	8 - 19	8
bytewrite	If set to 1, enabled support for byte and half-word writes	0 - 1	0
cacheable	Set to configure the memory area as prefetchable and cacheable on the AHB side of the memory.	0 - 1	1

10.5 Signal descriptions

Table 67 shows the interface signals of the core (VHDL ports).

Table 67. Signal descriptions

    write   : in std_logic_vector(0 to 3)-- active high byte write enable
  );
  end component;
```

11 AHBROM - Single-port ROM with AHB interface

11.1 Overview

The AHBROM core implements a 32/64/128-bit wide on-chip ROM with an AHB slave interface. Read accesses take zero waitstates, or one waitstate if the pipeline option is enabled. The ROM supports byte- and half-word accesses, as well as all types of AHB burst accesses.

11.2 PROM generation

The AHBPROM is automatically generated by the make utility in GRLIB. The input format is a sparc-elf binary file or a riscv-elf binary file, produced respectively by the BCC cross-compiler (sparc-elf-gcc) or by a RISCV compiler (riscv-elf-gcc). To create a PROM, first compile a suitable binary and then run the make utility:

```
bash$ sparc-elf-gcc prom.S -o prom.exe
bash$ make ahbrom.vhd

Creating ahbrom.vhd : file size 272 bytes, address bits 9
```

The default binary file for creating a PROM is prom.exe. To use a different file, run make with the FILE parameter set to the input file:

```
bash$ make ahbrom.vhd FILE=myfile.exe
```

The created PROM is realized in synthesizable VHDL code, using a CASE statement. For FPGA targets, most synthesis tools will map the CASE statement on a block RAM/ROM if available. For ASIC implementations, the ROM will be synthesized as gates. It is then recommended to use the *pipe* option to improve the timing.

The default is to build a 32-bit wide ahbrom, to instead build 64-bit or 128-bit wide ahbrom versions, use the flow described above but with the "make ahbrom64.vhd" and "make ahbrom128.vhd" make targets.

11.2.1 Endianness

The core supports both big-endian and little-endian systems.

11.3 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x01B. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

11.4 Implementation

11.4.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support the GRLIB config package setting *grlib_async_reset_enable*.

11.4.2 Endianness

The endianness of the core is selected through the AHB sideband signal *ahbsi.endian*. The AHB bus controller (i.e. AHBCTRL) drives this signal, according to its generic *ahbendian*.

11.5 Configuration options

Table 69 shows the configuration options of the core (VHDL generics).

Table 69. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave bus index	0 - NAHBSLV-1	0
haddr	The MSB address of the AHB area. Sets the 12 most significant bits in the 32-bit AHB address.	0 - 16#FFF#	16#FFF#
hmask	The AHB area address mask. Sets the size of the AHB area and the start address together with *haddr*.	0 - 16#FFF#	16#FF0#
tech	Not used		
pipe	Add a pipeline stage on read data	0	0
kbytes	Not used		
Only on ahbrom64 and ahbrom128:			
wideonly	Removes muxing logic needed to properly support 32-bit masters on wide bus	0 - 1	0

      port map ( rstn, clkm, ahbsi, ahbso(8));
```

12   AHBSTAT - AHB Status Registers

12.1   Overview

The status registers store information about AMBA AHB accesses triggering an error response. There is a status register and a failing address register capturing the control and address signal values of a failing AMBA bus transaction, or the occurrence of a correctable error being signaled from a another peripheral in the system.

The status register and the failing address register are accessed from the AMBA APB bus.

12.2   Operation

12.2.1   Errors

The registers monitor AMBA AHB bus transactions and store the current HADDR, HWRITE, HMASTER and HSIZE internally. The monitoring are always active after startup and reset until an error response (HRESP = "01") is detected. When the error is detected, the status and address register fields CE, HWRITE, HMASTER, HSIZE and HADDR are frozen and the New Error (NE) bit is set to one. At the same time an interrupt is generated, as described hereunder.

Note that many of the fault tolerant units containing EDAC signal an un-correctable error as an AMBA error response, so that it can be detected by the processor as described above.

12.2.2   Correctable errors

Not only error responses on the AHB bus can be detected. Many of the fault tolerant units containing EDAC have a correctable error signal which is asserted each time a correctable error is detected. When such an error is detected, the effect will be the same as for an AHB error response. The only difference is that the Correctable Error (CE) bit in the status register is set to one when a correctable error is detected.

When the CE bit is set the interrupt routine can acquire the address containing the correctable error from the failing address register and correct it. When it is finished it resets the NE bit and the monitoring becomes active again. Interrupt handling is described in detail hereunder.

The correctable error signals from the fault tolerant units should be connected to the *stati.cerror* input signal vector of the AHB status register core, which is or-ed internally and if the resulting signal is asserted, it will have the same effect as an AHB error response.

12.2.3   Interrupts

The interrupt is generated on the line selected by the *pirq* VHDL generic.

The interrupt is connected to the interrupt controller to inform the processor of the error condition. The normal procedure is that an interrupt routine handles the error with the aid of the information in the status registers. When it is finished it resets the NE bit (and ME bit, if implemented) and the monitoring becomes active again. Interrupts are generated for both AMBA error responses and correctable errors as described above.

12.2.4   Filtering and multiple error detection

The status register can optionally be implemented with two sets of status and failing address register. In this case the core also supports filtering on errors and has a status bit that gets set in case additional errors are detected when the New Error (NE) bit is set. The core will only react to the first error in a burst operation. After the first error has been detected, monitoring of the burst is suspended.

An error event will only be recorded by the first status register that should react based on filter settings. If register set 1 has reacted then register 2 will not be set for the same error event. In the case

where an error occurs and all register sets that could have recorded an error, based on filter settings, already have the NE bit set then the ME bit will be set for all the matching register sets.

The extra register set, filtering, and multiple error detection is available in revision 1 of the status register. The functionality is enabled through the *ver* VHDL generic. The value of this generic also affects the core version in the GRLIB plug&play information.

12.3 Registers

The core is programmed through registers mapped into APB address space.

Table 72. AHB Status registers

APB address offset	Registers
0x00	AHB Status register
0x04	AHB Failing address register
0x08	AHB Status register 2 (optional)
0x0C	AHB Failing Address register 2 (optional)

12.3.1 AHB Status register

Table 73. 0x00, 0x08- AHBS - AHB Status register

31	14	13	12	11	10	9	8	7	6	3	2	0
RESERVED		ME	FW	CF	AF	CE	NE	HWRITE	HMASTER		HSIZE	
0		0	0	0	0	0	0	NR	NR		NR	
r		rw*	w*	rw*	rw*	rw	rw	r	r		r	

31: 14	RESERVED
13	Multiple Error detection (ME) - This field is set to 1 when the New Error bit is set and one more error is detected. Filtering is considered when setting the ME bit.
	This field is only available in version 1 of the core (version is selected at implementation).
12	Filter Write (FW) - This bit needs to be set to '1' during a write operation for CF and AF fields to be updated in the same write operation. Always reads as zero.
	This field is only available in version 1 of the core (version is selected at implementation).
11	Correctable Error Filter (CF) - If this bit is set to 1 then this status register will ignore correctable errors. This field will only be written if the FW bit is set.
	This field is only available in version 1 of the core (version is selected at implementation).
10	AMBA ERROR Filter (AF) - If this bit is set to 1 then this status register will ignore AMBA ERROR. This field will only be written if the FW bit is set.
	This field is only available in version 1 of the core (version is selected at implementation).
9	Correctable Error (CE) - Set if the detected error was caused by a correctable error and zero otherwise.
8	New Error (NE) - Deasserted at start-up and after reset. Asserted when an error is detected. Reset by writing a zero to it.
7	The HWRITE signal of the AHB transaction that caused the error.
6: 3	The HMASTER signal of the AHB transaction that caused the error.
2: 0	The HSIZE signal of the AHB transaction that caused the error

12.3.2 AHB Failing address register

Table 74. 0x04, 0x0C - AHBFAR - AHB Failing address register

31	0
AHB FAILING ADDRESS	
NR	
t	

31: 0	The HADDR of the AHB transaction that caused the error.

12.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x052. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

12.5 Implementation

12.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). When reset is asserted the new error and correctable error registers are reset to zero.

12.6   Configuration options

Table 75 shows the configuration options of the core (VHDL generics).

Table 75. Configuration options

Generic	Function	Allowed range	Default
pindex	APB slave index	0 - NAHBSLV-1	0
paddr	APB address	0 - 16#FFF#	0
pmask	APB address mask	0 - 16#FFF#	16#FFF#
pirq	Interrupt line driven by the core	0 - 16#FFF#	0
nftslv	Number of FT slaves connected to the cerror vector	1 - NAHBSLV-1	3
ver	Selects version of the core. Setting this value to 1 implements the two sets of registers, multiple error detection, and filter functionality.	0 - 1	0

12.7   Signal descriptions

Table 76 shows the interface signals of the core (VHDL ports).

Table 76. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
AHBMI	*	Input	AHB slave input signals	-
AHBSI	*	Input	AHB slave output signals	-
STATI	CERROR	Input	Correctable Error Signals	High
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-

* see GRLIB IP Library User's Manual

12.8   Library dependencies

Table 77 shows libraries used when instantiating the core (VHDL libraries).

Table 77. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AHB signal definitions
GAISLER	MISC	Component	Component declaration

12.9   Instantiation

This example shows how the core can be instantiated.

The example design contains an AMBA bus with a number of AHB components connected to it including the status register. There are three Fault Tolerant units with EDAC connected to the status register *cerror* vector. The connection of the different memory controllers to external memory is not shown.

13   AHBTRACE - AHB Trace buffer

13.1   Overview

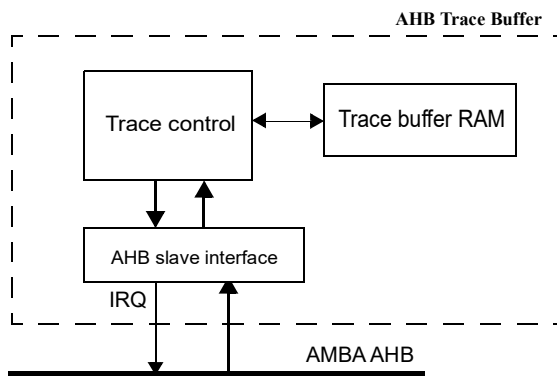
The trace buffer consists of a circular buffer that stores AMBA AHB data transfers. The address, data and various control signals of the AHB bus are stored and can be read out for later analysis.


Figure 15. Block diagram

When the trace buffer is configured in 32-bit bus mode, it is 128 bits wide. The information stored is indicated in the table below:

Table 78. AHB Trace buffer data allocation

Bits	Name	Definition
127:96	Time tag	The value of the time tag counter
95	AHB breakpoint hit	Set to '1' if a DSU AHB breakpoint hit occurred.
94:80	-	Not used
79	Hwrite	AHB HWRITE
78:77	Htrans	AHB HTRANS
76:74	Hsize	AHB HSIZE
73:71	Hburst	AHB HBURST
70:67	Hmaster	AHB HMASTER
66	Hmastlock	AHB HMASTLOCK
65:64	Hresp	AHB HRESP
63:32	Load/Store data	AHB HRDATA[31:0] or HWDATA[31:0]
31:0	Load/Store address	AHB HADDR

In addition to the AHB signals, a 32-bit counter is also stored in the trace as time tag.

When the trace buffer is configured in 64-bit or 128-bit bus mode, its contents are extended according to the table below.

Bits	Name	Definition
223:160	128-bit extended load/store data	AHB HRDATA[127:64] or HWDATA[127:64]
159:128	64-bit extended load/store data	AHB HRDATA[63:32] or HWDATA[63:32]

13.2   Operation

13.2.1   Overview

The trace buffer is enabled by setting the enable bit (EN) in the trace control register. Each AMBA AHB transfer is then stored in the buffer in a circular manner. The address to which the next transfer is written is held in the trace buffer index register, and is automatically incremented after each transfer. Tracing is stopped when the EN bit is reset, or when a AHB breakpoint is hit. An interrupt is generated when a breakpoint is hit.

Note: the LEON3 and LEON4 Debug Support Units (DSU3/DSU4) also includes an AHB trace buffer. The standalone trace buffer is intended to be used in system without a processor or when the DSU3 is not present.

The size of the trace buffer is configured by means of the *kbytes* VHDL generic, defining the size of the complete buffer in kbytes.

The number of lines in the trace buffer is *kbytes* * 1024 / 16 bytes.

The total size of the trace buffer depends on the *bwidth* generic. When the ahb trace buffer is in 32-bit bus mode, the size of the buffer is simply *kbytes* kbytes.

When the ahb trace buffer is configured in 64-bit or 128-bit bus mode, the *kbytes* generic will not reflect the exact amount of memory used in the core. You will have to multiply each line, calculated as above, for 20 bytes or 28 bytes, for 64-bit bus mode or 128-bit bus mode respectively. Therefore the total size for the buffer when in 64-bit mode is *kbytes* * 1.25 kbytes, and for the buffer in 128-bit bus mode it is *kbytes* * 1.75 kbytes.

13.2.2   AHB statistics

The core can be implemented to generate statistics from the traced AHB bus. When statistics collection is enabled the core will assert outputs that are suitable to connect to a LEON statistics unit (L3STAT and L4STAT). The statistical outputs can be filtered by the AHB trace buffer filters, this is controlled by the Performance counter Filter bit (PF) in the AHB trace buffer control register. The core can collect data for the events listed in table 79 below.

Table 79. AHB events

Event	Description	Note
idle	HTRANS=IDLE	Active when HTRANS IDLE is driven on the AHB slave inputs and slave has asserted HREADY.
busy	HTRANS=BUSY	Active when HTRANS BUSY is driven on the AHB slave inputs and slave has asserted HREADY.
nseq	HTRANS=NONSEQ	Active when HTRANS NONSEQ is driven on the AHB slave inputs and slave has asserted HREADY.
seq	HTRANS=SEQ	Active when HTRANS SEQUENTIAL is driven on the AHB slave inputs and slave has asserted HREADY.
read	Read access	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and the HWRITE input is low.
write	Write access	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and the HWRITE input is high.
hsize[5:0]	Transfer size	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and HSIZE is BYTE (hsize[0]), HWORD (HSIZE[1]), WORD (hsize[2]), DWORD (hsize[3]), 4WORD hsize[4], or 8WORD (hsize[5]).
ws	Wait state	Active when HREADY input to AHB slaves is low and AMBA response is OKAY.
retry	RETRY response	Active when master receives RETRY response

Table 79. AHB events

Event	Description	Note
split	SPLIT response	Active when master receives SPLIT response
spdel	SPLIT delay	Active during the time a master waits to be granted access to the bus after reception of a SPLIT response. The core will only keep track of one master at a time. This means that when a SPLIT response is detected, the core will save the master index. This event will then be active until the same master is re-allowed into bus arbitration and is granted access to the bus. This also means that the delay measured will include the time for re-arbitration, delays from other ongoing transfers and delays resulting from other masters being granted access to the bus before the SPLIT:ed master is granted again after receiving SPLIT complete. If another master receives a SPLIT response while this event is active, the SPLIT delay for the second master will not be measured.
locked	Locked access	Active while the HMASTLOCK signal is asserted on the AHB slave inputs. (Currently not used by L3STATand L4STAT)

13.3   Registers

13.3.1   Register address map

The trace buffer occupies 128 KiB of address space in the AHB I/O area. The address mapping in parentheses is only available when the core is in 64-bit or 128-bit bus mode. Only 32-bit single-accesses to the area are supported. The following register addresses are decoded:

Table 80. Trace buffer address space

Address	Register
0x000000	Trace buffer control register
0x000004	Trace buffer index register
0x000008	Time tag counter
0x00000C	Trace buffer master/slave filter register
0x000010	AHB break address 1
0x000014	AHB mask 1
0x000018	AHB break address 2
0x00001C	AHB mask 2
0x010000 - 0x020000	Trace buffer
...0	Trace bits 127 - 96
...4	Trace bits 95 - 64
...8	Trace bits 63 - 32
...C	Trace bits 31 - 0
(...10)	Trace bits 159 - 128, when in 64- or 128-bit bus mode
(...14)	Trace bits 223 - 192, when in 128-bit bus mode
(...18)	Trace bits 191 - 160, when in 128-bit bus mode
(...1C)	Zero

13.3.2 Trace buffer control register

The trace buffer is controlled by the trace buffer control register:

Table 81. 0x000000 - CTRL - Trace buffer control register

31 16	15	14 12	11 10	9	8	7 6	5	4	3	2	1	0
DCNT	BA	BSEL	RES	EF	PF	BW	RF	AF	FR	FW	DM	EN
0	*	0	0	(nr)	(nr)	*	(nr)	(nr)	(nr)	(nr)	(nr)	*
rw	r	rw	r	rw	rw	r	rw	rw	rw	rw	r	rw

31: 16	Trace buffer delay counter (DCNT) - Note that the number of bits actually implemented depends on the size of the trace buffer.
15	Bus select Available (BA) - If this field is set to '1', the core has several buses connected. The bus to trace is selected via the BSEL field. If this field is '0', the core is only capable of tracing one AHB bus.
14: 12	Bus select (BSEL) - If the BA field is '1' this field selects the bus to trace. If the BA field is '0', this field is not writable.
11: 10	RESERVED
9	Error filter (EF) - When set to 1, only error responses will be included in the trace buffer.
8	Performance counter Filter (PF) - If this bit is set to '1', the cores performance counter (statistical) outputs will be filtered using the same filter settings as used for the trace buffer. If a filter inhibits a write to the trace buffer, setting this bit to '1' will cause the same filter setting to inhibit the pulse on the statistical output.
7: 6	Bus width (BW) - This value corresponds to log2(Supported bus width / 32)
5	Retry filter (RF) - If this bit is set to '1', AHB retry responses will not be included in the trace buffer. This bit can only be set of the core has been implemented with support for filtering
4	Address Filter (AF) - If this bit is set to '1', only the address range defined by AHB trace buffer breakpoint 2's address and mask will be included in the trace buffer. This bit can only be set of the core has been implemented with support for filtering
3	Filter Reads (FR) - If this bit is set to '1', read accesses will not be included in the trace buffer. This bit can only be set of the core has been implemented with support for filtering.
2	Filter Writes (FW) - If this bit is set to '1', write accesses will not be included in the trace buffer. This bit can only be set of the core has been implemented with support for filtering.
1	Delay counter mode (DM) - Indicates that the trace buffer is in delay counter mode.
0	Trace enable (EN) - Enables the trace buffer

13.3.3 Trace buffer index register

The trace buffer index register indicates the address of the next 128-bit line to be written.

Table 82. 0x000004 - INDEX - Trace buffer index register

31 4	3 0
INDEX	0x0
NR	0
rw	r

31: 4	Trace buffer index counter (INDEX). Note that the number of bits actually implemented depends on the size of the trace buffer
3: 0	Read as 0x0

13.3.4 Trace buffer time tag register

The time tag register contains a 32-bit counter that increments each clock when the trace buffer is enabled. The value of the counter is stored in the trace to provide a time tag.

Table 83. 0x000008 - TIMETAG - Trace buffer time tag counter

31	0
TIME TAG VALUE	
0	
r	

13.3.5 Trace buffer master/slave filter register

The master/slave filter register allows filtering out specified master and slaves from the trace. This register can only be assigned if the trace buffer has been implemented with support for filtering.

Table 84. Trace buffer master/slave filter register

31	16	15	0
SMASK[15:0]		MMASK[15:0]	
0		0	
rw		rw	

31: 16	Slave Mask (SMASK) - If SMASK[n] is set to '1', the trace buffer will not save accesses performed to slave n.
15: 0	Master Mask (MMASK) - If MMASK[n] is set to '1', the trace buffer will not save accesses performed by master n.

13.3.6 Trace buffer breakpoint registers

The DSU contains two breakpoint registers for matching AHB addresses. A breakpoint hit is used to freeze the trace buffer by clearing the enable bit. Freezing can be delayed by programming the DCNT field in the trace buffer control register to a non-zero value. In this case, the DCNT value will be decremented for each additional trace until it reaches zero and after two additional entries, the trace buffer is frozen. A mask register is associated with each breakpoint, allowing breaking on a block of addresses. Only address bits with the corresponding mask bit set to '1' are compared during breakpoint detection. To break on AHB load or store accesses, the LD and/or ST bits should be set.

Table 85. Trace buffer AHB breakpoint address register

31	2	1	0
BADDR[31:2]		0b00	
NR		0	
rw		r	

31: 2	Breakpoint address (BADDR) - Bits 31:2 of breakpoint address
1: 0	Reserved, read as 0

Table 86. Trace buffer AHB breakpoint mask register

31	2	1	0
BMASK[31:2]		LD	ST
NR		0	0
rw		rw	rw

31: 2	Breakpoint mask (BMASK) - Bits 31:2 of breakpoint mask
1	Load (LD) - Break on data load address
0	Store (ST) - Break on data store address

13.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x017. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

13.5 Implementation

13.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

13.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core supports both big-endian and little-endian systems.

13.6 Configuration options

Table 87 shows the configuration options of the core (VHDL generics).

Table 87. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave bus index	0 - NAHBSLV-1	0
ioaddr	The MSB address of the I/O area. Sets the 12 most significant bits in the 20-bit I/O address.	0 - 16#FFF#	16#000#
iomask	The I/O area address mask. Sets the size of the I/O area and the start address together with ioaddr.	0 - 16#FFF#	16#E00#
irq	Interrupt number	0 - NAHBIRQ-1	0
tech	Technology to implement on-chip RAM	0 - NTECH	0
kbytes	Trace buffer size in kbytes	1 - 64	1
bwidth	Traced AHB bus width	32, 64, 128	64
ahbfilt	If this generic is set to 1 the core will be implemented with support for AHB trace buffer filters. If *ahbpf* is larger than 1 then the core's statistical outputs will be enabled.	0 - 2	0
ntrace	Number of buses to trace. This generic is only available if the entity ahbtrace_mmb is instantiated.	1 - 8	1
scantest	Support scan test and memory BIST	0 - 1	0
exttimer	If set to 1 then the time tag value will be taken from the core's timer signal input. Otherwise the core will use an internal timer.	0 - 1	0

14 AHBUART- AMBA AHB Serial Debug Interface

14.1 Overview

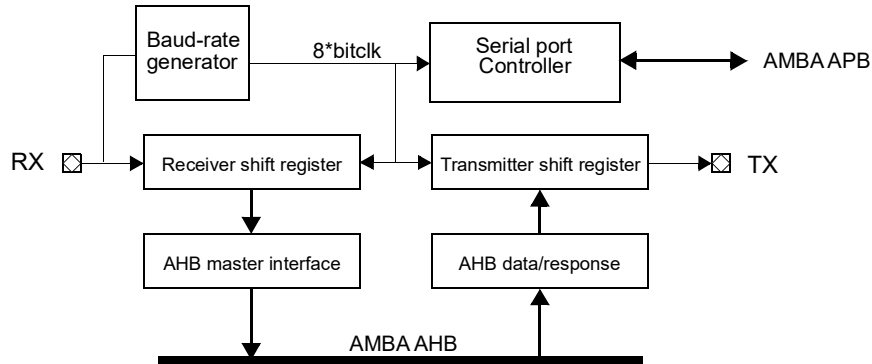
The interface consists of a UART connected to the AMBA AHB bus as a master. A simple communication protocol is supported to transmit access parameters and data. Through the communication link, a read or write transfer can be generated to any address on the AMBA AHB bus.


***Figure 16.* Block diagram**

14.2 Operation

14.2.1 Transmission protocol

The interface supports a simple protocol where commands consist of a control byte, followed by a 32-bit address, followed by optional write data. Write access does not return any response, while a read access only returns the read data. Data is sent on 8-bit basis as shown below.
***Figure 17.* Data frame**
***Figure 18.* Commands**

Block transfers can be performed be setting the length field to n-1, where n denotes the number of transferred words. For write accesses, the control byte and address is sent once, followed by the number of data words to be written. The address is automatically incremented after each data word. For

GRIP

+46 31 7758650 | frontgrade.com/gaisler

read accesses, the control byte and address is sent once and the corresponding number of data words is returned.

14.2.2 Baud rate generation

The UART contains a 18-bit down-counting scaler to generate the desired baud-rate. The scaler is clocked by the system clock and generates a UART tick each time it underflows. The scaler is reloaded with the value of the UART scaler reload register after each underflow. The resulting UART tick frequency should be 8 times the desired baud-rate.

If not programmed by software, the baud rate will be automatically discovered. This is done by searching for the shortest period between two falling edges of the received data (corresponding to two bit periods). When three identical two-bit periods has been found, the corresponding scaler reload value is latched into the reload register, and the BL and RXEN bits are set in the UART control register. If the BL bit is reset by software, the baud rate discovery process is restarted. The baud-rate discovery is also restarted when a 'break' or framing error is detected by the receiver, allowing to change to baudrate from the external transmitter. For proper baudrate detection, the value 0x55 should be transmitted to the receiver after reset or after sending break.

The best scaler value for manually programming the baudrate can be calculated as follows:

```
scaler = (((system_clk*10)/(baudrate*8))-5)/10
```

14.3 Registers

The core is programmed through registers mapped into APB address space.

Table 90. AHB UART registers

APB address offset	Register

0:	Receiver enable (EN) - if set, enables both the transmitter and receiver. Reset value: '0'.
1:	Baud rate locked (BL) - is automatically set when the baud rate is locked. Reset value: '0'.

14.3.2 AHB UART status register

Table 92. 0x04 - STAT - AHB UART status register

31	10	9	8	7	6	5	4	3	2	1	0
RESERVED				RX	FE	R	OV	BR	TH	TS	DR
0				MR	0	0	0	0	1	1	0
r				r	rw	r	rw	rw	r	r	r

0:	Data ready (DR) - indicates that new data has been received by the AMBA AHB master interface. Read only. Reset value: '0'.
1:	Transmitter shift register empty (TS) - indicates that the transmitter shift register is empty. Read only. Reset value: '1'
2:	Transmitter hold register empty (TH) - indicates that the transmitter hold register is empty. Read only. Reset value: '1
3:	Break (BR) - indicates that a BREAKE has been received. Reset value: '0'
4:	Overflow (OV) - indicates that one or more character have been lost due to receiver overflow. Reset value: '0'
6:	Frame error (FE) - indicates that a framing error was detected. Reset value: '0'

14.3.3 AHB UART scaler register

Table 93. 0x0C - SCALER - AHB UART scaler register

31	18	17	0
RESERVED		SCALER RELOAD VALUE	
0		0x3FFFB	
r		rw	

17: 0	Baudrate scaler reload value = (((system_clk*10)/(baudrate*8))-5)/10. Reset value: "3FFFF".

14.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x007. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

14.5 Implementation

14.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

14.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual).

14.6 Configuration options

Table 94 shows the configuration options of the core (VHDL generics).

Table 94. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB master index	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#

14.7 Signal descriptions

Table 95 shows the interface signals of the core (VHDL ports)..

Table 95. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
UARTI	RXD	Input	UART receiver data	High
	CTSN	Input	UART clear-to-send	High
	EXTCLK	Input	Use as alternative UART clock	-
UARTO	RTSN	Output	UART request-to-send	High
	TXD	Output	UART transmit data	High
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
AHBI	*	Input	AMB master input signals	-
AHBO	*	Output	AHB master output signals	-

 * see GRLIB IP Library User's Manual

14.8 Signal definitions and reset values

The signals and their reset values are described in table 96.

Table 96. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
dsutx	Output	UART transmit data line	-	Logical 1
dsurx	Input	UART receive data line	-	-

14.9 Timing

The timing waveforms and timing parameters are shown in figure 19 and are defined in table 97.
Figure 19. **Timing waveforms**

Table 97. Timing parameters

Name	Parameter	Reference edge	Min	Max	Unit
$t_{AHBUART0}$	clock to output delay	rising clk edge	TBD	TBD	ns
$t_{AHBUART1}$	input to clock hold	rising clk edge	-	-	ns
$t_{AHBUART2}$	input to clock setup	rising clk edge	-	-	ns

Note: The dsurx input is re-synchronized internally. The signal does not have to meet any setup or hold requirements.

14.10 Library dependencies

Table 98 shows libraries used when instantiating the core (VHDL libraries).

Table 98. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions
GAISLER	UART	Signals, component	Signals and component declaration

14.11 Instantiation

This example shows how the core can be instantiated.

```

   end;
```

15 AMBAMON - AMBA Bus Monitor

15.1 Overview

The AMBA bus monitor checks the AHB and APB buses for violations against a set of rules. When an error is detected a signal is asserted and error message is (optionally) printed.

15.2 Rules

This section lists all rules checked by the AMBA monitor. The rules are divided into four different tables depending on which type of device they apply to.

Some requirements of the AMBA specification are not adopted by the GRLIB implementation (on a system level). These requirements are listed in the table below.

Table 99. Requirements not checked in GRLIB

Rule Number	Description	References
1	A slave which issues RETRY must only be accessed by one master at a time.	AMBA Spec. Rev 2.0 3-38.

Table 100. AHB master rules.

Rule Number	Description	References
1	Busy can only occur in the middle of bursts. That is only after a NON-SEQ, SEQ or BUSY.	AMBA Spec. Rev 2.0 3-9. http://www.arm.com/support/faqip/492.html
2	Busy can only occur in the middle of bursts. It can be the last access of a burst but only for INCR bursts.	AMBA Spec. Rev 2.0 3-9. http://www.arm.com/support/faqip/492.html
3	The address and control signals must reflect the next transfer in the burst during busy cycles.	AMBA Spec. Rev 2.0 3-9.
4	The first transfer of a single access or a burst must be NONSEQ (this is ensured together with rule 1).	AMBA Spec. Rev 2.0 3-9.
5	HSIZE must never be larger than the bus width.	AMBA Spec. Rev 2.0 3-43.
6	HADDR must be aligned to the transfer size.	AMBA Spec. Rev 2.0 3-12, 3-25. http://www.arm.com/support/faqip/582.html
7	Address and controls signals can only change when hready is low if the previous HTRANS value was IDLE, BUSY or if an ERROR, SPLIT or RETRY response is given.	http://www.arm.com/support/faqip/487.html http://www.arm.com/support/faqip/579.html
8	Address and control signals cannot change between consecutive BUSY cycles.	AMBA Spec. Rev 2.0 3-9.
9	Address must be related to the previous access according to HBURST and HSIZE and control signals must be identical for SEQUENTIAL accesses.	AMBA Spec. Rev 2.0 3-9.
10	Master must cancel the following transfer when receiving an RETRY response.	AMBA Spec. Rev 2.0 3-22.
11	Master must cancel the following transfer when receiving an SPLIT response.	AMBA Spec. Rev 2.0 3-22.

Table 100. AHB master rules.

Rule Number	Description	References
12	Master must reattempt the transfer which received a RETRY response.	AMBA Spec. Rev 2.0 3-21. http://www.arm.com/support/faqip/603.html.
13	Master must reattempt the transfer which received a SPLIT response.	AMBA Spec. Rev 2.0 3-21. http://www.arm.com/support/faqip/603.html.
14	Master can optionally cancel the following transfer when receiving an ERROR response. Only a warning is given if assertions are enabled if it does not cancel the following transfer.	AMBA Spec. Rev 2.0 3-23.
15	Master must hold HWDATA stable for the whole data phase when wait states are inserted. Only the appropriate byte lanes need to be driven for subword transfers.	AMBA Spec. Rev 2.0 3-7. AMBA Spec. Rev 2.0 3-25.
16	Bursts must not cross a 1 kB address boundary.	AMBA Spec. Rev 2.0 3-11.
17	HMASTLOCK indicates that the current transfer is part of a locked sequence. It must have the same timing as address/control.	AMBA Spec. Rev 2.0 3-28.
18	HLOCK must be asserted at least one clock cycle before the address phase to which it refers.	AMBA Spec. Rev 2.0 3-28.
19	HLOCK must be asserted for the duration of a burst and can only be deasserted so that HMASTLOCK is deasserted after the final address phase.	http://www.arm.com/support/faqip/597.html
20	HLOCK must be deasserted in the last address phase of a burst.	http://www.arm.com/support/faqip/588.html
21	HTRANS must be driven to IDLE during reset.	http://www.arm.com/support/faqip/495.html
22	HTRANS can only change from IDLE to NONSEQ or stay IDLE when HREADY is deasserted.	http://www.arm.com/support/faqip/579.html

Table 101. AHB slave rules.

Rule Number	Description	References
1	AHB slave must respond with a zero wait state OKAY response to BUSY cycles in the same way as for IDLE.	AMBA Spec. Rev 2.0 3-9.
2	AHB slave must respond with a zero wait state OKAY response to IDLE.	AMBA Spec. Rev 2.0 3-9.
3	HRESP should be set to ERROR, SPLIT or RETRY only one cycle before HREADY is driven high.	AMBA Spec. Rev 2.0 3-22.
4	Two-cycle ERROR response must be given.	AMBA Spec. Rev 2.0 3-22.
5	Two-cycle SPLIT response must be given.	AMBA Spec. Rev 2.0 3-22.
6	Two-cycle RETRY response must be given.	AMBA Spec. Rev 2.0 3-22.
7	SPLIT complete signalled to master which did not have pending access.	AMBA Spec. Rev 2.0 3-36.
8	Split complete must not be signalled during same cycle as SPLIT.	http://www.arm.com/support/faqip/616.html
9	It is recommended that slaves drive HREADY high and HRESP to OKAY when not selected. A warning will be given if this is not followed.	http://www.arm.com/support/faqip/476.html

Table 101. AHB slave rules.

Rule Number	Description	References
10	It is recommended that slaves do not insert more than 16 wait states. If this is violated a warning will be given if assertions are enabled.	AMBA Spec. Rev 2.0 3-20.
11	Slaves should not assert the HSPLIT (Split complete) signal for more than one cycle for each SPLIT response. If a slave asserts HSPLIT for more than one cycle it will not cause the system to malfunction. It can however be a indication that a core does not perform as expected. Therefore assertion of HSPLIT during more than one cycle for a SPLIT response is reported as a warning.	No reference

Table 102. APB slave rules.

Rule Number	Description	References
1	The bus must move to the SETUP state or remain in the IDLE state when in the IDLE state.	AMBA Spec. Rev 2.0 5-4.
2	The bus must move from SETUP to ENABLE in one cycle.	AMBA Spec. Rev 2.0 5-4.
3	The bus must move from ENABLE to SETUP or IDLE in one cycle.	AMBA Spec. Rev 2.0 5-5.
4	The bus must never be in another state than IDLE, SETUP, ENABLE.	AMBA Spec. Rev 2.0 5-4.
5	PADDR must be stable during transition from SETUP to ENABLE.	AMBA Spec. Rev 2.0 5-5.
6	PWRITE must be stable during transition from SETUP to ENABLE.	AMBA Spec. Rev 2.0 5-5.
7	PWDATA must be stable during transition from SETUP to ENABLE.	AMBA Spec. Rev 2.0 5-5.
8	Only one PSEL must be enabled at a time.	AMBA Spec. Rev 2.0 5-4.
9	PSEL must be stable during transition from SETUP to ENABLE.	AMBA Spec. Rev 2.0 5-5.

16   APBCTRL - AMBA AHB/APB bridge with plug&play support

16.1   Overview

The AMBA AHB/APB bridge is a APB bus master according the AMBA 2.0 standard.

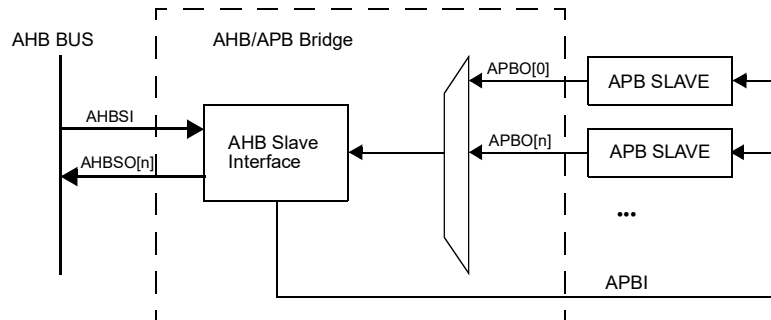
The controller supports up to 16 slaves. The actual maximum number of slaves is defined in the GRLIB.AMBA package, in the VHDL constant NAPBSLV. The number of slaves can also be set using the *nslaves* VHDL generic.


Figure 20. AHB/APB bridge block diagram

16.2   Operation

16.2.1   Decoding

Decoding (generation of PSEL) of APB slaves is done using the plug&play method explained in the GRLIB IP Library User's Manual. A slave can occupy any binary aligned address space with a size of 256 bytes - 1 Mbyte. Writes to unassigned areas will be ignored, while reads from unassigned areas will return an arbitrary value. AHB error response will never be generated.

16.2.2   Plug&play information

GRLIB APB slaves contain two plug&play information words which are included in the APB records they drive on the bus (see the GRLIB IP Library User's Manual for more information). These records are combined into an array which is connected to the APB bridge.

The plug&play information is mapped on a read-only address area at the top 4 kbytes of the bridge address space. Each plug&play block occupies 8 bytes. The address of the plug&play information for a certain unit is defined by its bus index. If the bridge is mapped on AHB address 0x80000000, the address for the plug&play records is thus 0x800FF000 + n*8.
Figure 21. APB plug&play information

16.3 APB bus monitor

An APB bus monitor is integrated into the core. It is enabled with the enbusmon generic. It has the same functionality as the APB parts in the AMBA monitor core (AMBAMON). For more information on which rules are checked se the AMBAMON documentation.

16.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x006. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

16.5 Implementation

16.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers if the GRLIB config package setting *grlib_async_reset_enable* is set.

16.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual).

16.6   Configuration options

Table 107 shows the configuration options of the core (VHDL generics).

*Table 107.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	0 - NAHBSLV-1	0
haddr	The MSB address of the AHB area. Sets the 12 most significant bits in the 32-bit AHB address.	0 - 16#FFF#	0
hmask	The AHB area address mask. Sets the size of the AHB area and the start address together with haddr.	0 - 16#FFF#	16#FFF#
nslaves	The maximum number of slaves	1 - NAPBSLV	NAPBSLV
debug	Print debug information during simulation	0 - 2	2
icheck	Enable bus index checking (PINDEX)	0 - 1	1
enbusmon	Enable APB bus monitor	0 - 1	0
asserterr	Enable assertions for AMBA requirements. Violations are asserted with severity error.	0 - 1	0
assertwarn	Enable assertions for AMBA recommendations. Violations are asserted with severity warning.	0 - 1	0
pslvdisable	Disable APB slave rule check. To disable a slave rule check a value is assigned so that the binary representation contains a one at the position corresponding to the rule number, e.g 0x80 disables rule 7.	N/A	0
mcheck	Check if there are any intersections between APB slave memory areas. If two areas intersect an assert with level failure will be triggered (in simulation).	0 - 1	1
ccheck	Perform sanity checks on PnP configuration records (in simulation).	0 - 1	1

16.7   Signal descriptions

Table 108 shows the interface signals of the core (VHDL ports).

16.11 Debug print-out

The APB bridge can print-out the plug-play information from the attached during simulation. This is enabled by setting the debug VHDL generic to 2. Reporting starts by scanning the array from 0 to NAPBSLV - 1 (defined in the grlib.amba package). It checks each entry in the array for a valid vendor-id (all nonzero ids are considered valid) and if one is found, it also retrieves the device-id. The description for these ids are obtained from the GRLIB.DEVICES package, and is printed on standard out together with the slave number. If the index check is enabled (done with a VHDL generic), the report module also checks if the pindex number returned in the record matches the array number of the record currently checked (the array index). If they do not match, the simulation is aborted and an error message is printed.

The address range and memory type is also checked and printed. The address information includes type, address and mask. The address ranges currently defined are AHB memory, AHB I/O and APB I/O. All APB devices are in the APB I/O range so the type does not have to be checked. From this information, the report module calculates the start address of the device and the size of the range. The information finally printed is start address and size.

17 APBPS2 - PS/2 host controller with APB interface

17.1 Introduction

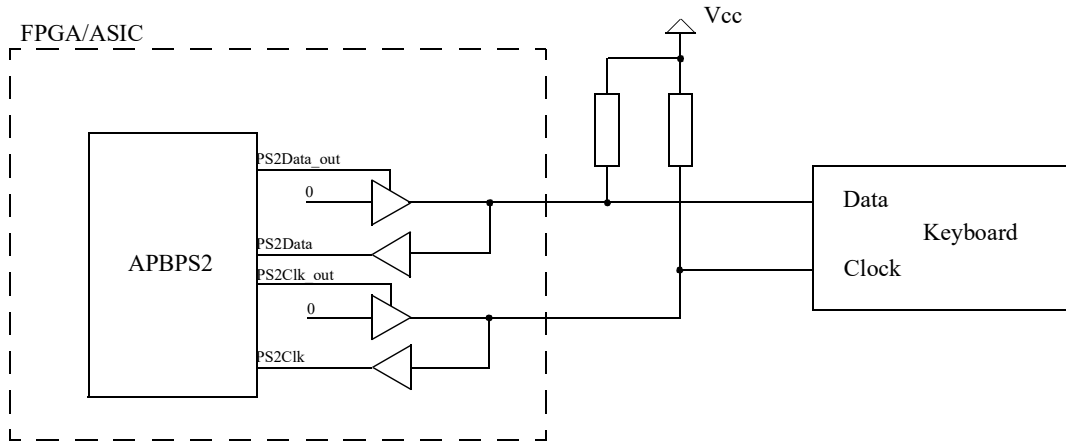
The PS/2 interface is a bidirectional synchronous serial bus primarily used for keyboard and mouse communications. The APBPS2 core implements the PS2 protocol with a APB back-end. Figure 22 shows a model of APBPS2 and the electrical interface.


Figure 22. APBPS2 electrical interface

PS/2 data is sent in 11 bits frames. The first bit is a start bit followed by eight data bits, one odd parity bit and finally one stop bit. Figure 23 shows a typical PS/2 data frame.

Data frame with parity:

Start	D0	D1	D2	D3	D4	D5	D6	D7	Parity	Stop

Figure 23. PS/2 data frame

17.2 Receiver operation

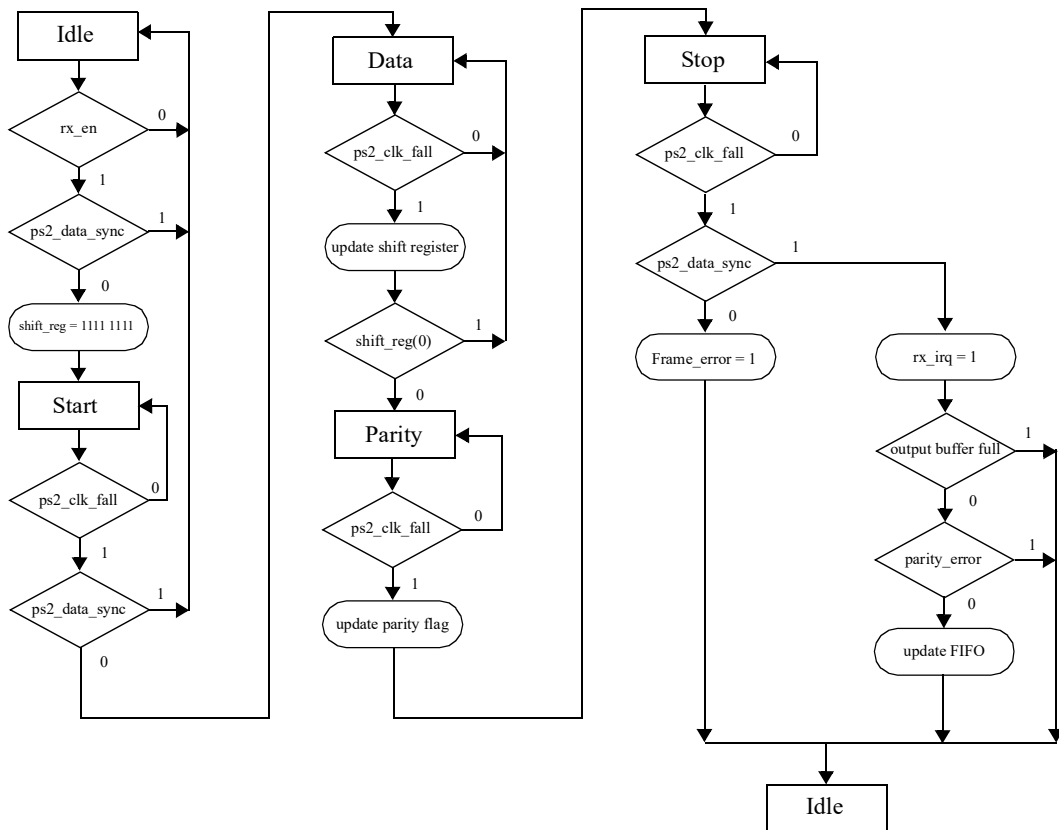
The receiver of APBPS2 receives the data from the keyboard or mouse, and converts it to 8-bit data frames to be read out via the APB bus. It is enabled through the receiver enable (RE) bit in the PS/2 control register. If a parity error or framing error occurs, the data frame will be discarded. Correctly received data will be transferred to a 16 byte FIFO. The data ready (DR) bit in the PS/2 status register will be set, and retained as long as the FIFO contains at least one data frame. When the FIFO is full, the receiver buffer full (RF) bit in the status register is set. The keyboard will be inhibited and buffer data until the FIFO gets read again. Interrupt is sent when a correct stop bit is received then it's up to the software to handle any resend operations if the parity bit is wrong. Figure 24 shows a flow chart for the operations of the receiver state machine.


Figure 24. Flow chart for the receiver state machine

17.3 Transmitter operations

The transmitter part of APBPS2 is enabled for through the transmitter enable (TE) bit in the PS/2 control register. The PS/2 interface has a 16 byte transmission FIFO that stores commands sent by the CPU. Commands are used to set the LEDs on the keyboard, and the typematic rate and delay. Typematic rate is the repeat rate of a key that is held down, while the delay controls for how long a key has to be held down before it begins automatically repeating. Typematic repeat rates, delays and possible other commands are listed in table 121.

If the TE bit is set and the transmission FIFO is not empty a transmission of the command will start. The host will pull the clock line low for at least 100 us and then transmit a start bit, the eight bit command, an odd parity bit, a stop bit and wait for an acknowledgement bit by the device. When this happens an interrupt is generated. Figure 25 shows the flow chart for the transmission state machine.

17.4 Clock generation

A PS/2 interface should generate a clock of 10.0 - 16.7 kHz. To transmit data, a PS/2 host must inhibit communication by pulling the clock low for at least 100 microseconds. To do this, APBPS2 divides the APB clock with either a fixed or programmable division factor. The divider consist of a 17-bit down-counter and can divide the APB clock with a factor of 1 - 131071. The division rate, and the reset value of the timer reload register, is set to the *fKHz* generic divided by 10 in order to generate the 100 microsecond clock low time. If the VHDL generic *fixed* is 0, the division rate can be programmed through the timer reload register and should be programmed with the system frequency in kHz divided by ten. The reset value of the reload register is always set to the *fKHz* value divided by ten. However, the register will not be readable via the APB interface unless the *fixed* VHDL generic has been set to 0.

17.5   Registers

The core is controlled through registers mapped into APB address space.

Table 110. APB PS/2 registers

APB address offset	Register
0x00	PS/2 Data register
0x04	PS/2 Status register
0x08	PS/2 Control register
0x0C	PS/2 Timer reload register

17.5.1   PS/2 Data Register

Table 111. 0x00 - DATA - PS/2 data register

31		8	7		0
RESERVED			DATA		
0			NR		
r			rw		

7: 0   Receiver holding FIFO (read access) and Transmitter holding FIFO (write access). If the receiver FIFO is not empty, read accesses retrieve the next byte from the FIFO. Bytes written to this field are stored in the transmitter holding FIFO if it is not full.

17.5.2 PS/2 Status Register

*Table 112.*0x04 - STAT - PS/2 status register

31 27	26 22									6 5	4	3	2	1	0
RCNT	TCNT	RESERVED								TF	RF	KI	FE	PE	DR
0	0	0								0	0	0	0	0	0
r	r	r								r	r	rw	rw	rw	r

0:	Data ready (DR) - indicates that new data is available in the receiver holding register (read only).
1:	Parity error (PE) - indicates that a parity error was detected
2:	Framing error (FE) - indicates that a framing error was detected.
3:	Keyboard inhibit (KI) - indicates that the keyboard is inhibited.
4:	Receiver buffer full (RF) - indicates that the output buffer (FIFO) is full (read only).
5:	Transmitter buffer full (TF) - indicates that the input buffer (FIFO) is full (read only).
26: 22	Transmit FIFO count (TCNT) - shows the number of data frames in the transmit FIFO (read only).
31: 27	Receiver FIFO count (RCNT) - shows the number of data frames in the receiver FIFO (read only).

17.5.3 PS/2 Control Register

*Table 113.*0x08 - CTRL - PS/2 control register

31		4	3	2	1	0
RESERVED			TI	RI	TE	RE
0			0	0	0	0
r			rw	rw	rw	rw

0:	Receiver enable (RE) - if set, enables the receiver.
1:	Transmitter enable (TE) - if set, enables the transmitter.
2:	Keyboard interrupt enable (RI) - if set, interrupts are generated when a frame is received.
3:	Host interrupt enable (TI) - if set, interrupts are generated when a frame is transmitted.

17.5.4 PS/2 Timer Reload Register

*Table 114.*0x0C - TIMER - PS/2 reload register

31	17 16	0
RESERVED	TIMER RELOAD REG	
0	*	
r	rw*	

16: 0	PS/2 timer reload register - Reset value determined by fktlz VHDL generic. Register only present it "fixed" VHDL generic is zero.

17.6 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x060. For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

17.7 Implementation

17.7.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

17.7.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual).

17.8 Configuration options

Table 115 shows the configuration options of the core (VHDL generics).

Table 115. Configuration options

Generic	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#
pirq	Index of the interrupt line.	0 - NAHBIRQ-1	0
fKHz	Frequency of APB clock in KHz. This value divided by 10 is the reset value of the timer reload register.	1 - 1310710	50000
fixed	Used fixed clock divider to generate PS/2 clock.	0 - 1	0
oepol	Output enable polarity	0 - 1	0

17.9 Signal descriptions

Table 116 shows the interface signals of the core (VHDL ports).

Table 116. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
PS2I	PS2_CLK_I	Input	PS/2 clock input	-
	PS2_DATA_I	Input	PS/2 data input	-
PS2O	PS2_CLK_O	Output	PS/2 clock output	-
	PS2_CLK_OE	Output	PS/2 clock output enable	Low
	PS2_DATA_O	Output	PS/2 data output	-
	PS2_DATA_OE	Output	PS/2 data output enable	Low

 * see GRLIB IP Library User's Manual

17.10 Library dependencies

Table 117 shows libraries used when instantiating the core (VHDL libraries).

Table 117. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	APB signal definitions
GAISLER	MISC	Signals, component	PS/2 signal and component declaration

17.11 Instantiation

This example shows how the core can be instantiated.

17.13 Keyboard commands

*Table 121.*Transmit commands:

Command	Description
0xED	Set status LED's - keyboard will reply with ACK (0xFA). The host follows this command with an argument byte*
0xEE	Echo command - expects an echo response
0xF0	Set scan code set - keyboard will reply with ACK (0xFA) and wait for another byte. 0x01-0x03 which determines the scan code set to use. 0x00 returns the current set.
0xF2	Read ID - the keyboard responds by sending a two byte device ID of 0xAB 0x83
0xF3	Set typematic repeat rate - keyboard will reply with ACK (0xFA) and wait for another byte which determines the typematic rate.
0xF4	Keyboard enable - clears the keyboards output buffer, enables keyboard scanning and returns an acknowledgement.
0xF5	Keyboard disable - resets the keyboard, disables keyboard scanning and returns an acknowledge-ment.
0xF6	Set default - load default typematic rate/delay (10.9cps/500ms) and scan code set 2
0xFE	Resend - upon receipt of the resend command the keyboard will retransmit the last byte
0xFF	Reset - resets the keyboard

* bit 0 controls the scroll lock, bit 1 the num lock, bit 2 the caps lock, bit 3-7 are ignored

*Table 122.*Receive commands:

Command	Description
0xFA	Acknowledge
0xAA	Power on self test passed (BAT completed)

18 APBUART - AMBA APB UART Serial Interface

18.1 Overview

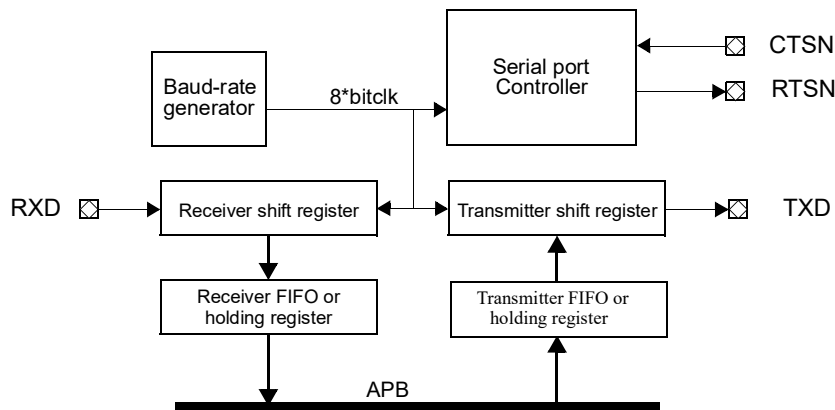
The interface is provided for serial communications. The UART supports data frames with 8 data bits, one optional parity bit and one or two stop bits. To generate the bit-rate, each UART has a programmable 12-bit clock divider. Two FIFOs are used for data transfer between the APB bus and UART, when *fifosize* VHDL generic > 1. Two holding registers are used data transfer between the APB bus and UART, when *fifosize* VHDL generic = 1. Hardware flow-control is supported through the RTSN/ CTSN hand-shake signals, when *flow* VHDL generic is set. Parity is supported for all VHDL generic configurations.


Figure 26. Block diagram

18.2 Operation

18.2.1 Transmitter operation

The transmitter is enabled through the TE bit in the UART control register. Data that is to be transferred is stored in the FIFO/holding register by writing to the data register. This FIFO is configurable to different sizes via the *fifosize* VHDL generic. When the size is 1, only a single holding register is used but in the following discussion both will be referred to as FIFOs. When ready to transmit, data is transferred from the transmitter FIFO/holding register to the transmitter shift register and converted to a serial stream on the transmitter serial output pin (TXD). It automatically sends a start bit followed by eight data bits, an optional parity bit, and one stop bit (figure 27). The least significant bit of the data is sent first. It is also possible to use two stop bits, this is configured via the control register.

Data frame, no parity:

| Start | D0 | D1 | D2 | D3 | D4 | D5 | D6 | D7 | Stop | |

Data frame with parity:

| Start | D0 | D1 | D2 | D3 | D4 | D5 | D6 | D7 | Parity | Stop |
Figure 27. UART data frames

Following the transmission of the stop bit, if a new character is not available in the transmitter FIFO, the transmitter serial data output remains high and the transmitter shift register empty bit (TS) will be set in the UART status register. Transmission resumes and the TS is cleared when a new character is loaded into the transmitter FIFO. When the FIFO is empty the TE bit is set in the status register. If the transmitter is disabled, it will immediately stop any active transmissions including the character currently being shifted out from the transmitter shift register. The transmitter holding register may not be loaded when the transmitter is disabled or when the FIFO (or holding register) is full. If this is done, data might be overwritten and one or more frames are lost.

The discussion above applies to any FIFO configurations including the special case with a holding register (VHDL generic *fifosize* = 1). If FIFOs are used (VHDL generic *fifosize* > 1) some additional status and control bits are available. The TF status bit (not to be confused with the TF control bit) is set if the transmitter FIFO is currently full and the TH bit is set as long as the FIFO is *less* than half-full (less than half of entries in the FIFO contain data). The TF control bit enables FIFO interrupts when set. The status register also contains a counter (TCNT) showing the current number of data entries in the FIFO.

When flow control is enabled, the CTSN input must be low in order for the character to be transmitted. If it is deasserted in the middle of a transmission, the character in the shift register is transmitted and the transmitter serial output then remains inactive until CTSN is asserted again. If the CTSN is connected to a receivers RTSN, overrun can effectively be prevented.

18.2.2 Receiver operation

The serial input signal is first passed through a meta-stability filter. The first stage of this filter consists of two flip-flops connected in series that are clocked by the system clock. The output of the second flip-flop is then sampled into a three-bit shift register at a rate of 8 times the configured baudrate. Finally, the majority vote of the bits in the shift register is used as the serial data input for the rest of the receiver. Loosely, this can be thought of as a low-pass filter with cut-off frequency of roughly 8/3 times the configured baudrate.

The receiver is enabled for data reception through the receiver enable (RE) bit in the UART control register. The receiver looks for a high to low transition of a start bit on the receiver serial data input. If a transition is detected, the state of the serial input is sampled a half bit clocks later. If the serial input is sampled, high the start bit is invalid and the search for a valid start bit continues. If the serial input is still low, a valid start bit is assumed and the receiver continues to sample the serial input at one bit time intervals (at the theoretical centre of the bit) until the proper number of data bits and the parity bit have been assembled and one stop bit has been detected. If more than one stop bit is received then the all but the first are interpreted as the serial input being idle. In particular, the number of stop bits configured in the control register (via the NS bit) has no effect on receiver operation.

The receiver also has a configurable FIFO which is identical to the one in the transmitter. As mentioned in the transmitter part, both the holding register and FIFO will be referred to as FIFO.

During reception, the least significant bit is received first. The data is then transferred to the receiver FIFO and the data ready (DR) bit is set in the UART status register as soon as the FIFO contains at least one data frame. The parity, framing and overrun error bits are set at the received byte boundary, at the same time as the data ready bit would have been set. The data frame is not stored in the FIFO if an error is detected. Also, the new error status bits are or:ed with the old values before they are stored into the status register. Thus, they are not cleared until written to with zeros from the AMBA APB bus. If both the receiver FIFO and shift registers are full when a new start bit is detected, then the character held in the receiver shift register will be lost and the overrun bit will be set in the UART status register. A break received (BR) is indicated when a BREAK has been received, which is a framing error with all data received being zero.

RTSN will be negated (high) when a valid start bit is detected and the receiver FIFO is full. When the holding register is read, the RTSN will automatically be reasserted again. This behavior applies regardless of the flow control configuration, i.e. even if the *flow* generic is set to 0 or the FL bit in the control register is set to 0.

When the VHDL generic *fifosize* > 1, which means that holding registers are not considered here, some additional status and control bits are available. The RF status bit (not to be confused with the RF control bit) is set when the receiver FIFO is full. The RH status bit is set when the receiver FIFO is half-full (at least half of the entries in the FIFO contain data frames). The RF control bit enables receiver FIFO interrupts when set. A RCNT field is also available showing the current number of data frames in the FIFO.

18.3 Baud-rate generation

Each UART contains a 12-bit down-counting scaler to generate the desired baud-rate, the number of scaler bits can be increased with VHDL generic *sbits*. The scaler is clocked by the system clock and generates a UART tick each time it underflows. It is reloaded with the value of the UART scaler reload register after each underflow. The resulting UART tick frequency should be 8 times the desired baud-rate. One appropriate formula to calculate the scaler value for a desired baud rate, using integer division where the remainder is discarded, is:

*scaler value = (system_clock_frequency) / (baud_rate * 8 + 7).*

To calculate the exact required scaler value use:

*scaler value = (system_clock_frequency) / (baud_rate * 8) - 1*

If the EC bit is set, the ticks will be generated with the same frequency as the external clock input instead of at the scaler underflow rate. In this case, the frequency of external clock must be less than half the frequency of the system clock.

18.4 Loop back mode

If the LB bit in the UART control register is set, the UART will be in loop back mode. In this mode, the transmitter output is internally connected to the receiver input and the RTSN is connected to the CTSN. It is then possible to perform loop back tests to verify operation of receiver, transmitter and associated software routines. In this mode, the outputs remain in the inactive state, in order to avoid sending out data.

18.5 FIFO debug mode

FIFO debug mode is entered by setting the debug mode bit in the control register. In this mode it is possible to read the transmitter FIFO and write the receiver FIFO through the FIFO debug register. The transmitter output is held inactive when in debug mode. A write to the receiver FIFO generates an interrupt if receiver interrupts are enabled.

FIFO debug mode requires that the hardware implementation supports flow control (VHDL generic *flow* = 1).

18.6   Interrupt generation

Interrupts are generated differently when a holding register is used (VHDL generic *fifosize* = 1) and when FIFOs are used (VHDL generic *fifosize* > 1). When holding registers are used, the UART will generate an interrupt under the following conditions: when the transmitter is enabled, the transmitter interrupt is enabled and the transmitter holding register moves from full to empty; when the receiver is enabled, the receiver interrupt is enabled and the receiver holding register moves from empty to full; when the receiver is enabled, the receiver interrupt is enabled and a character with either parity, framing or overrun error is received.

For FIFOs, two different kinds of interrupts are available: normal interrupts and FIFO interrupts. Normal interrupts from the transmitter are generated when transmitter interrupts are enabled (TI), the transmitter is enabled and the transmitter FIFO goes from containing data to being empty. For the receiver normal interrupts are generated when receiver interrupts are enabled (RI), the receiver is enabled and a character is received. The interrupt is generated if the character is correct and stored in the receive FIFO or if an error, such as parity; framing or overrun occurred.

Transmitter FIFO interrupts are generated when the transmitter FIFO interrupts are enabled (TF), transmissions are enabled (TE) and the UART is less than half-full (that is, whenever the TH status bit is set). This is a level interrupt and the interrupt signal is continuously driven high as long as the condition prevails. Receiver FIFO interrupts are generated when receiver FIFO interrupts are enabled (RF), the receiver is enabled and the FIFO is half-full. The interrupt signal is continuously driven high as long as the receiver FIFO is half-full (at least half of the entries contain data frames).

Note that the processor acknowledges and clears the corresponding interrupt pending register but for FIFO interrupts the interrupt signal from the UART is continuously driven high, resulting in a new pending interrupt immediately being set in the interrupt controller. If FIFO interrupts are used for controlling FIFO handling, an interrupt handler need to check that there is room in the transmit FIFO before writing and that characters are available in the receive FIFO before reading.

To reduce interrupt occurrence a delayed receiver interrupt is available. It is enabled using the delayed interrupt enable (DI) bit. When enabled a timer is started each time a character is received and an interrupt is only generated if another character has not been received within 4 character + 4 bit times. If receiver FIFO interrupts are enabled a pending character interrupt will be cleared when the FIFO interrupt is active since the character causing the pending irq state is already in the FIFO and is noticed by the driver through the FIFO interrupt. In order to not take one additional interrupt (due to the interrupt signal being driven continuously high as described above), software should clear the corresponding pending bit in the interrupt controller after the FIFO has been emptied.

There is also a separate interrupt for break characters. When enabled an interrupt will always be generated immediately when a break character is received even when delayed receiver interrupts are enabled. When break interrupts are disabled no interrupt will be generated for break characters when delayed interrupts are enabled.

When delayed interrupts are disabled the behavior is the same for the break interrupt bit except that an interrupt will be generated for break characters if receiver interrupt enable is set even if break interrupt is disabled.

An interrupt can also be enabled for the transmitter shift register. When enabled the core will generate an interrupt each time the shift register goes from a non-empty to an empty state.

r				rw	rw	rw	rw	rw	rw	rw	rw	rw	rw	rw	rw	rw	rw	rw	rw

31	FIFOs available (FA) - Set to 1 when receiver and transmitter FIFOs are available. When 0, only holding register are available.
30: 16	RESERVED
15	Number of stop bits (NS) - When set to '1' then two stop bits will be used, otherwise one stop bit will be used.
14	Transmitter shift register empty interrupt enable (SI) - When set, an interrupt will be generated when the transmitter shift register becomes empty. See section 18.6 for more details.
13	Delayed interrupt enable (DI) - When set, delayed receiver interrupts will be enabled and an interrupt will only be generated for received characters after a delay of 4 character times + 4 bits if no new character has been received during that interval. This is only applicable if receiver interrupt enable is set. See section 18.6 for more details.
12	Break interrupt enable (BI) - When set, an interrupt will be generated each time a break character is received. See section 16.6 for more details.
11	FIFO debug mode enable (DB) - when set, it is possible to read and write the FIFO debug register.
10	Receiver FIFO interrupt enable (RF) - when set, Receiver FIFO level interrupts are enabled.
9	Transmitter FIFO interrupt enable (TF) - when set, Transmitter FIFO level interrupts are enabled.
8	External Clock (EC) - if set, the UART scaler will be clocked by UARTI.EXTCLK.
7	Loop back (LB) - if set, loop back mode will be enabled.
6	Flow control (FL) - if set, enables flow control using CTS/RTS (when implemented).
5	Parity enable (PE) - if set, enables parity generation and checking.
4	Parity select (PS) - selects parity polarity (0 = even parity, 1 = odd parity) (when PE=1).
3	Transmitter interrupt enable (TI) - if set, interrupts are generated when characters are transmitted (see section 18.6 for details).
2	Receiver interrupt enable (RI) - if set, interrupts are generated when characters are received (see section 18.6 for details).
1	Transmitter enable (TE) - if set, enables the transmitter.
0	Receiver enable (RE) - if set, enables the receiver.

18.8   Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x00C. For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

18.9   Implementation

18.9.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

18.9.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual).

18.9.3 ProASIC3-specific issues

The core does not explicitly instantiate any RAM blocks. However, when the core is synthesized for ProASIC3 using Synplify, the tool may still implement the transmitter FIFO in a RAM block. This is known to occur with the following Synplify versions:

- Synplify Pro ME L-2016.09M-SP1-5
- Synplify Pro ME P-2019.03A-SP1

In such an implementation, a write to the data register that occurs on the same cycle as a scaler tick will result in simultaneous read and write of one RAM address if the transmitter FIFO is empty. This can result in incorrect data being transmitted in the core's serial data output.

Implementation of the transmitter FIFO in a RAM block can be prevented by adding the following constraint (e.g. to the file "synplify.sdc"):

```
define_attribute {v:gaisler.apbuart*} {syn_ramstyle} {registers}
```

With this constraint in place, Synplify will still infer that the transmitter FIFO is logically a RAM. But the RAM will be implemented in registers and logic instead of in a RAM block.

19   APBVGA - VGA controller with APB interface

19.1   Introduction

The APBVGA core is a text-only video controller with a resolution of 640x480 pixels, creating a display of 80x37 characters. The controller consists of a video signal generator, a 4 Kbyte text buffer, and a ROM for character pixel information. The video controller is controlled through an APB interface.

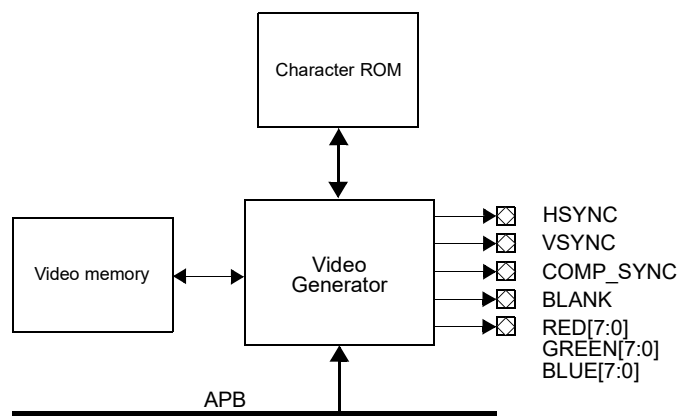
A block diagram for the data path is shown in figure 29.


Figure 29. APBVGA block diagram

19.2   Operation

The video timing of APBVGA is fixed to generate a 640x480 display with 60 Hz refresh rate. The text font is encoded using 8x13 pixels. The display is created by scanning a segment of 2960 characters of the 4 Kbyte text buffer, rasterizing the characters using the character ROM, and sending the pixel data to an external video DAC using three 8-bit color channels. The required pixel clock is 25.175 MHz, which should be provided on the VGACLK input.

Writing to the video memory is made through the VGA data register. Bits [7:0] contains the character to be written, while bits [19:8] defines the text buffer address. Foreground and background colours are set through the background and foreground registers. These 24 bits corresponds to the three pixel colors, RED, GREEN and BLUE. The eight most significant bits defines the red intensity, the next eight bits defines the green intensity and the eight least significant bits defines the blue intensity. Maximum intensity for a color is received when all eight bits are set and minimum intensity when none of the bits are set. Changing the foreground color results in that all characters change their color, it is not possible to just change the color of one character. In addition to the color channels, the video controller generates HSYNC, VSYNC, CSYNC and BLANK. Togetherm the signals are suitable to drive an external video DAC such as ADV7125 or similar.

APBVGA implements hardware scrolling to minimize processor overhead. The controller monitors maintains a reference pointer containing the buffer address of the first character on the top-most line. When the text buffer is written with an address larger than the reference pointer + 2960, the pointer is incremented with 80. The 4 Kbyte text buffer is sufficient to buffer 51 lines of 80 characters. To simplify hardware design, the last 16 bytes (4080 - 4095) should not be written. When address 4079 has been written, the software driver should wrap to address 0. Sofware scrolling can be implemented by only using the first 2960 address in the text buffer, thereby never activating the hardware scolling mechanism.

19.3 Registers

The APB VGA is controlled through three registers mapped into APB address space.

Table 137. APB VGA registers

APB address offset	Register
0x0	VGA Data register (write-only, reads will return 0x00000000).
0x4	VGA Background color (write-only, reads will return 0x00000000).
0x8	VGA Foreground color (write-only, reads will return 0x00000000).

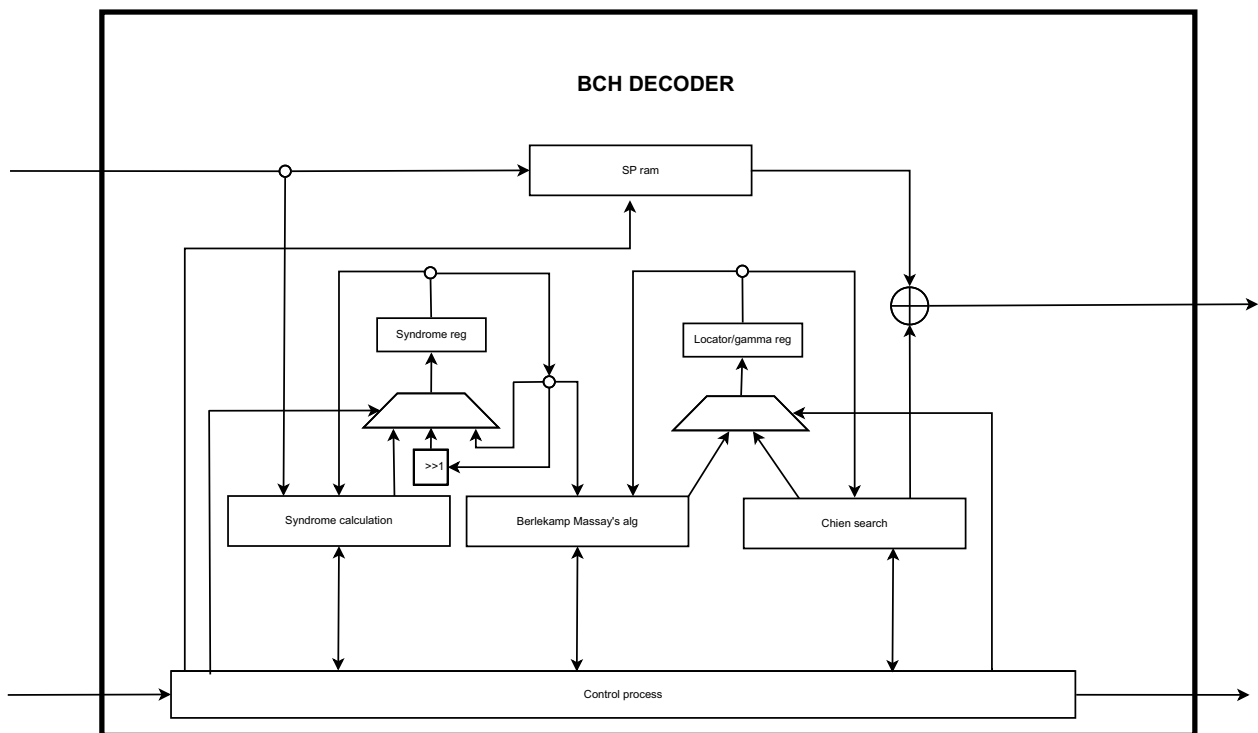
20   BCH_DECODER - Highly configurable systematic BCH decoder

20.1   Overview

The BCH decoder is expected to be used in a system together with the BCH_ENCODER core.

The BCH decoder reads an encoded data frame, including checkbits and corrects any errors. If the checkbits are computed using the BCH encoder with appropriate parametrization, it is guaranteed that the component will be able to correct all bit flips, up to a number, configured through VHDL generics.

Should there be more errors than the correctable amount, the device will identify this. In that case, the data and estimates of the number of errors should be viewed as corrupted.


20.2 Operation

20.2.1 Transaction overview

The decoder works on a transaction basis, consisting of several input and output cycles. A transaction consists of the following steps:

Table 144. Transaction overview

Step	Input signalling	Output signalling	Behaviour
1. Start transaction	bchi.start = '1' All other signals = '0'	All control outputs are '0'	Restarts the device.
2. Input data	bchi.valid = '1' bchi.codeword is the data to be decoded All other signals = '0'	All control outputs are '0'	The device accepts the inputted data and computes the syndrome. The device keeps track of how many inputs have been received and automatically starts the decoding process.
	bchi.valid = '0' All other signals = '0'	All control outputs are '0'	The device is idle, waiting for next data input.
3. Data processing	bchi.enable is don't-care. All other signals = '0'	All control outputs are '0'	Berlekamp-Massay's algorithm is running.
4.Output is ready	bchi.enable is don't-care. All other signals = '0'	bcho.out.start = '1' All other control outputs are '0'	Berlkamp-Massay's algorithm is finished and the device notifies it's ready to output decoded data.
5. Output data bits	bchi.enable = '1' All other signals = '0'	Same cycle: bcho.valid = '1' bcho.data is the corrected data bits All other control outputs are '0'	Performs Chien search on data bits. Outputs corrected data bits.
	bchi.enable = '0' All other signals = '0'	All control outputs are '0'	The device is idle, waiting for the host to accept next output.
6. Data processing	bchi.enable is don't-care. All other signals = '0'	All control outputs are '0'	Chien search is being performed on the check bits
7. End transaction	bchi.enable is don't-care All other signals = '0'	bcho.done = '1' If the decoding was successful, then bcho.nr_errors is the number of detected errors in the entire frame. bcho.cw_ok is high if and only if the frame was correctly decoded.	Ends the transaction and outputs decoding information.

20.3 Algorithm overview

The decoding is done in three steps. First step in reading input data and simultaneously compute the syndrome. In the second step the syndrome is used to compute a locator polynomial. This is done with Berlekamp-Massey's algorithm. The zeros of the locator polynomial are computed using Chien search. Because of the iterative nature of said algorithm, the corrected data is output simultaneously

GRIP

Apr 2024, Version 2024.1

145

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

as the error positions are computed. Finally, the decoding is deemed successful if and only if the number of unique zeros found in the locator polynomial is the same as the degree of said polynomial.

For resource reduction purposes, the syndrome registers are located on top level and shared between the Syndrome and Berlekamp-Massay subcomponents and the locator registers are located on top level and shared between the Berlekamp-Massay and Chien subcomponents.

20.3.1 Primitive polynomial

All data processing computations are done in a Galois field, with the size determined by the generic GF_SIZE. The primitive polynomial is chosen in the following manner

Table 145. Primitive polynomials

GF_SIZE	Max code length	Polynomial
13	8191	$x^{13} + x^8 + x^6 + x + 1$
14	16383	$x^{14} + x^4 + x^3 + x + 1$

20.3.2 Syndrome computation

Since the underlying field is the same as in the BCH encoder and the roots of the generator polynomial are $\alpha^i, i \in [1, 2 \times \text{ECC\_CAPABILITY}]$, the code polynomial will be evaluated in the same points.

20.3.3 Berlekamp Massay's algorithm

The Berlekamp-Massay algorithm is used to compute the locator polynomial from the syndrome polynomial. An instantiation which can correct t errors will use $2t$ clock cycles for this computation.

20.3.4 Chien search

Since there exists no know way of efficiently finding the roots of a polynomial over a Galois field, an exhaustive search is performed. Each cycle WORD_SIZE number of possible polynomial zeros are checked. The locator polynomial is also updated in order to make it possible to reuse the exact same circuitry to check for the next WORD_SIZE values.

20.4 Implementation

20.4.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

GRIP
Apr 2024, Version 2024.1

146

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

20.5 Configuration options

Table 146 shows the configuration options of the core (VHDL generics).

Table 146. List of generics

Generic name	Function	Allowed range	Default
WORD_SIZE	The number of bits processed per cycle. Applies to bch_encode_in.data and bch_encode_out.codeword.	1 to 32	8
ECC_CAPABIL-ITY	The maximum number of errors the code should be able to correct.	1 to 60	60
GF_SIZE	The logarithm of the size of the underlying field.	13,14	14
DATA_BITS	Number of databits (i.e. not counting checkbits)	1 to $2^{\text{GF\_SIZE}} - \text{GF\_SIZE} \times \text{ECC\_CAPABILITY} - 1$	8192
TECH	Target technology	0 to NTECH	INFERRED(0)

The number of expected check bits will be $\text{GF\_SIZE} \times \text{ECC\_CAPABILITY}$. Should the number of code bits not be a multiple of WORD_SIZE, then the last input is expected to be zeropadded.

Note that the number of data bits does not have to be a multiple of WORD_SIZE. If it isn't, then check bits and data bits will be in the same input word.

If this component is used in conjunction with BCH_ENCODER, all three generics are expected to match with the corresponding generics in the decoder block.

The total number of bits, including both data and check bits, must be no more than $2^{\text{GF\_SIZE}} - 1$.

20.6 Signal description

Table 147 shows the interface signals of the core (VHDL ports).

Table 147: Signal list

Signal name	Field	Type	Function	Active
rstn	N/A	Input	Reset	Low
clk	N/A	Input	Clock	-
BCHI	VALID	Input	Valid data	High
	START	Input	Starts a new transaction	High
	ENABLE	Input	Enables output of check bits	High
	CODEWORD(31:0)	Input	Data input. Lower indices used if WORD_SIZE < 32	-
BCHO	CW_OK	Output	All errors were correctable	High
	NR_ERRORS	Output	Number of detected errors in the codeword	
	VALID	Output	Output data is valid	High
	START	Output	First data indicator	High
	DONE	Output	Transaction completed	High
	DATA(31:0)	Output	Data output. Lower indices used if WORD_SIZE < 32	-

21 BCH_ENCODER - Highly configurable systematic BCH encoder

21.1 Overview

The BCH encoder accepts a data frame of configurable length and computes check bits. The check bits are computed in such a way that it is guaranteed that BCH_DECODER can correct up to and including a number of independent bit flips, which is configured at implementation time via VHDL generics.

GRIP

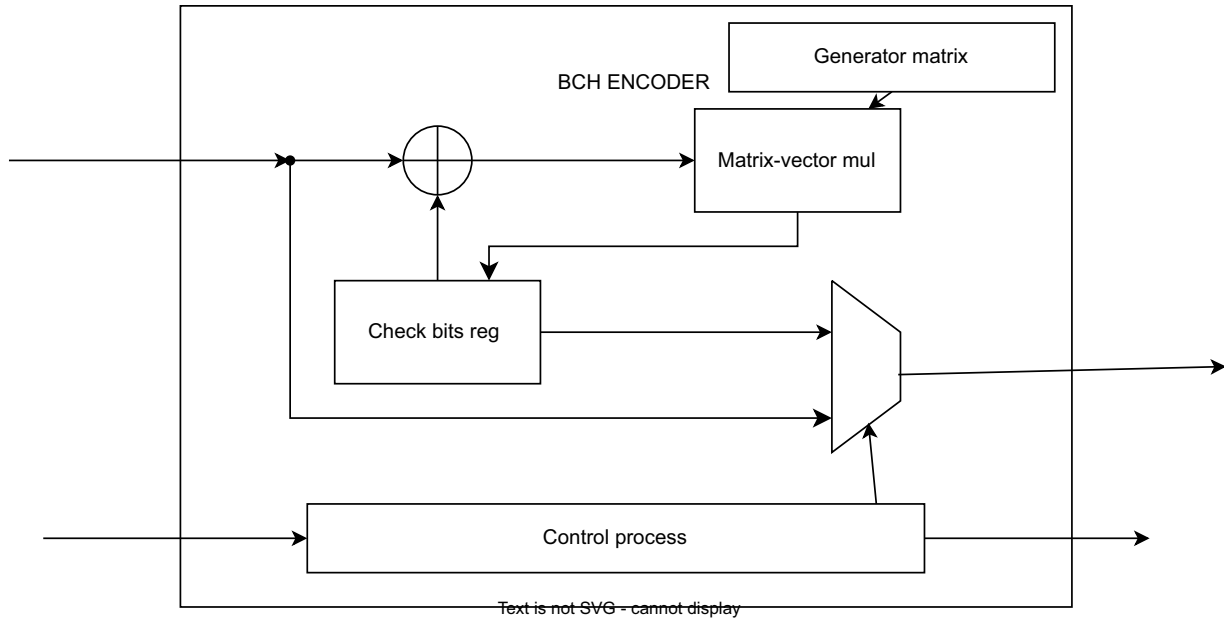
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler


21.2 Operation

21.2.1 Transaction overview

The encoder works on a transaction basis, consisting of several input and output cycles. A transaction consists of the following steps:

Table 149. Transaction overview

Step	Input signalling	Output signalling	Behaviour
1.Start	bchi.start = '1' All other signals = '0'	All outputs are '0'	Restarts the device.
2. Input data	bchi.valid = '1' bchi.data is the data to be encoded bchi.enable is don't-care All other signals = '0'	Next cycle: bcho.valid = '1' bcho.codeword is the data from the previous cycle All other signals = '0'	The device accepts the input data. During the next clk cycle, the same data will be outputted regardless of other signaling.
	bchi.valid = '0' bchi.data and bchi.enable are don't-care. All other signals = '0'	Next cycle: bcho.valid = '0' bcho.codeword is undefined All other signals = '0'	The device ignores the input data this cycle.
3. Stop input	bchi.stop = '1' All other signals = '0'	Possible valid and codeword from input in the previous cycle.	Marks end of data. After this, the device will be ready to output check bits.
4. Output check bits	bchi.enable = '1' All other signals = '0'	Same cycle: bcho.valid = '1' bcho.codeword is checkbits computed by the device.	Outputs checkbits, controlled by the enable flag on the input.
	bchi.enable = '0' All other signals = '0'		The holds off transmitting check bits until next time bch_encoder_in.enable is high.
5. End transaction	bchi.enable is don't-care All other signals = '0'	bch_encoder_out.done = '1'	Ends the transaction

All signals will be sampled on every clock cycle, i.e. bch_encoder_in.start and stop should be high for exactly one cycle to start or stop input. In a similar manner, bch_encoder_out.done will be high for exactly one cycle to signal finished transaction.

The component computes checkbits in accordance with a BCH coding scheme.

21.2.2 Input restrictions

Data may only be input during a transaction. In practice this means:

All bchi.valid pulses must come after bchi.start and before bchi.stop.

Should bchi.start be high in the middle of a transaction, all calculated checkbits will be discarded and a new transaction initialized.

21.2.3 Primitive polynomial

The underlying field and hence the corresponding primitive polynomial is chosen based on the generic GF_SIZE in the following manner

Table 150. Primitive polynomial

GF_SIZE	Max code length	Polynomial
13	8191	$x^{13} + x^8 + x^6 + x + 1$
14	16383	$x^{14} + x^4 + x^3 + x + 1$

21.2.4 Generator

The choice of generator polynomial is dependent on the underlying field and the error correction capability. If the code is designed to correct t errors, then $g(x) = LCM(m_1, m_2, ..., m_{2t})$ over GF(2) where $m_i(x)$ is the minimal polynomial of α^i where α is a primitive element in the field.

Since the code is systematic, the generator matrix $G = (I|A)$ where I is the quadratic identity matrix and A is chosen such that the code is equivalent to one generated by simply multiplying with the generator polynomial. Note that A is unique.

21.3 Implementation

21.3.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

21.4 Configuration options

Table 151 shows the configuration options of the core (VHDL generics).

Table 151. Generic options

Generic name	Function	Allowed range	Default
WORD_SIZE	The number of bits processed per cycle. Applies to bch_encode_in.data and bch_encode_out.codeword.	1-32	8
ECC_CAPABILITY	The maximum number of errors the code should be able to correct.	1-60	60
GF_SIZE	The logarithm of the size of the underlying field.	13,14	14

The number of check bits generated will be $GF\_SIZE \times ECC\_CAPABILITY$. Should this not be a multiple of WORD_SIZE, the bottom bits of the last output will be padded with zeros.

If this component is used in conjunction with BCH_DECODER, all three generics are expected to agree with the corresponding generics in the decoder block.

The total number of bits, including both data and check bits, must be no more than $2^{GF\_SIZE} - 1$.

22 CAN_OC - GRLIB wrapper for OpenCores CAN Interface core

22.1 Overview

CAN_OC is GRLIB wrapper for the CAN core from Opencores. It provides a bridge between AMBA AHB and the CAN Core registers. The AHB slave interface is mapped in the AHB I/O space using the GRLIB plug&play functionality. The CAN core interrupt is routed to the AHB interrupt bus, and the interrupt number is selected through the *irq* generic. The FIFO RAM in the CAN core is implemented using the GRLIB parametrizable SYNCRAM_2P memories, assuring portability to all supported technologies.

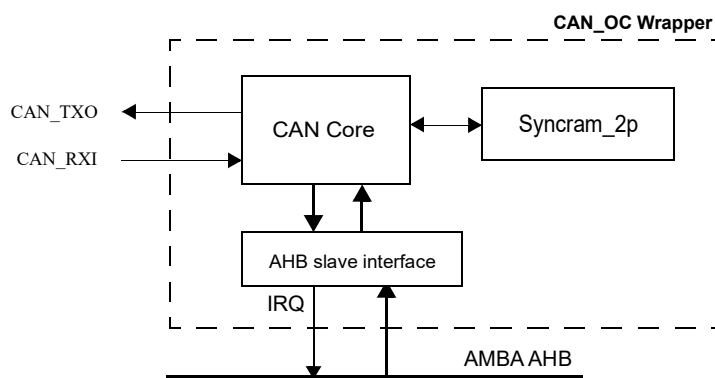
This CAN interface implements the CAN 2.0A and 2.0B protocols. The functionality and operational modes of CAN_OC are based on the Philips SJA1000 CAN controller IC, and has a compatible register map with a few exceptions.


Figure 30. Block diagram

22.2 Opencores CAN controller overview

This CAN controller is based on the Philips SJA1000 and has a compatible register map with a few exceptions. It also supports both BasicCAN (PCA82C200 like) and PeliCAN mode. In PeliCAN mode the extended features of CAN 2.0B are supported. The mode of operation is chosen through the Clock Divider register.

This document lists the registers and their functionality. The Philips SJA1000 data sheet can be used as a reference if further clarification is necessary regarding the register map and the functionality implemented in the IP. However, other sections of the SJA1000 datasheet such as those related to timing and electrical parameters, pinout and package information do not apply to CAN_OC. The differences in functionality and register map between CAN_OC and SJA1000 can be found in the Design considerations section later in this document.

The register map and functionality is different between the two modes of operation. First the Basic-CAN mode will be described followed by PeliCAN. Common registers (clock divisor and bus timing) are described in a separate chapter. The register map also differs depending on whether the core is in operating mode or in reset mode. When reset the core starts in reset mode awaiting configuration. Operating mode is entered by clearing the reset request bit in the command register. To re-enter reset mode set this bit high again.

22.3 AHB interface

All registers are one byte wide and the addresses specified in this document are byte addresses. Byte reads and writes should be used when interfacing with this core. The read byte is duplicated on all byte lanes of the AHB bus. The wrapper is big endian so the core expects the MSB at the lowest address.

The bit numbering in this document uses bit 7 as MSB and bit 0 as LSB.

The core is designed for big-endian systems.

22.4 BasicCAN mode

22.4.1 BasicCAN register map

Table 154. BasicCAN address allocation

22.4.2 Control register

The control register contains interrupt enable bits as well as the reset request bit.

*Table 155.*Bit interpretation of control register (CR) (address 0)

Bit	Name	Description	Reset value
CR.7	-	reserved	0
CR.6	-	reserved	0
CR.5	-	reserved (reads as 1)	1
CR.4	Overrun Interrupt Enable	1 - enabled, 0 - disabled	0
CR.3	Error Interrupt Enable	1 - enabled, 0 - disabled	0
CR.2	Transmit Interrupt Enable	1 - enabled, 0 - disabled	0
CR.1	Receive Interrupt Enable	1 - enabled, 0 - disabled	0
CR.0	Reset request	Writing 1 to this bit aborts any ongoing transfer and enters reset mode. Writing 0 returns to operating mode.	1

22.4.3 Command register

Writing a one to the corresponding bit in this register initiates an action supported by the core.

*Table 156.*Bit interpretation of command register (CMR) (address 1)

Bit	Name	Description	Reset value
CMR.7	-	reserved	1
CMR.6	-	reserved	1
CMR.5	-	reserved	1
CMR.4	-	not used (go to sleep in SJA1000 core)	1
CMR.3	Clear data overrun	Clear the data overrun status bit	1
CMR.2	Release receive buffer	Free the current receive buffer for new reception	1
CMR.1	Abort transmission	Aborts a not yet started transmission.	1
CMR.0	Transmission request	Starts the transfer of the message in the TX buffer	1

A transmission is started by writing 1 to CMR.0. It can only be aborted by writing 1 to CMR.1 and only if the transfer has not yet started. If the transmission has started it will not be aborted when setting CMR.1 but it will not be retransmitted if an error occurs.

Giving the Release receive buffer command should be done after reading the contents of the receive buffer in order to release this memory. If there is another message waiting in the FIFO a new receive interrupt will be generated (if enabled) and the receive buffer status bit will be set again.

To clear the Data overrun status bit CMR.3 must be written with 1.

GRIP

Apr 2024, Version 2024.1

156

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

22.4.4 Status register

The status register is read only and reflects the current status of the core.

*Table 157.*Bit interpretation of status register (SR) (address 2)

Bit	Name	Description	Reset value
SR.7	Bus status	1 when the core is in bus-off and not involved in bus activities	0
SR.6	Error status	At least one of the error counters have reached or exceeded the CPU warning limit (96).	0
SR.5	Transmit status	1 when transmitting a message	0
SR.4	Receive status	1 when receiving a message	0
SR.3	Transmission complete	1 indicates the last message was successfully transferred.	1
SR.2	Transmit buffer status	1 means CPU can write into the transmit buffer	1
SR.1	Data overrun status	1 if a message was lost because no space in fifo.	0
SR.0	Receive buffer status	1 if messages available in the receive fifo.	0

Receive buffer status is cleared when the Release receive buffer command is given and set high if there are more messages available in the fifo.

The data overrun status signals that a message which was accepted could not be placed in the fifo because not enough space left. NOTE: This bit differs from the SJA1000 behavior and is set first when the fifo has been read out.

When the transmit buffer status is high the transmit buffer is available to be written into by the CPU. During an on-going transmission the buffer is locked and this bit is 0.

The transmission complete bit is set to 0 when a transmission request has been issued and will not be set to 1 again until a message has successfully been transmitted.

22.4.5 Interrupt register

The interrupt register signals to CPU what caused the interrupt. The interrupt bits are only set if the corresponding interrupt enable bit is set in the control register.

*Table 158.*Bit interpretation of interrupt register (IR) (address 3)

Bit	Name	Description	Reset value
IR.7	-	reserved (reads as 1)	1
IR.6	-	reserved (reads as 1)	1
IR.5	-	reserved (reads as 1)	1
IR.4	-	not used (wake-up interrupt of SJA1000)	0
IR.3	Data overrun interrupt	Set when SR.1 goes from 0 to 1.	0
IR.2	Error interrupt	Set when the error status or bus status are changed.	0
IR.1	Transmit interrupt	Set when the transmit buffer is released (status bit 0->1)	0
IR.0	Receive interrupt	This bit is set while there are more messages in the fifo.	0

This register is reset on read with the exception of IR.0. Note that this differs from the SJA1000 behavior where all bits are reset on read in BasicCAN mode. This core resets the receive interrupt bit when the release receive buffer command is given (like in PeliCAN mode).

Also note that bit IR.5 through IR.7 reads as 1 but IR.4 is 0.

+46 31 7758650 | frontgrade.com/gaisler

22.4.6 Transmit buffer

The table below shows the layout of the transmit buffer. In BasicCAN only standard frame messages can be transmitted and received (EFF messages on the bus are ignored).

Table 159. Transmit buffer layout

Addr	Name	Bits							
		7	6	5	4	3	2	1	0
10	ID byte 1	ID.10	ID.9	ID.8	ID.7	ID.6	ID.5	ID.4	ID.3
11	ID byte 2	ID.2	ID.1	ID.0	RTR	DLC.3	DLC.2	DLC.1	DLC.0
12	TX data 1	TX byte 1							
13	TX data 2	TX byte 2							
14	TX data 3	TX byte 3							
15	TX data 4	TX byte 4							
16	TX data 5	TX byte 5							
17	TX data 6	TX byte 6							
18	TX data 7	TX byte 7							
19	TX data 8	TX byte 8							

If the RTR bit is set no data bytes will be sent but DLC is still part of the frame and must be specified according to the requested frame. Note that it is possible to specify a DLC larger than 8 bytes but should not be done for compatibility reasons. If DLC > 8 still only 8 bytes can be sent.

22.4.7 Receive buffer

The receive buffer on address 20 through 29 is the visible part of the 64 byte RX FIFO. Its layout is identical to that of the transmit buffer.

22.4.8 Acceptance filter

Messages can be filtered based on their identifiers using the acceptance code and acceptance mask registers. The top 8 bits of the 11 bit identifier are compared with the acceptance code register only comparing the bits set to zero in the acceptance mask register. If a match is detected the message is stored to the fifo.

22.5.2 Mode register

*Table 161.*Bit interpretation of mode register (MOD) (address 0)

Bit	Name	Description	Reset value
MOD.7	-	reserved	0
MOD.6	-	reserved	0
MOD.5	-	reserved	0
MOD.4	-	not used (sleep mode in SJA1000)	0
MOD.3	Acceptance filter mode	1 - single filter mode, 0 - dual filter mode	0
MOD.2	Self test mode	If set the controller is in self test mode	0
MOD.1	Listen only mode	If set the controller is in listen only mode	0
MOD.0	Reset mode	Writing 1 to this bit aborts any ongoing transfer and enters reset mode. Writing 0 returns to operating mode	1

Writing to MOD.1-3 can only be done when reset mode has been entered previously.

In Listen only mode the core will not send any acknowledgements. Note that unlike the SJA1000 the Opencores core does not become error passive and active error frames are still sent!

When in Self test mode the core can complete a successful transmission without getting an acknowledgement if given the Self reception request command. Note that the core must still be connected to a real bus, it does not do an internal loopback.

22.5.3 Command register

Writing a one to the corresponding bit in this register initiates an action supported by the core.

*Table 162.*Bit interpretation of command register (CMR) (address 1)

Bit	Name	Description	Reset value
CMR.7	-	reserved	0
CMR.6	-	reserved	0
CMR.5	-	reserved	0
CMR.4	Self reception request	Transmits and simultaneously receives a message	0
CMR.3	Clear data overrun	Clears the data overrun status bit	0
CMR.2	Release receive buffer	Free the current receive buffer for new reception	0
CMR.1	Abort transmission	Aborts a not yet started transmission.	0
CMR.0	Transmission request	Starts the transfer of the message in the TX buffer	0

A transmission is started by writing 1 to CMR.0. It can only be aborted by writing 1 to CMR.1 and only if the transfer has not yet started. Setting CMR.0 and CMR.1 simultaneously will result in a so called single shot transfer, i.e. the core will not try to retransmit the message if not successful the first time.

Giving the Release receive buffer command should be done after reading the contents of the receive buffer in order to release this memory. If there is another message waiting in the FIFO a new receive interrupt will be generated (if enabled) and the receive buffer status bit will be set again.

The Self reception request bit together with the self test mode makes it possible to do a self test of the core without any other cores on the bus. A message will simultaneously be transmitted and received and both receive and transmit interrupt will be generated.

+46 31 7758650 | frontgrade.com/gaisler

22.5.4 Status register

The status register is read only and reflects the current status of the core.

Table 163. Bit interpretation of command register (SR) (address 2)

Bit	Name	Description	Reset value
SR.7	Bus status	1 when the core is in bus-off and not involved in bus activities	0
SR.6	Error status	At least one of the error counters have reached or exceeded the error warning limit.	0
SR.5	Transmit status	1 when transmitting a message	0
SR.4	Receive status	1 when receiving a message	0
SR.3	Transmission complete	1 indicates the last message was successfully transferred.	1
SR.2	Transmit buffer status	1 means CPU can write into the transmit buffer	1
SR.1	Data overrun status	1 if a message was lost because no space in fifo.	0
SR.0	Receive buffer status	1 if messages available in the receive fifo.	0

Receive buffer status is cleared when there are no more messages in the fifo. The data overrun status signals that a message which was accepted could not be placed in the fifo because not enough space left. NOTE: This bit differs from the SJA1000 behavior and is set first when the fifo has been read out.

When the transmit buffer status is high the transmit buffer is available to be written into by the CPU. During an on-going transmission the buffer is locked and this bit is 0.

The transmission complete bit is set to 0 when a transmission request or self reception request has been issued and will not be set to 1 again until a message has successfully been transmitted.

22.5.5 Interrupt register

The interrupt register signals to CPU what caused the interrupt. The interrupt bits are only set if the corresponding interrupt enable bit is set in the interrupt enable register.

Table 164. Bit interpretation of interrupt register (IR) (address 3)

Bit	Name	Description	Reset value
IR.7	Bus error interrupt	Set if an error on the bus has been detected	0
IR.6	Arbitration lost interrupt	Set when the core has lost arbitration	0
IR.5	Error passive interrupt	Set when the core goes between error active and error passive	0
IR.4	-	not used (wake-up interrupt of SJA1000)	0
IR.3	Data overrun interrupt	Set when data overrun status bit is set	0
IR.2	Error warning interrupt	Set on every change of the error status or bus status	0
IR.1	Transmit interrupt	Set when the transmit buffer is released	0
IR.0	Receive interrupt	Set while the fifo is not empty.	0

This register is reset on read with the exception of IR.0 which is reset when the fifo has been emptied.

22.5.6 Interrupt enable register

In the interrupt enable register the separate interrupt sources can be enabled/disabled. If enabled the corresponding bit in the interrupt register can be set and an interrupt generated. This register does not have a reset value.

*Table 165.*Bit interpretation of interrupt enable register (IER) (address 4)

Bit	Name	Description
IR.7	Bus error interrupt	1 - enabled, 0 - disabled
IR.6	Arbitration lost interrupt	1 - enabled, 0 - disabled
IR.5	Error passive interrupt	1 - enabled, 0 - disabled
IR.4	-	not used (wake-up interrupt of SJA1000)
IR.3	Data overrun interrupt	1 - enabled, 0 - disabled
IR.2	Error warning interrupt	1 - enabled, 0 - disabled.
IR.1	Transmit interrupt	1 - enabled, 0 - disabled
IR.0	Receive interrupt	1 - enabled, 0 - disabled

22.5.7 Arbitration lost capture register

*Table 166.*Bit interpretation of arbitration lost capture register (ALC) (address 11)

Bit	Name	Description	Reset value
ALC.7-5	-	reserved	0
ALC.4-0	Bit number	Bit where arbitration is lost	0

When the core loses arbitration the bit position of the bit stream processor is captured into arbitration lost capture register. The register will not change content again until read out.

22.5.8 Error code capture register

*Table 167.*Bit interpretation of error code capture register (ECC) (address 12)

Bit	Name	Description	Reset value
ECC.7-6	Error code	Error code number	0
ECC.5	Direction	1 - Reception, 0 - transmission error	0
ECC.4-0	Segment	Where in the frame the error occurred	0

When a bus error occurs the error code capture register is set according to what kind of error occurred, if it was while transmitting or receiving and where in the frame it happened. As with the ALC register the ECC register will not change value until it has been read out. The table below shows how to interpret bit 7-6 of ECC.

*Table 168.*Error code interpretation

ECC.7-6	Description
0	Bit error
1	Form error
2	Stuff error
3	Other

Bit 4 downto 0 of the ECC register is interpreted as below

Table 169. Bit interpretation of ECC.4-0

ECC.4-0	Description
0x03	Start of frame
0x02	ID.28 - ID.21
0x06	ID.20 - ID.18
0x04	Bit SRTR
0x05	Bit IDE
0x07	ID.17 - ID.13
0x0F	ID.12 - ID.5
0x0E	ID.4 - ID.0
0x0C	Bit RTR
0x0D	Reserved bit 1
0x09	Reserved bit 0
0x0B	Data length code
0x0A	Data field
0x08	CRC sequence
0x18	CRC delimiter
0x19	Acknowledge slot
0x1B	Acknowledge delimiter
0x1A	End of frame
0x12	Intermission
0x11	Active error flag
0x16	Passive error flag
0x13	Tolerate dominant bits
0x17	Error delimiter
0x1C	Overload flag

22.5.9 Error warning limit register

This registers allows for setting the CPU error warning limit. It defaults to 96. Note that this register is only writable in reset mode.

22.5.10 RX error counter register (address 14)

This register shows the value of the rx error counter. It is writable in reset mode. A bus-off event resets this counter to 0.

22.5.11 TX error counter register (address 15)

This register shows the value of the tx error counter. It is writable in reset mode. If a bus-off event occurs this register is initialized as to count down the protocol defined 128 occurrences of the bus-free signal and the status of the bus-off recovery can be read out from this register. The CPU can force a bus-off by writing 255 to this register. Note that unlike the SJA1000 this core will signal bus-off immediately and not first when entering operating mode. The bus-off recovery sequence starts when entering operating mode after writing 255 to this register in reset mode.

22.5.12 Transmit buffer

The transmit buffer is write-only and mapped on address 16 to 28. Reading of this area is mapped to the receive buffer described in the next section. The layout of the transmit buffer depends on whether a standard frame (SFF) or an extended frame (EFF) is to be sent as seen below.

Table 170.

#	Write (SFF)	Write(EFF)
16	TX frame information	TX frame information
17	TX ID 1	TX ID 1
18	TX ID 2	TX ID 2
19	TX data 1	TX ID 3
20	TX data 2	TX ID 4
21	TX data 3	TX data 1
22	TX data 4	TX data 2
23	TX data 5	TX data 3
24	TX data 6	TX data 4
25	TX data 7	TX data 5
26	TX data 8	TX data 6
27	-	TX data 7
28	-	TX data 8

TX frame information (this field has the same layout for both SFF and EFF frames)

*Table 171.*TX frame information address 16

Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1	Bit 0
FF	RTR	-	-	DLC.3	DLC.2	DLC.1	DLC.0

Bit 7 -   FF selects the frame format, i.e. whether this is to be interpreted as an extended or standard frame. 1 = EFF, 0 = SFF.

Bit 6 -   RTR should be set to 1 for an remote transmission request frame.

Bit 5:4 - are don't care.

Bit 3:0 - DLC specifies the Data Length Code and should be a value between 0 and 8. If a value greater than 8 is used 8 bytes will be transmitted.

TX identifier 1 (this field is the same for both SFF and EFF frames)

*Table 172.*TX identifier 1 address 17

Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1	Bit 0
ID.28	ID.27	ID.26	ID.25	ID.24	ID.23	ID.22	ID.21

Bit 7:0 - The top eight bits of the identifier.

TX identifier 2, SFF frame

*Table 173.*TX identifier 2 address 18

Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1	Bit 0
ID.20	ID.19	ID.18	-	-	-	-	-

Bit 7:5 - Bottom three bits of an SFF identifier.

Bit 4:0 - Don't care.

Bit 1:0 - Don't care

Data field

For received SFF frames the data field is located at address 19 to 26 and for EFF frames at 21 to 28.

22.5.14 Acceptance filter

The acceptance filter can be used to filter out messages not meeting certain demands. If a message is filtered out it will not be put into the receive fifo and the CPU will not have to deal with it.

There are two different filtering modes, single and dual filter. Which one is used is controlled by bit 3 in the mode register. In single filter mode only one 4 byte filter is used. In dual filter two smaller filters are used and if either of these signals a match the message is accepted. Each filter consists of two parts the acceptance code and the acceptance mask. The code registers are used for specifying the pattern to match and the mask registers specify don't care bits. In total eight registers are used for the acceptance filter as shown in the table below. Note that they are only read/writable in reset mode.

GRIP
Apr 2024, Version 2024.1

167

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Table 184. Acceptance filter registers

Address	Description
16	Acceptance code 0 (ACR0)
17	Acceptance code 1 (ACR1)
18	Acceptance code 2 (ACR2)
19	Acceptance code 3 (ACR3)
20	Acceptance mask 0 (AMR0)
21	Acceptance mask 1 (AMR1)
22	Acceptance mask 2 (AMR2)
23	Acceptance mask 3 (AMR3)

Single filter mode, standard frame

When receiving a standard frame in single filter mode the registers ACR0-3 are compared against the incoming message in the following way:

    ACR0.7-0 & ACR1.7-5 are compared to ID.28-18
    ACR1.4 is compared to the RTR bit.
    ACR1.3-0 are unused.
    ACR2 & ACR3 are compared to data byte 1 & 2.

The corresponding bits in the AMR registers selects if the results of the comparison doesn't matter. A set bit in the mask register means don't care.

Single filter mode, extended frame

When receiving an extended frame in single filter mode the registers ACR0-3 are compared against the incoming message in the following way:

    ACR0.7-0 & ACR1.7-0 are compared to ID.28-13
    ACR2.7-0 & ACR3.7-3 are compared to ID.12-0
    ACR3.2 are compared to the RTR bit
    ACR3.1-0 are unused.

The corresponding bits in the AMR registers selects if the results of the comparison doesn't matter. A set bit in the mask register means don't care.

Dual filter mode, standard frame

When receiving a standard frame in dual filter mode the registers ACR0-3 are compared against the incoming message in the following way:

Filter 1

    ACR0.7-0 & ACR1.7-5 are compared to ID.28-18
    ACR1.4 is compared to the RTR bit.
    ACR1.3-0 are compared against upper nibble of data byte 1
    ACR3.3-0 are compared against lower nibble of data byte 1

Filter 2

    ACR2.7-0 & ACR3.7-5 are compared to ID.28-18
    ACR3.4 is compared to the RTR bit.

The corresponding bits in the AMR registers selects if the results of the comparison doesn't matter. A set bit in the mask register means don't care.

Dual filter mode, extended frame

When receiving a standard frame in dual filter mode the registers ACR0-3 are compared against the incoming message in the following way:

Filter 1

ACR0.7-0 & ACR1.7-0 are compared to ID.28-13

Filter 2

ACR2.7-0 & ACR3.7-0 are compared to ID.28-13

The corresponding bits in the AMR registers selects if the results of the comparison doesn't matter. A set bit in the mask register means don't care.

22.5.15 RX message counter

The RX message counter register at address 29 holds the number of messages currently stored in the receive fifo. The top three bits are always 0.

22.6 Common registers

There are three common registers with the same addresses and the same functionality in both Basi-CAN and PeliCAN mode. These are the clock divider register and bus timing register 0 and 1.

22.6.1 Clock divider register

The only real function of this register in the GRLIB version of the Opencores CAN is to choose between PeliCAN and BasiCAN. The clkout output of the Opencore CAN core is not connected and it is its frequency that can be controlled with this register.

*Table 185.*Bit interpretation of clock divider register (CDR) (address 31)

Bit	Name	Description	Reset value
CDR.7	CAN mode	1 - PeliCAN, 0 - BasiCAN	0
CDR.6	-	unused (cbp bit of SJA1000)	0
CDR.5	-	unused (rxinten bit of SJA1000)	0
CDR.4	-	reserved	0
CDR.3	Clock off	Disable the clkout output	0
CDR.2-0	Clock divisor	Frequency selector	0

22.6.2 Bus timing 0

*Table 186.*Bit interpretation of bus timing 0 register (BTR0) (address 6)

Bit	Name	Description
BTR0.7-6	SJW	Synchronization jump width
BTR0.5-0	BRP	Baud rate prescaler

The CAN core system clock is calculated as:

$$t_{scl} = 2 * t_{clk} * (BRP+1)$$

where t_{clk} is the system clock.

The sync jump width defines how many clock cycles (t_{scl}) a bit period may be adjusted with by one re-synchronization. This register does not have a reset value.

22.6.3 Bus timing 1

*Table 187.*Bit interpretation of bus timing 1 register (BTR1) (address 7)

Bit	Name	Description
BTR1.7	SAM	1 - The bus is sampled three times, 0 - single sample point
BTR1.6-4	TSEG2	Time segment 2
BTR1.3-0	TSEG1	Time segment 1

The CAN bus bit period is determined by the CAN system clock and time segment 1 and 2 as shown in the equations below:

$$t_{tseg1} = t_{scl} * (TSEG1+1)$$
$$t_{tseg2} = t_{scl} * (TSEG2+1)$$
$$t_{bit} = t_{tseg1} + t_{tseg2} + t_{scl}$$

The additional t_{scl} term comes from the initial sync segment. Sampling is done between TSEG1 and TSEG2 in the bit period. This register does not have a reset value.

22.7 Design considerations

This section lists known differences between this CAN controller and SJA1000 on which is it based:

- All bits related to sleep mode are unavailable

- Output control and test registers do not exist (reads 0x00)

- Clock divisor register bit 6 (CBP) and 5 (RXINTEN) are not implemented

- Overrun irq and status not set until fifo is read out

BasicCAN specific differences:

- The receive irq bit is not reset on read, works like in PeliCAN mode

- Bit CR.6 always reads 0 and is not a flip flop with no effect as in SJA1000

PeliCAN specific differences:

- Writing 256 to tx error counter gives immediate bus-off when still in reset mode

- Read Buffer Start Address register does not exist

- Addresses above 31 are not implemented (i.e. the internal RAM/FIFO access)

- The core transmits active error frames in Listen only mode

22.8 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x019. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

22.9 Implementation

22.9.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). See the description of the *syncrst* VHDL generic for further information.

22.9.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

22.10 Configuration options

Table 188 shows the configuration options of the core (VHDL generics).

Table 188. Configuration options

Generic	Function	Allowed range	Default
slvndx	AHB slave bus index	0 - NAHBSLV-1	0
ioaddr	The AHB I/O area base address. Compared with bit 19-8 of the 32-bit AHB address.	0 - 16#FFF#	16#FFF#
iomask	The I/O area address mask. Sets the size of the I/O area and the start address together with ioaddr.	0 - 16#FFF#	16#FF0#
irq	Interrupt number	0 - NAHBIRQ-1	0
memtech	Technology to implement on-chip RAM	0	0 - NTECH
syncrst	Reset implementation 0: Use asynchronous reset 1: Use synchronous reset, leave internal buffers without reset 2: Use synchronous reset, initialize internal buffers to zero at reset.	0 - 2	0
ft	Enable fault-tolerance	0 - 1	0

22.11 Signal descriptions

Table 189 shows the interface signals of the core (VHDL ports).

Table 189. Signal descriptions

Signal name	Field	Type	Function	Active
CLK		Input	AHB clock	
RESETN		Input	Reset	Low
AHBSI	*	Input	AMBA AHB slave inputs	-

23 CLKGEN - Clock generation

23.1 Overview

The CLKGEN clock generator implements internal clock generation and buffering.

23.2 Technology specific clock generators

23.2.1 Overview

The core is a wrapper that instantiates technology specific primitives depending on the value of the *tech* VHDL generic. Each supported technology has its own subsection below. Table 193 lists the subsection applicable for each technology setting. The table is arranged after the technology's numerical value in GRLIB. The subsections are ordered in alphabetical order after technology vendor.

*Table 193.*Overview of technology specific clock generator sections

23.2.2 Generic technology

This implementation is used when the clock generator does not support instantiation of technology specific primitives or when the inferred technology has been selected.

This implementation connects the input clock, CLKIN or PCICLKIN depending on the *pcien* and *pcisysclk* VHDL generic, to the SDCLK, CLK1XU, and CLK outputs. The CLKN output is driven by the inverted input clock. The PCICLK output is directly driven by PCICLKIN. Both clock lock signals are always driven to '1' and the CLK2X output is always driven to '0'.

In simulation, CLK, CLKN and CLK1XU transitions are skewed 1 ns relative to the SDRAM clock output.

23.2.3 ProASIC

Generics used in this technology:	pcisysclk
Instantiated technology primitives:	None
Signals not driven in this technology:	clk4x, clk1xu, clk2xu, clkb, clkc

This technology selection does not instantiate any technology specific primitives. The core's clock output, CLK, is driven by the CLKIN or PCICLKIN input depending on the value of VHDL generics *pcien* and *pcisysclk*.

The PCICLK is always directly connected to PCICLKIN. Outputs SDCLK, CLKN and CLK2X, are driven to ground. Both clock lock signals, CGO.CLKLOCK and CGO.PCILOCK, are always driven high.

23.2.4 Actel Axcelerator

Generics used in this technology:	pcisysclk, clk_mul, clk_div, pcien, freq
Instantiated technology primitives:	PLL
Signals not driven in this technology:	clk4x, clk1xu, clk2xu, clkb, clkc

This technology selection has two modes. The first one is used if VHDL generics *clk_mul* and *clk_div* are equal and does not instantiate any technology specific primitives. The core's clock output, CLK, is driven by the CLKIN or PCICLKIN input depending on the value of VHDL generics *pcien* and *pcisysclk*.

The second mode is used if VHDL generics *clk_mul* and *clk_div* are different and instantiates a PLL. The core's clock output CLK is either driven by the pciclkin input or the main output from the PLL

GRIP
Apr 2024, Version 2024.1

175

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

depending on the values of VHDL generics *pcien* and *pcisysclk*. When the PLL drives the CLK output the resulting frequency is the frequency of CLKIN multiplied by the VHDL generic *clk_mul* and divided by the VHDL generic *clk_div*. Clock buffers are not instantiated within the clock generator and has to be done externally.

For both modes the following applies:

The PCICLK is always directly connected to PCICLKIN. Outputs SDCLK, CLKN and CLK2X, are driven to ground. Both clock lock signals, CGO.CLKLOCK and CGO.PCILOCK, are always driven high.

23.2.5 Actel ProASIC3

Generics used in this technology:	clk_mul, clk_div, clk_odiv, pcisysclk, pcien, freq, clkb_odiv, clkc_odiv
Instantiated technology primitives:	PLLINT, PLL
Signals not driven in this technology:	clkn, sdclk, clk2x, clk4x, clk1xu, clk2xu

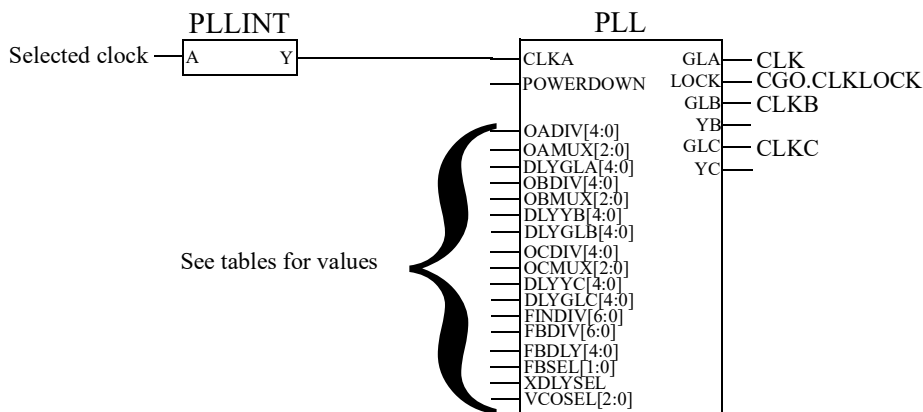
This technology instantiates a PLL and a PLLINT to generate the main clock. The instantiation of a PLLINT macro allows the PLL reference clock to be driven from an I/O that is routed through the regular FPGA routing fabric. Figure 32 shows the instantiated primitives, the PLL EXTFB input is not shown and the EXTFB port on the instantiated component is always tied to ground. The figure shows which of the core's output ports that are driven by the PLL. The PCICLOCK will directly connected to PCICLKIN if VHDL generic *pcien* is non-zero, while CGO.PCILOCK is always driven high. The VHDL generics *pcien* and *pcisysclk* are used to select the reference clock. The values driven on the PLL inputs are listed in tables 194 and 195.


Figure 32. Actel ProASIC3 clock generation

Apr 2024, Version 2024.1

178

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Table 198 lists the connections of the core's input and outputs to the ALTPLL ports.

Table 198. Connections between core ports and ALTPLL ports

Core signal	Core direction	ALTPLL signal
CLKIN/PCICLKIN*	Input	INCLK[0]
CLK	Output	CLK[0]
CLKN	Output	$\overline{\text{CLK}[0]}$ (CLK[0] through an inverter)
CLK2X	Output	CLK[2]
SDCLK	Output	CLK[1]
CGO.CLKLOCK	Output	LOCKED

* Depending on VHDL generics PCIEN and PCISYSCLK, as described below.

The clocks can be generated using either the CLKIN input or the PCICLKIN input. This is selected with the VHDL generics *pcien* and *pcisysclk*. If *pcien* is 0 or *pcisysclk* is 0 the input clock to the ALT-PLL will be CLKIN. If *pcien* is non-zero and *pcisysclk* is 1 the input to the ALTPLL will be PCI-CLKIN.

The PCICLK output will connected to the PCICLKIN input if VHDL generic *pcien* is non-zero. Otherwise the PCICLK output will be driven to ground. The CGO.PCILOCK signal is always driven high.

23.2.7 Altera Stratix 1/2

Generics used in this technology:	clk_mul, clk_div, sdramen, pcien, pcisysclk, freq, clk2xen
Instantiated technology primitives:	ALTPLL
Signals not driven in this technology:	clk4x, clk1xu, clk2xu, clkb, clkc

This technology instantiates an ALTPLL primitive to generate the required clocks, see figure 34. The ALTPLL attributes are listed in table 199. As can be seen in this table the OPERATION_MODE attribute depends on the VHDL generic *sdramen*.

Table 199. Altera Stratix 1/2 ALTPLL attributes

Attribute name*	Value with *sdramen* = 1	Value with *sdramen* = 0
OPERATION_MODE	"ZERO_DELAY_BUFFER"	"NORMAL"
INCLK0_INPUT_FREQUENCY	1000000000 / (VHDL generic *freq*)	1000000000 / (VHDL generic *freq*)
WIDTH_CLOCK	6	6
CLK0_MULTIPLY_BY	VHDL generic *clk_mul*	VHDL generic *clk_mul*
CLK0_DIVIDE_BY	VHDL generic *clk_div*	VHDL generic *clk_div*
CLK1_MULTIPLY_BY	VHDL generic *clk_mul* * 2	VHDL generic *clk_mul* * 2
CLK1_DIVIDE_BY	VHDL generic *clk_div*	VHDL generic *clk_div*

The values driven on the ALTPLL clock enable signals are dependent on the VHDL generic *clk2xen*, table 200 lists the effect of *clk2xen*.

*Table 200.*Effect of VHDL generic *clk2xen* on ALTPLL clock enable inputs

Signal	Value with *clk2xen* = 0	Value with *clk2xen* /= 0
CLKENA[5:0]	0b000001	0b000011
EXTCLKENA[3:0]	0b0001	0b0011

Table 201 lists the connections of the core's input and outputs to the ALTPLL ports.

*Table 201.*Connections between core ports and ALTPLL ports

Core signal	Core direction	ALTPLL signal
CLKIN/PCICLKIN*	Input	INCLK[0]
CLK	Output	CLK[0]
CLKN	Output	$\overline{CLK[0]}$ (CLK[0] through an inverter)
CLK2X	Output	CLK[1]
SDCLK	Output	EXTCLK[0]
CGO.CLKLOCK	Output	LOCKED

  * Depending on VHDL generics PCIEN and PCISYSCLK, as described below.

The clocks can be generated using either the CLKIN input or the PCICLKIN input. This is selected with the VHDL generics *pcien* and *pcisysclk*. If *pcien* is 0 or *pcisysclk* is 0 the input clock to the ALT-PLL will be CLKIN. If *pcien* is non-zero and *pcisysclk* is 1 the input to the ALTPLL will be PCI-CLKIN.

The PCICLK output will connected to the PCICLKIN input if VHDL generic *pcien* is non-zero. Otherwise the PCICLK output will be driven to ground. The CGO.PCILOCK signal is always driven high.

23.2.8 Altera Stratix 3

This technology is not fully supported at this time.

23.2.9 RHLIB18t

Generics used in this technology:	clk_mul, clk_div
Instantiated technology primitives:	lfdll_top
Signals not driven in this technology:	-

Please contact Frontgrade Gaisler for information concerning the use of this clock generator.

23.2.10 RHUMC

Generics used in this technology:	None
Instantiated technology primitives:	pll_ip
Signals not driven in this technology:	-

Please contact Frontgrade Gaisler for information concerning the use of this clock generator.

Generics used in this technology:	clk_mul, clk_div, sdramen, noclkfb, pcien, pcidll, pcisysclk, freq, clk2xen, clksel
Instantiated technology primitives:	BUFG, BUFMUX, DCM, BUFGDLL
Signals not driven in this technology:	clk4x, clkb, clkc

The main clock is generated with a DCM which is instantiated with the attributes listed in table 202. The input clock source connected to the CLKIN input is either the core's CLKIN input or the PCI-CLKIN input. This is selected with the VHDL generics *pcien* and *pcisysclk*. The main DCM's connections is shown in figure 35.

Table 202. Spartan 3/e DCM attributes

Attribute name*	Value
CLKDV_DIVIDE	2.0
CLKFX_DIVIDE	Determined by core's VHDL generic *clk_div*
CLKFX_MULTIPLY	Determined by core's VHDL generic *clk_mul*
CLKIN_DIVIDE_BY_2	false
CLKIN_PERIOD	10.0
CLKOUT_PHASE_SHIFT	"NONE"
CLK_FEEDBACK	"2X"
DESKEW_ADJUST	"SYSTEM_SYNCHRONOUS"
DFS_FREQUENCY_MODE	"LOW"
DLL_FREQUENCY_MODE	"LOW"
DSS_MODE	"NONE"
DUTY_CYCLE_CORRECTION	true
FACTORY_JF	X"C080"
PHASE_SHIFT	0
STARTUP_WAIT	false

*Any attributes not listed are assumed to have their default value

Figure 35. Spartan 3/e generation of main clock

If the VHDL generic *clk2xen* is non-zero the DCM shown in figure 36 is instantiated. The attributes of this DCM are the same as in table 202, except that the CLKFX_MULTIPLY and CLKFX_DIVIDE attributes are both set to 2 and the CLK_FEEDBACK attribute is set to "1X". The dll0lock signal is connected to the LOCKED output of the main clock DCM. When this signal is low all the bits in the

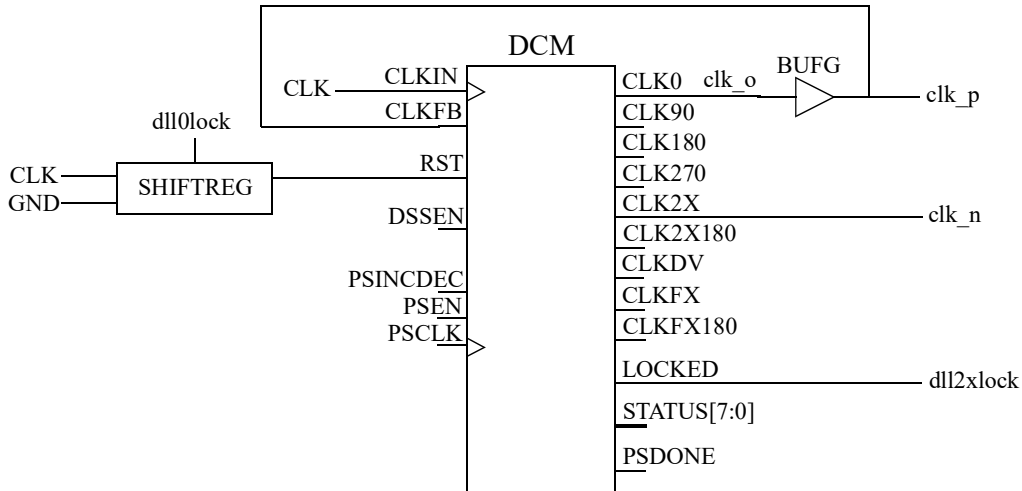
shift register connected to the CLK2X DCM's RST input are set to '1'. When the dll0lock signal is asserted it will take four main clock cycles until the RST input is deasserted. Depending on the value of the *clksel* VHDL generic the core's CLK2X output is either driven by a BUFG or a BUFGMUX. Figure 37 shows the two alternatives and how the CGI.CLKSEL(0) input is used to selected between the CLK0 and CLK2X output of the CLK2X DCM.


Figure 36. Spartan 3/e generation of CLK2X clock when VHDL generic *clk2xen* is non-zero
Figure 37. Spartan 3/e selection of CLK2X clock when VHDL generic *clk2xen* is non-zero

The value of the *clk2xen* VHDL generic also decides which output that drives the core's CLK output. If the VHDL generic is non-zero the CLK output is driven by the clk_p signal originating from the CLK2X DCM. Otherwise the CLK output is connected to the clk_i signal originating from the main clock DCM. The core's CLKN output is driven by the selected signal through an inverter. Figure 38 illustrates the connections.
Figure 38. Spartan 3/e clock generator outputs CLK and CLKN

If the VHDL generic *clk2xen* is zero the dll0lock signal from the main clock DCM is either connected to the SDRAM DCM, described below, or if the SDRAM DCM is non-existent, to the core's CGO.CLKLOCK output. This setting also leads to the core's CLK2X output being driven by the main clock DCM's CLK2X output via a BUFG, please see figure 39.

Figure 39. Spartan 3/e generation of CLK2X clock when VHDL generic *clk2xen* is zero

If the SDRAM clock is enabled, via the *sdramen* VHDL generic, and the clock generator is configured to use clock feedback the DCM shown in figure 40 is instantiated. This DCM has the same attributes as the CLK2X DCM. The input to the SDRAM DCM input clock is determined via the *clk2xen* VHDL generic. If the VHDL generic is set to 0 the input is the main CLK, if the generic is set to 1 the input is the clk_p out of the CLK2X DCM shown in figure 37. If the *clk2xen* VHDL generic is set to 2 the clock input to the SDRAM DCM depends on the *clksel* VHDL generic. The input in this last case is the CLK2X output shown in figure 39.

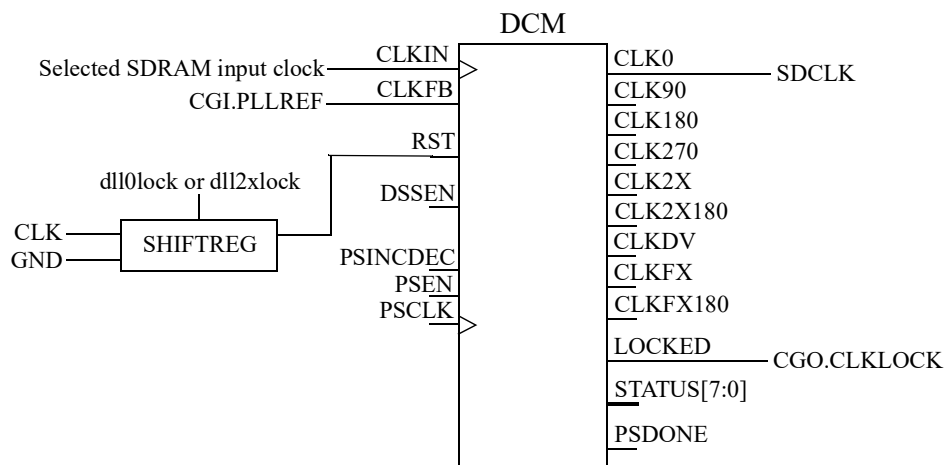
If the CLK2X DCM has been instantiated the SDRAM DCM RST input depends on the LOCKED output of the CLK2X DCM. If the CLK2X DCM has not been instantiated the SDRAM DCM RST input depends on the LOCKED output from the main clock DCM. The applicable LOCKED signal is utilized to keep the SDRAM DCM in reset until its input clock has been stabilized. This is done with a shift register with the same method used for the CLK2X DCM RST.


Figure 40. Spartan 3/e generation of SDRAM clock

If the SDRAM clock is disabled (*sdramen* VHDL generic set to 0) or the core has been configured not to use clock feedback (*noclockfb* VHDL generic set to 1) the driver of the core's SDCLK output is determined by the value of the *clk2xen* VHDL generic. If the *clk2xen* VHDL generic is set to 2, the SDRAM clock output is the same as the CLK2X output shown in figure 37, in other words it also depends on the *clksel* VHDL generic. If the *clk2xen* VHDL generic has any other value the SDCLK output is the same as the core's CLK output.

When the *sdramen* VHDL generic is set to 0 the core's CGO.CLKLOCK output is connected to the CLK2X DCM's LOCKED output, if the DCM exists, otherwise the CGO.CLKLOCK output is connected to the main clock DCM's LOCKED output.

If PCI clock generation is enabled via the *pcien* VHDL generic the core instantiates either a BUFG or a BUFGDLL as depicted in figure 41 below. Note that the PCI clock must be enabled if the main clock is to be driven by the PCICLKIN input. If the PCI clock is disabled the PCICLK output is driven to zero. The CGO.PCILOCK output is always driven high in all configurations.

Figure 41. Spartan 3/e PCI clock generation

23.2.12 Xilinx Virtex

Generics used in this technology:	clk_mul, clk_div, sdramen, noclkfb, pcien, pcidll, pcisysclk
Instantiated technology primitives:	BUFG, BUFGDLL, CLKDLL
Signals not driven in this technology:	clk4x, clk1xu, clk2xu, clkb, clkc

The main clock is generated with the help of a CLKDLL. Figure 42 below shows how the CLKDLL primitive is connected. The input clock source is either the core's CLKIN input or the PCICLKIN input. This is selected with the VHDL generics *pcien* and *pcisysclk*. The figure shows three potential drivers of the BUFG driving the output clock CLK, the driver is selected via the VHDL generics *clk_mul* and *clk_div*. If *clk_mul/clk_div* is equal to 2 the CLK2X output is selected, if *clk_div/clk_mul* equals 2 the CLKDV output is selected, otherwise the CLK0 output drives the BUFG. The inverted main clock output, CLKN, is the BUFG output connected via an inverter.

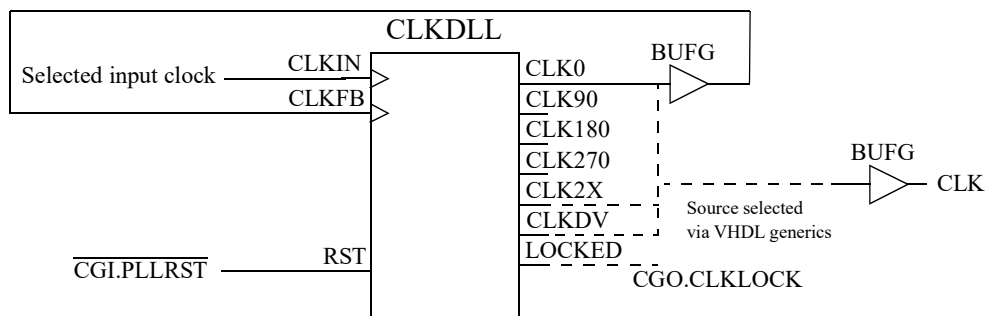
The figure shows a dashed line connecting the CLKDLL's LOCKED output to the core output CGO.CLKLOCK. The driver of the CGO.CLKLOCK output depends on the instantiation of a CLK-DLL for the SDRAM clock. See description of the SDRAM clock below.


Figure 42. Virtex generation of main clock

If the SDRAM clock is enabled, via the *sdramen* VHDL generic, and the clock generator is configured to use clock feedback, VHDL generic *noclkfb* set to 0, a CLKDLL is instantiated as depicted in figure 43. Note how the CLKDLL's RST input is connected via a shift register clocked by the main clock. The shift register is loaded with all '1' when the LOCKED signal of the main clock CLKDLL is low. When the LOCKED signal from the main clock CLKDLL is asserted the SDRAM CLKDLL's RST input will be deasserted after four main clock cycles.

For all other configurations the SDRAM clock is driven by the main clock and the CGO.CLKLOCK signal is driven by the main clock CLKDLL's LOCKED output. The SDRAM CLKDLL must be present if the core's CLK2X output shall be driven.

                                                                            +46 31 7758650 | frontgrade.com/gaisler
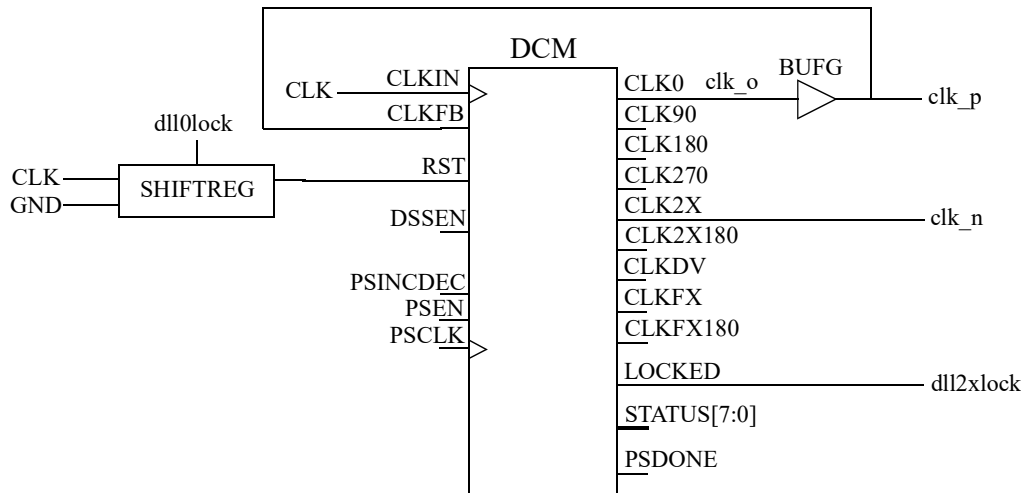

Figure 52. Virtex 5 generation of CLK2X clock when VHDL generic *clk2xen* is non-zero

The value of the *clk2xen* VHDL generic also decides which output that drives the core's CLK output. If the VHDL generic is non-zero the CLK output is driven by the clk_p signal originating from the CLK2X DCM. Otherwise the CLK output is connected to the clk_i signal originating from the main clock DCM. Note that the CLKN output always originates from the main clock DCM, as shown in figure 51.
Figure 53. Virtex 5 selection of CLK2X clock when VHDL generic *clk2xen* is non-zero

If the VHDL generic *clk2xen* is zero the dll0lock signal from the main clock DCM is either connected to the SDRAM DCM, described below, or if the SDRAM DCM is non-existent, to the core's CGO.CLKLOCK output. This setting also leads to the core's CLK2X output being driven directly by the main clock DCM's CLK2X output.

If the SDRAM clock is enabled, via the *sdramen* VHDL generic, and the clock generator is configured to use clock feedback the DCM shown in figure 54. This DCM has the same attributes as the main clock DCM described in table 204, with the exceptions that CLKFX_MULTIPLY and CLKFX-_DIVIDE are both set to 2 and DESKEW_ADJUST is set to "SOURCE_SYNCHRONOUS".

The input to the SDRAM DCM input clock is determined via the *clk2xen* VHDL generic. If the VHDL generic is set to 0 the input is the main CLK, if the generic is set to 1 the input is the clk_p out of the CLK2X DCM shown in figure 46. If the *clk2xen* VHDL generic is set to 2 the clock input to the SDRAM DCM depends on the *clksel* VHDL generic. The input in this last case is the CLK2X output shown in figure 53.

If the CLK2X DCM has been instantiated the SDRAM DCM RST input depends on the LOCKED output of the CLK2X DCM. If the CLK2X DCM has not been instantiated the SDRAM DCM RST input depends on the LOCKED output from the main clock DCM. The applicable LOCKED signal is utilized to keep the SDRAM DCM in reset until its input clock has been stabilized. This is done with a shift register with the same method used for the CLK2X DCM RST.

Generics used in this technology:	clk_mul, clk_div, freq, pcisysclk, pcien, sdramen, clk2xen
Instantiated technology primitives:	eclkgen
Signals not driven in this technology:	clk1xu, clk2xu, clkb, clkc

An example instantiating eASIC's clock generator wrapper that generates clk, clkn and clk2x is provided. Note that the example does not instantiate buffers on the clock outputs. Please contact Frontgrade Gaisler for information concerning the use of this clock generator.

23.2.17 Actel Fusion

Generics used in this technology:	clk_mul, clk_div, clk_odiv, pcisysclk, pcien, freq, clkb_odiv, clkc_odiv
Instantiated technology primitives:	PLLINT, PLL
Signals not driven in this technology:	clkn, sdclk, clk2x, clk4x, clk1xu, clk2xu

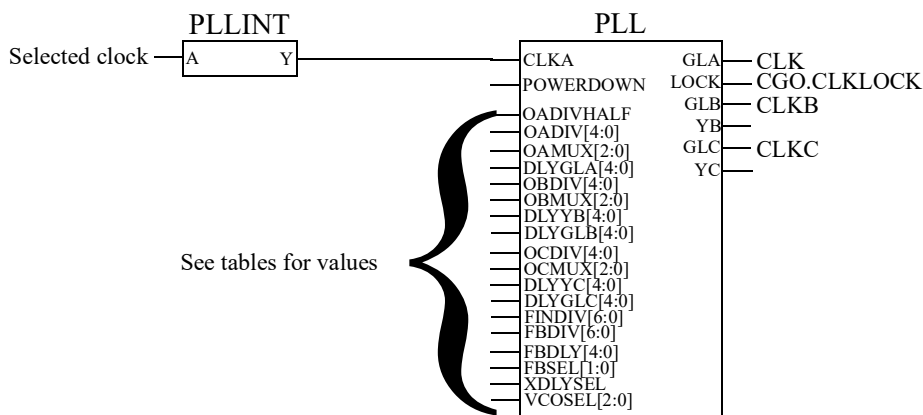
This technology instantiates a PLL and a PLLINT to generate the main clock. The instantiation of a PLLINT macro allows the PLL reference clock to be driven from an I/O that is routed through the regular FPGA routing fabric. Figure 56 shows the instantiated primitives, the PLL EXTFB input is not shown and the EXTFB port on the instantiated component is always tied to ground. The OADIVRST port on the PLL is driven by CGI.PLLRST. The figure shows which of the core's output ports that are driven by the PLL. The PCICLOCK will directly connected to PCICLKIN if VHDL generic *pcien* is non-zero, while CGO.PCILOCK is always driven high. The VHDL generics *pcien* and *pcisysclk* are used to select the reference clock. The values driven on the PLL inputs are listed in tables 205 and 206.


Figure 56. Actel Fusion clock generation

Signals not driven in this technology:	clkn, sdclk, clk4x, clk1xu, clk2xu,clk8x

For this technology, the input clock frequency has to be in range 20-200 MHz.

For the correct use of the clkgen, it is necessary to specify the generic **freq**, which indicates the input clock frequency in KHz, and the generic **clksel**. In particular, the generic **clksel** selects if the clkgen will use the PLL internal feedback or the external feedback. In fact, the implementation makes use of

a NX_PLL primitive, which allows the user to select a feedback internal to the primitive itself or external to it. Since the implementation is quite different depending on the value of **clksel**, the two possibilities are described separately in the following sections.

clksel = 0

For this implementation, the NX_PLL makes use of the feedback path internal to the primitive. The clock generation is supported only if the condition

$$\text{freq} \times \text{clk\_mul} \times 2 < 1200 \text{ MHz}$$

is satisfied.

The internal feedback allows the multiplication of the input clock frequency for any number from 1 to 15 but the generated clock won't be phase aligned with the reference clock.

In this case, three clocks are generated: *clk, clkb* and *clkc*. Their frequency depends on the values of the generics **freq**, **clk_mul**, **clk_odiv**, **clkb_odiv** and **clkc_odiv**. In particular:

if **freq** < 100 Mhz then

$$\left(\text{clk\_freq} = \frac{\text{freq} \times \text{clk\_mul} \times 2}{2^{\text{clk\_odiv}}} \right) \quad \left(\text{clkb\_freq} = \frac{\text{freq} \times \text{clk\_mul} \times 2}{2^{\text{clkb\_odiv}}} \right) \quad \left(\text{clkc\_freq} = \frac{\text{freq} \times \text{clk\_mul} \times 2}{2^{\text{clkc\_odiv}}} \right)$$

if **freq** > 100 Mhz then

$$\left(\text{clk\_freq} = \frac{\text{freq} \times \text{clk\_mul}}{2^{\text{clk\_odiv}}} \right) \quad \left(\text{clkb\_freq} = \frac{\text{freq} \times \text{clk\_mul}}{2^{\text{clkb\_odiv}}} \right) \quad \left(\text{clkc\_freq} = \frac{\text{freq} \times \text{clk\_mul}}{2^{\text{clkc\_odiv}}} \right)$$

clksel = 1

For this implementation the NX_PLL makes use of the external feedback. The generated clock will be phase aligned with the reference clock but it will also be at the same frequency as the reference clock (the generic **clk_mul** has to be set to 1).

By setting the generic "**noclkfb**" to 1, the feedback will be handled inside the clkgen module. Instead, if "**noclkfb**" is set to 0 the feedback has to be handled externally and the feedback clock has to be provided through the input *cgi.pllref*.

In this case, the clkgen generates two clocks: *clk* and *clk2x*.

The first one, *clk*, has a frequency equal to the reference clock. Instead, *clk2x* doubles the input clock frequency if

$$\text{freq} \leq 100 Mhz$$

Otherwise *clk2x* has also the same frequency as the reference clock.

Both for **clksel** = 1 or 0, the output *cgo.clklock* (active high) signals if the PLL is locked and if it generates stable clocks. Instead, the output *cgo.pcilock* is always high.

Moreover, there are several possibilities regarding the PCI clock :

- If **pcien**= 0 then the input *pciclkin* is not used and the output *pciclk* is set low

- If **pcien**/= 0 then *pciclk* output is fed throught a buffer by the *pciclkin* input

- If **pcien** /= 0 and **pcisysclk** is /=0 then *pciclkin* input is also used as the main clock reference and the *clkin* input is not used.

In the last case, the generic **freq** has to be set to the value of the *pciclkin* frequency in KHz.

23.3   Configuration options

Table 207 shows the configuration options of the core (VHDL generics).

*Table 207.*Configuration options

Generic name	Function	Allowed range	Default
tech	Target technology	0 - NTECH	inferred
clk_mul	Clock multiplier, used in clock scaling. Not all techbologies support clock scaling.		1
clk_div	Clock divisor, used in clock scaling. Not all technologies support clock scaling.		1
sdramen	When this generic is set to 1 the core will generate a clock on the SDCLK. Not supported by all technologies. See technology specific description.		0
noclkfb	When this generic is set to 0 the core will use the CGI.PLLREF input as feedback clock for some technologies. See technology specific description.		1
pcien	When this generic is set to 1 the PCI clock is activated. Otherwise the PCICLKIN input is typically unused. See technology specific descriptions.		0
pcidll	When this generic is set to 1, a DLL will be instantiated for the PCI input clock for some technologies. See the technology specific descriptions.		0
pcisysclk	When this generic is set to 1 the clock generator will use the pciclkin input as the main clock reference. This also requires generic pcien to be set to 1.		0
freq	Clock frequency in kHz		25000
clk2xen	Enables 2x clock output. Not available in all technolgies and may have additional options. See technology specific description.		0
clksel	Enable clock select. Not available in all technologies.		0
clk_odiv	ProASIC3/Fusion output divider for GLA. Only used in ProASIC3/Fusion technology.	1 - 32	1
clkb_odiv	ProASIC3/Fusion output divider for GLB. Only used in ProASIC3/Fusion technology. Set this value to 0 to disable generation of GLB.	0 - 32	0
clkc_odiv	ProASIC3/Fusion output divider for GLC. Only used in ProASIC3/Fusion technology. Set this value to 0 to disable generation of GLC.	0 - 32	0

23.4   Signal descriptions

Table 208 shows the interface signals of the core (VHDL ports).

*Table 208.*Signal descriptions

Signal name	Field	Type	Function	Active

24 DDRSPA - 16-, 32- and 64-bit DDR266 Controller

24.1 Overview

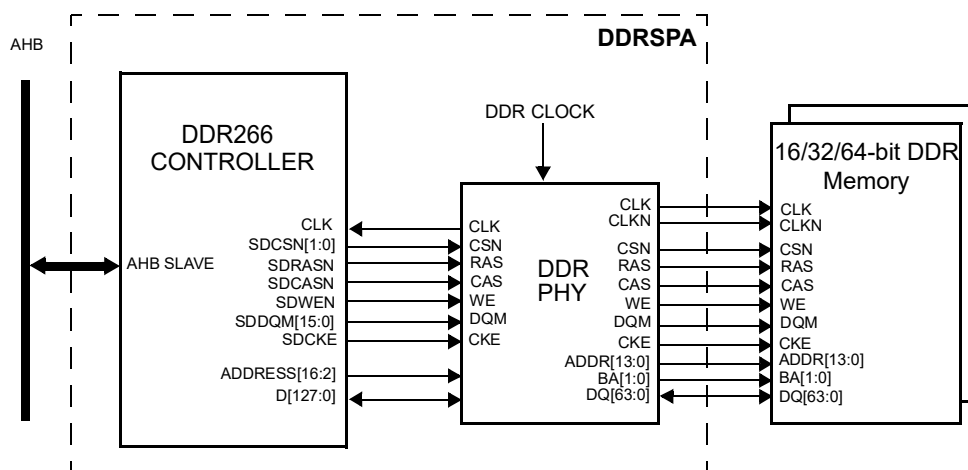
DDRSPA is a DDR266 SDRAM controller with AMBA AHB back-end. The controller can interface two 16-, 32- or 64-bit DDR266 memory banks to a 32-bit AHB bus. The controller acts as a slave on the AHB bus where it occupies a configurable amount of address space for DDR SDRAM access. The DDR controller is programmed by writing to a configuration register mapped located in AHB I/O address space. Internally, DDRSPA consists of a ABH/DDR controller and a technology specific DDR PHY. For currently supported technologies for the PHY see section 24.7.2. The modular design of DDRSPA allows to add support for other target technologies in a simple manner.


Figure 58. DDRSPA Memory controller conected to AMBA bus and DDR SDRAM

24.2 Operation

24.2.1 General

Double data-rate SDRAM (DDR RAM) access is supported to two banks of 16-, 32- or 64-bit DDR266 compatible memory devices. The controller supports 64M, 128M, 256M, 512M and 1G devices with 9- 12 column-address bits, up to 14 row-address bits, and 4 internal banks. The size of each of each chip select can be programmed in binary steps between 8 Mbyte and 1024 Mbyte. The DDR data width is set by the *ddrbits* VHDL generic, and will affect the width of DM, DQS and DQ signals. The DDR data width does not change the behavior of the AHB interface, except for data latency. When the VHDL generic *mobile* is set to a value not equal to 0, the controller supports mobile DDR SDRAM (LPDDR).

24.2.2 Read cycles

An AHB read access to the controller will cause a corresponding access to the external DDR RAM. The read cycle is started by performing an ACTIVATE command to the desired bank and row, followed by a READ command. CAS latency of 2 (CL=2) or 3 (CL=3) can be used. Byte, half-word (16-bit) and word (32-bit) AHB accesses are supported. Incremental AHB burst access are supported for 32-bit words only. The read cycle(s) are always terminated with a PRE-CHARGE command, no banks are left open between two accesses. DDR read cycles are always performed in (aligned) 8-word bursts, which are stored in a FIFO. After an initial latency, the data is then read out on the AHB bus with zero waitstates.

GRIP

Apr 2024, Version 2024.1

198

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

24.2.3 Write cycles

Write cycles are performed similarly to read cycles, with the difference that WRITE commands are issued after activation. An AHB write burst will store up to 8 words in a FIFO, before writing the data to the DDR memory. As in the read case, only word bursts are supported

24.2.4 Initialization

If the *pwron* VHDL generic is 1, then the DDR controller will automatically perform the DDR initialization sequence as described in the JEDEC DDR266 standard: PRE-CHARGE, LOAD-EXTMODE-REG, LOAD-MODE-REG, PRE-CHARGE, 2xREFRESH and LOAD-MODE-REG; or as described in the JEDEC LPDDR standard when mobile DDR is enabled: PRE-CHARGE, 2xREFRESH, LOAD-MODE-REG and LOAD-EXTMODE-REG. The VHDL generics *col* and *Mbyte* can be used to also set the correct address decoding after reset. In this case, no further software initialization is needed. The DDR initialization can be performed at a later stage by setting bit 15 in the DDR control register.

24.2.5 Configurable DDR SDRAM timing parameters

To provide optimum access cycles for different DDR devices (and at different frequencies), three timing parameters can be programmed through the memory configuration register (SDCFG): TRCD, TRP and TRFCD. The value of these field affects the SDRAM timing as described in table 212.

*Table 212.*DDR SDRAM programmable minimum timing parameters

SDRAM timing parameter	Minimum timing (clocks)
Precharge to activate (t_{RP})	TRP + 2
Auto-refresh command period (t_{RFC})	TRFC + 3
Activate to read/write (t_{RCD})	TRCD + 2
Activate to Activate (t_{RC})	TRCD + 8
Activate to Precharge (t_{RAS})	TRCD + 6

If the TCD, TRP and TRFC are programmed such that the DDR200/266 specifications are fulfilled, the remaining SDRAM timing parameters will also be met. The table below shows typical settings for 100 and 133 MHz operation and the resulting SDRAM timing (in ns):

*Table 213.*DDR SDRAM example programming

DDR SDRAM settings	t_{RCD}	t_{RC}	t_{RP}	t_{RFC}	t_{RAS}
100 MHz: CL=2, TRP=0, TRFC=4, TRCD=0	20	80	20	70	60
133 MHz: CL=2, TRP=1, TRFC=6, TRCD=1	22.5	75	22.5	67.5	52.5

When the DDRSPA controller uses CAS latency (CL) of two cycles a DDR SDRAM speed grade of -75Z or better is needed to meet 133 MHz timing.

When mobile DDR support is enabled, two additional timing parameters can be programmed though the Power-Saving configuration register.

*Table 214.*Mobile DDR SDRAM programmable minimum timing parameters

SDRAM timing parameter	Minimum timing (clocks)
Exit Power-down mode to first valid command (t_{XP})	TXP + 1
Exit Self Refresh mode to first valid command (t_{XSR})	TXSR + 1
CKE minimum pulse width (t_{CKE})	TCKE + 1

199

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

24.2.6 Extended timing fields

The DDRSPA controller can be configured with extended timing fields to provide support for DDR333 and DDR400. These fields can be detected by checking the XTF bit in the SDCFG register.

When the extended timing fields are enabled, extra upper bits are added to increase the range of the TRP, TRFC, TXSR and TXP fields. A new TWR field allow increasing the write recovery time. A new TRAS field to directly control the Active to Precharge period has been added.

*Table 215.*DDR SDRAM extended timing parameters

SDRAM timing parameter	Minimum timing (clocks)
Activate to Activate (t_{RC})	TRAS+TRCD + 2
Activate to Precharge (t_{RAS})	TRAS + 6
Write recovery time (t_{WR})	TWR+2

*Table 216.*DDR SDRAM extended timing example programming

DDR SDRAM settings	t_{RCD}	t_{RC}	t_{RP}	t_{RFC}	t_{RAS}	t_{WR}
166 MHz: CL=2, TRP=1, TRFC=9, TRCD=1, TRAS=1, TWR=1	18	60	18	72	42	18
200 MHz: CL=3, TRP=1, TRFC=11, TRCD=1, TRAS=2, TWR=1	15	55	15	70	40	15

24.2.7 Refresh

The DDRSPA controller contains a refresh function that periodically issues an AUTO-REFRESH command to both SDRAM banks. The period between the commands (in clock periods) is programmed in the refresh counter reload field in the SDCFG register. Depending on SDRAM type, the required period is typically 7.8 us (corresponding to 780 at 100 MHz). The generated refresh period is calculated as (reload value+1)/sysclk. The refresh function is enabled by bit 31 in SDCTRL register.

24.2.8 Self Refresh

The self refresh mode can be used to retain data in the SDRAM even when the rest of the system is powered down. When in the self refresh mode, the SDRAM retains data without external clocking and refresh are handled internally. The memory array that is refreshed during the self refresh operation is defined in the extended mode register. These settings can be changed by setting the PASR bits in the Power-Saving configuration register. The extended mode register is automatically updated when the PASR bits are changed. The supported "Partial Array Self Refresh" modes are: Full, Half, Quarter, Eighth, and Sixteenth array. "Partial Array Self Refresh" is only supported when mobile DDR functionality is enabled. To enable the self refresh mode, set the PMODE bits in the Power-Saving configuration register to "010" (Self Refresh). The controller will enter self refresh mode after every memory access (when the controller has been idle for 16 clock cycles), until the PMODE bits are cleared. When exiting this mode and mobile DDR is disabled, the controller introduce a delay of 200 clock cycles and a AUTO REFRESH command before any other memory access is allowed. When mobile DDR is enabled the delay before the AUTO REFRESH command is defined by tXSR in the Power-Saving configuration register. The minimum duration of this mode is defined by tRFC. This mode is only available when the VHDL generic *mobile* is >= 1.

24.2.9 Clock Stop

In the clock stop mode, the external clock to the SDRAM is stop at a low level (DDR_CLK is low and DDR_CLKB is high). This reduce the power consumption of the SDRAM while retaining the data. To enable the clock stop mode, set the PMODE bits in the Power-Saving configuration register to "100" (Clock Stop). The controller will enter clock stop mode after every memory access (when the controller has been idle for 16 clock cycles), until the PMODE bits are cleared. The REFRESH com-

GRIP
Apr 2024, Version 2024.1

200

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

mand will still be issued by the controller in this mode. This mode is only available when the VHDL generic *mobile* is >= 1 and mobile DDR functionality is enabled.

24.2.10 Power-Down

When entering the power-down mode all input and output buffers, including DDR_CLK and DDR_-CLKB and excluding DDR_CKE, are deactivated. This is a more efficient power saving mode then clock stop mode, with a grater reduction of the SDRAM's power consumption. All data in the SDRAM is retained during this operation. To enable the power-down mode, set the PMODE bits in the Power-Saving configuration register to "001" (Power-Down). The controller will enter power-down mode after every memory access (when the controller has been idle for 16 clock cycles), until the PMODE bits is cleared. The REFRESH command will still be issued by the controller in this mode. When exiting this mode a delay of one or two (when tXP in the Power-Saving configuration register is '1') clock cycles are added before issue any command to the memory. This mode is only available when the VHDL generic *mobile* is >= 1.

24.2.11 Deep Power-Down

The deep power-down operating mode is used to achieve maximum power reduction by eliminating the power of the memory array. Data will not be retained after the device enters deep power-down mode. To enable the deep power-down mode, set the PMODE bits in the Power-Saving configuration register to "101" (Deep Power-Down). To exit the deep power-down mode the PMODE bits in the Power-Saving configuration register must be cleared followed by the mobile SDRAM initialization sequence. The mobile SDRAM initialization sequence can be performed by setting bit 15 in the DDR control register. This mode is only available when the VHDL generic *mobile* is >= 1 and mobile DDR functionality is enabled.

24.2.12 Status Read Register

The status read register (SRR) is used to read the manufacturer ID, revision ID, refresh multiplier, width type, and density of the SDRAM. To Read the SSR a LOAD MODE REGISTER command with BA0 = 1 and BA1 = 0 must be issued followed by a READ command with the address set to 0. This command sequence is executed then the Status Read Register is read. This register is only available when the VHDL generic *mobile* is >= 1 and mobile DDR functionality is enabled. Only DDR_CSB[0] is enabled during this operation.

24.2.13 Temperature-Compensated Self Refresh

The settings for the temperature-compensation of the Self Refresh rate can be controlled by setting the TCSR bits in the Power-Saving configuration register. The extended mode register is automatically updated when the TCSR bits are changed. Note that some vendors implements a Internal Temperature-Compensated Self Refresh feature, which makes the memory to ignore the TCSR bits. This functionality is only available when the VHDL generic *mobile* >= 1 and mobile DDR functionality is enabled.

24.2.14 Drive Strength

The drive strength of the output buffers can be controlled by setting the DS bits in the Power-Saving configuration register. The extended mode register is automatically updated when the DS bits are changed. The available options are: full, three-quarter, one-half, and one-quarter drive strengths. This functionality is only available when the VHDL generic *mobile* is >= 1 and mobile DDR functionality is enabled.

GRIP

Apr 2024, Version 2024.1

201

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

24.2.15 SDRAM commands

The controller can issue four SDRAM commands by writing to the SDRAM command field in SDCFG: PRE-CHARGE, LOAD-EXTMODE-REG, LOAD-MODE-REG and REFRESH. If the LEMR command is issued, the PLL Reset bit as programmed in SDCFG will be used, when mobile DDR support is enabled the DS, TCSR and PASR as programmed in Power-Saving configuration register will be used. If the LMR command is issued, the CAS latency as programmed in the Power-Saving configuration register will be used and remaining fields are fixed: 8 word sequential burst. The command field will be cleared after a command has been executed.

24.2.16 Clocking

The DDR controller is designed to operate with two clock domains, one for the DDR memory clock and one for the AHB clock. The two clock domains do not have to be the same or be phase-aligned. The DDR input clock (CLK_DDR) can be multiplied and divided by the DDR PHY to form the final DDR clock frequency. The final DDR clock is driven on one output (CLKDDRO), which should always be connected to the CLKDDRI input. If the AHB clock and DDR clock area generated from the same clock source, a timing-ignore constraint should be placed between the CLK_AHB and CLKDDRI to avoid optimization of false-paths during synthesis and place&route.

The Xilinx version of the PHY generates the internal DDR read clock using an external clock feed-back. The feed-back should have the same delay as DDR signals to and from the DDR memories. The feed-back should be driven by DDR_CLK_FB_OUT, and returned on DDR_CLK_FB. Most Xilinx FPGA boards with DDR provides clock feed-backs of this sort. The supported frequencies for the Xilinx PHY depends on the clock-to-output delay of the DDR output registers, and the internal delay from the DDR input registers to the read data FIFO. Virtex2 and Virtex4 can typically run at 120 MHz, while Spartan3e can run at 100 MHz.

The read data clock in the Xilinx version of the PHY is generated using a DCM to offset internal delay of the DDR clock feed back. If the automatic DCM phase adjustment does not work due to unsuitable pin selection, extra delay can be added through the RSKEW VHDL generic. The VHDL generic can be between -255 and 255, and is passed directly to the PHASE_SHIFT generic of the DCM.

The Altera version of the PHY use the DQS signals and an internal PLL to generate the DDR read clock. No external clock feed-back is needed and the DDR_CLK_FB_OUT/DDR_CLK_FB signals are not used. The supported frequencies for the Altera PHY are 100, 110, 120 and 130 MHz. For Altera CycloneIII, the read data clock is generated by the PLL. The phase shift of the read data clock is set be the VHDL generic RSKEW in ps (e.g. a value of 2500 equals 90' phase for a 100MHz system).

24.2.17 Pads

The DDRSPA core has technology-specific pads inside the core. The external DDR signals should therefore be connected directly the top-level ports, without any logic in between.

24.2.18 Endianness

The core is designed for big-endian systems.

24.3.1 Control Register

Table 218. SDRAM control register (SDCTRL)

31	30	29 27	26	25 23	22 21	20 18	17	16	15	14 0
Refresh	tRP	tRFC	tRCD	SDRAM bank size	SDRAM col. size	SDRAM command	PR	IN	CE	SDRAM refresh load value

31	SDRAM refresh. If set, the SDRAM refresh will be enabled. This register bit is read only when Power-Saving mode is other then none.
30	SDRAM tRP timing. tRP will be equal to 2 or 3 system clocks (0/1). When mobile DDR support is enabled, this bit also represent the MSB in the tRFC timing.
29: 27	SDRAM tRFC timing. tRFC will be equal to 3 + field-value system clocks. When mobile DDR support is enabled, this field is extended with the bit 30.
26	SDRAM tRCD delay. Sets tRCD to 2 + field value clocks.
25: 23	SDRAM banks size. Defines the decoded memory size for each SDRAM chip select: "000"= 8 Mbyte, "001"= 16 Mbyte, "010"= 32 Mbyte .... "111"= 1024 Mbyte.
22: 21	SDRAM column size. "00"=512, "01"=1024, "10"=2048, "11"=4096
20: 18	SDRAM command. Writing a non-zero value will generate an SDRAM command: "010"=PRE-CHARGE, "100"=AUTO-REFRESH, "110"=LOAD-COMMAND-REGISTER, "111"=LOAD-EXTENDED-COMMAND-REGISTER. The field is reset after command has been executed.
17	PLL Reset. This bit is used to set the PLL RESET bit during LOAD-CONFIG-REG commands.
16	Initialize (IN). Set to '1' to perform power-on DDR RAM initialisation. Is automatically cleared when initialisation is completed. This register bit is read only when Power-Saving mode is other then none.
15	Clock enable (CE). This value is driven on the CKE inputs of the DDR RAM. Should be set to '1' for correct operation. This register bit is read only when Power-Saving mode is other then none.
14: 0	The period between each AUTO-REFRESH command - Calculated as follows: tREFRESH = ((reload value) + 1) / DDRCLOCK

24.3.2 Configuration Register

24.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x025. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

24.5 Implementation

24.5.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

24.6   Configuration options

Table 224 shows the configuration options of the core (VHDL generics).

Table 224. Configuration options

Generic	Function	Allowed range	Default
fabtech	PHY technology selection	virtex2, virtex4, spartan3e, altera	virtex2
memtech	Technology selection for DDR FIFOs	infered, virtex2, virtex4, spartan3e, altera	infered
hindex	AHB slave index	0 - NAHBSLV-1	0
haddr	ADDR field of the AHB BAR0 defining SDRAM area. Default is 0xF0000000 - 0xFFFFFFFF.	0 - 16#FFF#	16#000#
hmask	MASK field of the AHB BAR0 defining SDRAM area.	0 - 16#FFF#	16#F00#
ioaddr	ADDR field of the AHB BAR1 defining I/O address space where DDR control register is mapped.	0 - 16#FFF#	16#000#
iomask	MASK field of the AHB BAR1 defining I/O address space	0 - 16#FFF#	16#FFF#
ddrbits	Data bus width of external DDR memory	16, 32, 64	16
MHz	DDR clock input frequency in MHz.	10 - 200	100
clkmul, clkdiv	The DDR input clock is multiplied with the clkmul generic and divided with clkdiv to create the final DDR clock	2 - 32	2
rstdel	Clock reset delay in micro-seconds.	1 - 1023	200
col	Default number of column address bits	9 - 12	9
Mbyte	Default memory chip select bank size in Mbyte	8 - 1024	16
pwron	Enable SDRAM at power-on initialization	0 - 1	0
oepol	Polarity of bdrive and vbdrive signals. 0=active low, 1=active high	0 - 1	0
ahbfreq	Frequency in MHz of the AHB clock domain	1 - 1023	50
rskew	Additional read data clock skew Read data clock phase for Altera CycloneIII	-255 - 255. 0 - 9999	0
mobile	Enable Mobile DDR support 0: Mobile DDR support disabled 1: Mobile DDR support enabled but not default 2: Mobile DDR support enabled by default 3: Mobile DDR support only (no regular DDR support)	0 - 3	0
confapi	Set the PHY configuration register API: 0 = standard register API (conf0 and conf1 disabled). 1 = TCI RTL_PHY register API.		
conf0	Reset value for PHY register 0, conf[31:0]	0 - 16#FFFFFFFF#	0
conf1	Reset value for PHY register1, conf[63:32]	0 - 16#FFFFFFFF#	0
regoutput	Enables registers on signal going from controller to PHY	0 - 1	0
ddr400	Enables extended timing fields for DDR400 support	0 - 1	1
scantest	Enable scan test support	0 - 1	0
phyiconf	PHY implementation configuration. This generic sets technology specific implementation options for the DDR PHY. Meaning of values depend on the setting of VHDL generic *fabtech*. For fabtech:s virtex4, virtex5, virtex6: phyiconf selects type of pads used for DDR clock pairs. 0 instantiates a differenial pad and 1 instantiates two outpads.	0 - 16#FFFFFFFF#	0

24.7 Implementation

24.7.1 Technology mapping

The core has two technology mapping VHDL generics: *memtech* and *fabtech*. The VHDL generic *memtech* controls the technology used for memory cell implementation. The VHDL generic *fabtech* controls the technology used in the PHY implementation. See the GRLIB Users's Manual for available settings.

24.7.2 FPGA support

Complete PHY:s for a number FPGA technologies are included in the distribution, see table below. Unless otherwise noted these have been only functionally tested on evaluation board in lab environment and detailed timing analysis has not been performed. Note also that some of the FPGA phy:s use simplified sampling approaches which may require the memory timing to be better than the JEDEC standard specifies.

Scripts for post-layout static timing analysis are not included. Because these PHY:s are based on dedicated hard macros with fixed placement in the FPGA:s pad structure, just a minimal set of constraints are normally neccessary for synthesis purposes.

Table 225.FPGA DDR PHYs included in GRLIB

Technology	fabtech	Read clock method	Built-in pads
Virtex4,5,6	virtex4, virtex5, virtex6	Clock feedback loop + static shift	Yes
Virtex2, Spartan3	virtex2, spartan3	Clock feedback loop + static shift	Yes
Spartan3E,6	spartan3	Clock feedback loop + static shift	Yes
Stratix II	stratix2	Tech intrinsics (DQS based)	Yes
Cyclone 3	cyclone3	Static shift	Yes

24.7.3 RAM usage

The FIFOs in the core are implemented with the *syncram_2p* (with separate clock for each port) component found in the technology mapping library (TECHMAP). The number of RAMs used for the FIFO implementation depends on the DDR data width, set by the *ddrbits* VHDL generic.

Table 226.RAM usage

RAM dimension (depth x width)	Number of RAMs (DDR data width 64)	Number of RAMs (DDR data width 32)	Number of RAMs (DDR data width 16)
4 x 128	1		
4 x 32	4		
5 x 64		1	
5 x 32		2	
6 x 32			2

25 DDR2SPA - 16-, 32- and 64-bit Single-Port Asynchronous DDR2 Controller

25.1 Overview

DDR2SPA is a DDR2 SDRAM controller with AMBA AHB back-end. The controller can interface 16-, 32- or 64-bit wide DDR2 memory with one or two chip selects. The controller acts as a slave on the AHB bus where it occupies a configurable amount of address space for DDR2 SDRAM access. The DDR2 controller is programmed by writing to configuration registers mapped located in AHB I/O address space.

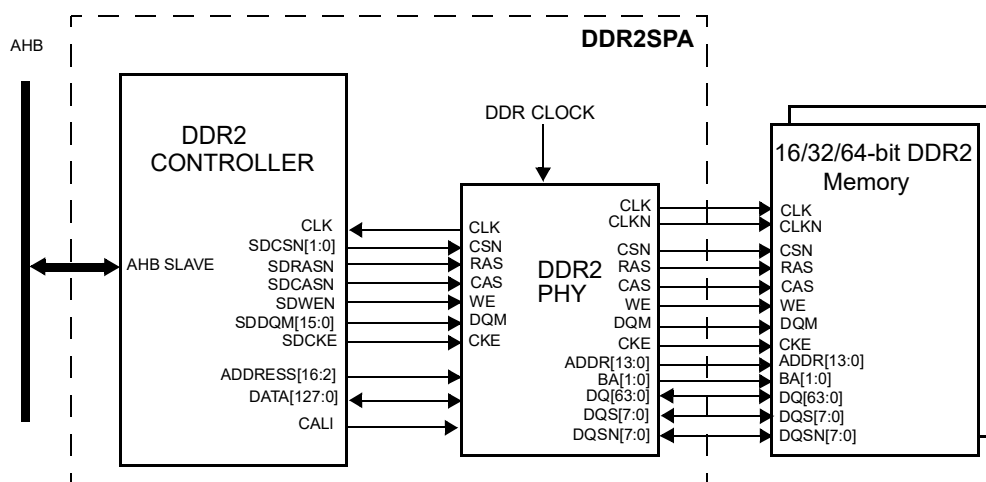
Internally, DDR2SPA consists of a ABH/DDR2 controller and a technology specific DDR2 PHY. For currently supported technologies for the PHY, see section 25.8.2. The modular design of DDR2SPA allows to add support for other target technologies in a simple manner.


Figure 59. DDR2SPA Memory controller connected to AMBA bus and DDR2 SDRAM

25.2 Operation

25.2.1 General

Single DDR2 SDRAM chips are typically 4,8 or 16 data bits wide. By putting multiple identical chips side by side, wider SDRAM memory banks can be built. Since the command signals are common for all chips, the memories behave as one single wide memory chip.

This memory controller supports one or two (identical) such 16/32/64-bit wide DDR2 SDRAM memory banks. The size of the memory can be programmed in binary steps between 8 Mbyte and 1024 Mbyte, or between 32 Mbyte and 4096 Mbyte. The DDR data width is set by the DDRBITS generic, and will affect the width of DM, DQS and DQ signals. The DDR data width does not change the behavior of the AHB interface, except for data latency.

25.2.2 Data transfers

An AHB read or write access to the controller will cause a corresponding access cycle to the external DDR2 RAM. The cycle is started by performing an ACTIVATE command to the desired bank and row, followed by a sequence of READ or WRITE commands (the count depending on memory width and burst length setting). After the sequence, a PRECHARGE command is performed to deactivate the SDRAM bank.

All access types are supported, but only incremental bursts of 32 bit width and incremental bursts of maximum width (if wider than 32) are handled efficiently. All other bursts are handled as single-

GRIP

Apr 2024, Version 2024.1

212

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

accesses. For maximum throughput, incremental bursts of full AHB width with both alignment and length corresponding to the burstlen generic should be performed.

The maximum supported access size can be limited by using the ahbbits generic, which is set to the full AHB bus size by default. Accesses larger than this size are not supported.

The memory controller's FIFO has room for two write bursts which improves throughput, since the second write can be written into the FIFO while the first write is being written to the DDR memory.

In systems with high DDR clock frequencies, the controller may have to insert wait states for the minimum activate-to-precharge time (t_{RAS}) to expire before performing the precharge command. If a new AHB access to the same memory row is performed during this time, the controller will perform the access in the same access cycle.

25.2.3 Initialization

If the **pwron** VHDL generic is 1, then the DDR2 controller will automatically on start-up perform the DDR2 initialization sequence as described in the JEDEC DDR2 standard. The VHDL generics **col** and **Mbyte** can be used to also set the correct address decoding after reset. In this case, no further software initialization is needed except for enabling the auto-refresh function. If power-on initialization is not enabled, the DDR2 initialization can be started at a later stage by setting bit 16 in the DDR2 control register DDR2CFG1.

25.2.4 Big memory support

The total memory size for each chip select is set through the 3-bit wide SDRAM banks size field, which can be set in binary steps between 8 Mbyte and 1024 Mbyte. To support setting even larger memory sizes of 2048 and 4096 Mbyte, a fourth bit has been added to this configuration field.

Only 8 different sizes are supported by the controller, either the lower range of 8 MB - 1 GB, or the higher range of 32 MB - 4 GB. Which range is determined by the bigmem generic, and can be read by software through the DDR2CFG2 register.

25.2.5 Configurable DDR2 SDRAM timing parameters

To provide optimum access cycles for different DDR2 devices (and at different frequencies), six timing parameters can be programmed through the memory configuration registers: TRCD, TCL, TRTP, TWR, TRP and TRFC. For faster memories (DDR2-533 and higher), the TRAS setting also needs to be configured to satisfy timing. The value of these fields affects the DDR2RAM timing as described in table 229. Note that if the CAS latency setting is changed after initialization, this change needs also to be programmed into the memory chips by executing the Load Mode Register command.

*Table 229.*DDR2 SDRAM programmable minimum timing parameters

DDR2 SDRAM timing parameter	Minimum timing (clocks)
CAS latency, CL	TCL + 3
Activate to read/write command (t_{RCD})	TRCD + 2
Read to precharge (t_{RTP})	TRTP + 2
Write recovery time (t_{WR})	TWR-2
Precharge to activate (t_{RP})	TRP + 2
Activate to precharge (t_{RAS})	TRAS + 1
Auto-refresh command period (t_{RFC})	TRFC + 3

If TRCD, TCL, TRTP, TWR, TRP, TRFC and TRAS are programmed such that the DDR2 specifications are full filled, the remaining SDRAM timing parameters will also be met. The table below

shows typical settings for 130, 200 and 400 MHz operation and the resulting DDR2 SDRAM timing (in ns):

Table 230. DDR2 SDRAM example programming

DDR2 SDRAM settings	CL	t_{RCD}	t_{RC}	t_{RP}	t_{RFC}	t_{RAS}
130 MHz: TCL=0,TRCD=0,TRTP=0,TRP=0,TRAS=0,TRFC=7	3	15	76	15	76	61
200 MHz: TCL=0,TRCD=1,TRTP=0,TRP=1,TRAS=1,TRFC=13	3	15	60	15	80	45
400 MHz: TCL=2,TRCD=4,TRTP=1,TRP=4,TRAS=10,TRFC=29	5	15	60	15	80	45

25.2.6 Refresh

The DDR2SPA controller contains a refresh function that periodically issues an AUTO-REFRESH command to both SDRAM banks. The period between the commands (in clock periods) is programmed in the refresh counter reload field in the DDR2CFG1 register. Depending on SDRAM type, the required period is typically 7.8 us (corresponding to 780 at 100 MHz). The generated refresh period is calculated as (reload value+1)/sysclk. The refresh function is enabled by bit 31 in DDR2CFG1 register.

25.2.7 DDR2 SDRAM commands

The controller can issue four SDRAM commands by writing to the SDRAM command field in SDCFG1: PRE-CHARGE, LOAD-EXTMODE-REG, LOAD-MODE-REG and REFRESH. If the LMR command is issued, the PLL Reset bit as programmed in DDR2CFG1, CAS Latency setting as programmed in DDR2CFG4 and the WR setting from DDR2CFG3 will be used, remaining fields are fixed: 4 word sequential burst. If the LEMR command is issued, the OCD bits will be used as programmed in the DDR2CFG1 register, and all other bits are set to zero. The command field will be cleared after a command has been executed.

25.2.8 Registered SDRAM

Registered memory modules (RDIMM:s) have one cycle extra latency on the control signals due to the external register. They can be supported with this core by setting the REG bit in the DDR2CFG4 register.

This should not be confused with Fully-Buffered DDR2 memory, which uses a different protocol and is <u>not</u> supported by this controller.

25.2.9 Clocking

The DDR2 controller operates in two separate clock domains, one domain synchronous to the DDR2 memory and one domain synchronous to the AHB bus. The two clock domains do not have to be the same or be phase-aligned.

The clock for the DDR2 memory domain is generated from the controller's ddr_clk input via a technology-specific PLL component. The multiplication and division factor can be selected via the clkmul/clkdiv configuration options. The final DDR2 clock is driven on one output (CLKDDRO), which should always be connected to the CLKDDRI input.

The ddr_rst input asynchronously resets the PHY layer and the built-in PLL. The ahb_rst input should be reset simultaneously and then kept in reset until the PLL has locked (indicated by the lock output).

If the AHB and DDR2 clocks are based on the same source clock and are kept phase-aligned by the PLL, the clock domain transition is synchronous to the least common multiple of the two clock frequencies. In this case, the nosync configuration option can be used to remove the synchronization and handshaking between the two clock domains, which saves a few cycles of memory access latency. If nosync is not set in this case, a timing-ignore constraint should be placed between the CLK_AHB and CLKDDRI to avoid optimization of false-paths during synthesis and place&route.

The supported DDR2 frequencies depends on the clock-to-output delay of the DDR output registers, and the internal delay from the DDR input registers to the read data FIFO. Virtex5 can typically run at 200 MHz.

When reading data, the data bus (DQ) signals should ideally be sampled 1/4 cycle after each data strobe (DQS) edge. How this is achieved is technology-specific as described in the following sections.

25.2.10 Read data clock calibration on Xilinx Virtex

On Xilinx Virtex4/5 the data signal inputs are delayed via the I/O pad IDELAY feature to get the required 1/4 cycle shift. The delay of each byte lane is tuned independently between 0-63 tap delays, each tap giving 78 ps delay, and the initial value on startup is set via the generics ddelayb[7:0].

The delays can be tuned at runtime by using the DDR2CFG3 control register. There are two bits in the control register for each byte. One bit determines if the delay should be increased or decreased and the other bit is set to perform the update. Setting bit 31 in the DDR2CFG3 register resets the delays to the initial value.

To increase the calibration range, the controller can add additional read latency cycles. The number of additional read latency cycles is set by the RD bits in the DDR2CFG3 register.

25.2.11 Read data clock calibration on Altera Stratix

On Altera StratixIII, the technology's delay chain feature is used to delay bytes of input data in a similar fashion as the Virtex case above. The delay of each byte lane is tuned between 0-15 tap delays, each tap giving 50 ps delay, and the initial value on startup is 0.

The delays are tuned at runtime using the DDR2CFG3 register, and extra read cycles can be added using DDR2CFG3, the same way as described for Virtex.

The data sampling clock can also be skewed on Stratix to increase the calibration range. This is done writing the PLL_SKEW bits in the DDR2CFG3 register.

25.2.12 Read data clock calibration on Xilinx Spartan-3

On Spartan3, a clock loop is utilized for sampling of incoming data. The DDR_CLK_FB_OUT port should therefore be connected to a signal path of equal length as the DDR_CLK + DDR_DQS signal path. The other end of the signal path is to be connected to the DDR_CLK_FB port. The fed back clock can then be skewed for alignment with incoming data using the rskew generic. The rskew generic can be set between +/-255 resulting in a linear +/-360 degree change of the clock skew. Bits 29 and 30 in the DDR2CFG3 register can be used for altering the skew at runtime.

25.2.13 Pads

The DDR2SPA core has technology-specific pads inside the core. The external DDR2 signals should therefore be connected directly the top-level ports, without any logic in between.

25.2.14 Endianness

The core is designed for big-endian systems.

25.3 Fault-tolerant operation (preliminary)

25.3.1 Overview

The memory controller can be configured to support bit-error tolerant operation by setting the ft generic (not supported in all versions of GRLIB). In this mode, the DDR data bus is widened and the extra bits are used to store 16 or 32 checkbits corresponding to each 64 bit data word. The variant to

be used can be configured at run-time depending on the connected DDR2 data width and the desired level of fault tolerance.

When writing, the controller generates the check bits and stores them along with the data. When reading, the controller will transparently correct any correctable bit errors and provide the corrected data on the AHB bus. However, the corrected bits are not written back to the memory so external scrubbing is necessary to avoid uncorrectable errors accumulating over time.

An extra corrected error output signal is asserted when a correctable read error occurs, at the same cycle as the corrected data is delivered. This can be connected to an interrupt input or to a memory scrubber. In case of uncorrectable error, this is signaled by giving an AHB error response to the master.

25.3.2 Memory setup

In order to support error-correction, the DDR2 data bus needs to be expanded. The different possible physical configurations are tabulated below. For software, there is no noticeable difference between these configurations.

If the hardware is built for the wider code, it is still possible to leave the upper half of the checkbit data bus unconnected and use it for code B.

*Table 231.*Configurations of FT DDR2 memory banks

Data bits (DDRBITS)	Checkbits (FTBITS)	Interleaving modes supported
64	32	A and B
64	16	B only
32	16	A and B
32	8	B only
16	8	A only

25.3.3 Error-correction properties

The memory controller uses an interleaved error correcting code which works on nibble (4-bit) units of data. The codec can be used in two interleaving modes, mode A and mode B.

In mode A, the basic code has 16 data bits, 8 check bits and can correct one nibble error. This code is interleaved by 4 using the pattern in table 232 to create a code with 64 data bits and 32 check bits.

This code can tolerate one nibble error in each of the A,B,C,D groups shown below. This means that we can correct 100% of single errors in two adjacent nibbles, or in any 8/16-bit wide data bus lane, that would correspond to a physical DDR2 chip. The code can also correct 18/23=78% of all possible random two-nibble errors.

This interleaving pattern was designed to also provide good protection in case of reduced (32/16-bit) DDR bus width with the same data-checkbit relation, so software will see the exact same checkbits on diagnostic reads.

In mode B, the basic code has 32 data bits, 8 check bits and can correct one nibble error. This code is then interleaved by a factor of two to create a code with 64 data bits and 16 check bits.

Note that when configured for a 16-bit wide DDR data bus, code A must be used to get protection from multi-column errors since each data bus nibbles holds four code word nibbles.

*Table 232.*Mode Ax4 interleaving pattern (64-bit data width)

63:60	59:56	55:52	51:48	47:44	43:40	39:36	35:32	31:28	27:24	23:20	19:16	15:12	11:8	7:4	3:0

												95:88	87:80	79:72	71:64
												A_{cb}	B_{cb}	A_{cb}	B_{cb}

25.3.4 Data transfers

The read case behaves the same way as the non-FT counterpart, except a few cycles extra are needed for error detection and correction. There is no extra time penalty in the case data is corrected compared to the error-free case.

Only writes of 64 bit width or higher will translate directly into write cycles to the DDR memory. Other types of write accesses will generate a read-modify-write cycle in order to correctly update the check-bits. In the special case where an uncorrectable error is detected while performing the RMW cycle, the write is aborted and the incorrect checkbits are left unchanged so they will be detected upon the next read.

Only bursts of maximum AHB width is supported, other bursts will be treated as single accesses.

The write FIFO only has room for one write (single or burst).

25.3.5 DDR2 behavior

The behavior over the DDR2 interface is largely unchanged, the same timing parameters and setup applies as for the non-FT case. The checkbit data and data-mask signals follow the same timing as the corresponding signals for regular data.

25.3.6 Configuration

Whether the memory controller is the FT or the non-FT version can be detected by looking at the FTV bit in the DDR2CFG2 register.

Checkbits are always written out to memory when writing even if EDACEN is disabled. Which type of code, A or B, that is used for both read and write is controlled by the CODE field in the DDR2FTCFG register.

Code checking on read is disabled on reset and is enabled by setting the EDACEN bit in the DDR2FTCFG register. Before enabling this, the code to be used should be set in the CODE field and the memory contents should be (re-)initialized.

25.3.7 Diagnostic checkbit access

The checkbits and data can be accessed directly for testing and fault injection. This is done by writing the address of into the DDR2FTDA register. The check-bits and data can then be read and written via the DDR2FTDC and DDR2FTDD register. Note that for checkbits the DDR2FTDA address is 64-bit aligned, while for data it is 32-bit aligned.

After the diagnostic data register has been read, the FT control register bits 31:19 can be read out to see if there were any correctable or uncorrectable errors detected, and where the correctable errors were located. For the 64 databit wide version, there is one bit per byte lane describing whether a correctable error occurred.

25.3.8 Code boundary

The code boundary feature allows you to gradually switch the memory from one interleaving mode to the other and regenerate the checkbits without stopping normal operation. This can be used when recovering from memory faults, as explained further below.

GRIP

Apr 2024, Version 2024.1

217

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

If the boundary address enable (BAEN) control bit is set, the core will look at the address of each access, and use the interleaving mode selected in the CODE field for memory accesses above or equal to the boundary address, and the opposite code for memory accesses below to the boundary address.

If the boundary address update (BAUPD) control bit is also set, the core will shift the boundary upwards whenever the the address directly above the boundary is written to. Since the written data is now below the boundary, it will be written using the opposite code. The write can be done with any size supported by the controller.

25.3.9 Data muxing

When code B is used instead of code A, the upper half of the checkbits are unused. The controller supports switching in this part of the data bus to replace another faulty part of the bus. To do this, one sets the DATAMUX field to a value between 1-4 to replace a quarter of the data bus, or to 5 to replace the active checkbit half.

25.3.10 Memory fault recovery

The above features are designed to, when combined and integrated correctly, make the system cabable to deal with a permanent fault in an external memory chip.

A basic sequence of events is as follows:

1.   The system is running correctly with EDAC enabled and the larger code A is used.

2.   A memory chip gets a fault and delivers incorrect data. The DDR2 controller keeps delivering error-free data but reports a correctable error on every read access.

3.   A logging device (such as the memory scrubber core) registers the high frequency of correctable errors and signals an interrupt.

4.   The CPU performs a probe using the DDR2 FT diagnostic registers to confirm that the error is permanent and on which physical lane the error is.

5.   After determining that a permanent fault has occurred, the CPU reconfigures the FTDDR2 controller as follows (all configuration register fields changed with a single register write):

The data muxing control field is set so the top checkbit half replaces the failed part of the data bus.

The code boundary register is set to the lowest memory address.

The boundary address enable and boundary address update enable bits are set.

The mask correctable error bit is set

6.   The memory data and checkbits are now regenerated using locked read-write cycles to use the smaller code and replace the broken data with the upper half of the checkbit bus. This can be done in hardware using an IP core, such as the AHB memory scrubber, or by some other means depending on system design.

7.   After the whole memory has been regenerated, the CPU disables the code boundary, changes the code selection field to code B, and unsets the mask correctable error bit.

After this sequence, the system is now again fully operational, but running with the smaller code and replacement chip and can again recover from any single-nibble error. Note that during this sequence, it is possible for the system to operate and other masters can both read and write to memory while the regeneration is ongoing.

25.4 Registers

The DDR2SPA core implements between 5 and 12 control registers, depending on the FT generic and target technology. The registers are mapped into AHB I/O address space defined by the AHB BAR1 of the core. Only 32-bit single-accesses to the registers are supported.

Older revisions of the core only have registers DDRCFG1-4, which are aliased on the following addresses. For that reason, check the REG5 bit in DDR2CFG2 before using these bits for backward compatibility.

For backward compatibility, some of the bits in DDR2CFG5 are mirrored in other registers. Writing to these bits will affect the contents of DDR2CFG5 and vice versa.

*Table 234.*DDR2 controller registers

Address offset - AHB I/O - BAR1	Register
0x00	DDR2 SDRAM control register (DDR2CFG1)
0x04	DDR2 SDRAM configuration register (DDR2CFG2)
0x08	DDR2 SDRAM control register (DDR2CFG3)
0x0C	DDR2 SDRAM control register (DDR2CFG4)
0x10*	DDR2 SDRAM control register (DDR2CFG5)
0x14*	Reserved
0x18	DDR2 Technology specific register (DDR2TSR1)
0x1C*	DDR2 Technology specific register (DDR2TSR2)
0x20	DDR2 FT Configuration Register (FT only) (DDR2FTCFG)
0x24	DDR2 FT Diagnostic Address register (FT only) (DDR2FTDA)
0x28	DDR2 FT Diagnostic Checkbit register (FT only) (DDR2FTDC)
0x2C	DDR2 FT Diagnostic Data register (FT only) (DDR2FTDD)
0x30	DDR2 FT Code Boundary Register (FT only) (DDR2FTBND)

* Older DDR2SPA versions contain aliases of DDR2CFG1-4 at these addresses. Therefore, check bit 15 of DDR2CFG2 before using these registers.

25.4.1 DDR2 SDRAM Configuration Register 1

Table 235. 0x00 - DDR2CFG1 - DDR2 SRAM control register 1

25.6 Implementation

25.6.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

25.7 Configuration options

Table 245 shows the configuration options of the core (VHDL generics).

Table 245. Configuration options

Generic	Function	Allowed range	Default
fabtech	PHY technology selection	virtex4, virtex5, stratix3	virtex4
memtech	Technology selection for DDR FIFOs	inferred, virtex2, virtex4, spartan3e, altera	inferred
hindex	AHB slave index	0 - NAHBSLV-1	0
haddr	ADDR field of the AHB BAR0 defining SDRAM area. Default is 0xF0000000 - 0xFFFFFFFF.	0 - 16#FFF#	16#000#
hmask	MASK field of the AHB BAR0 defining SDRAM area.	0 - 16#FFF#	16#F00#
ioaddr	ADDR field of the AHB BAR1 defining I/O address space where DDR control register is mapped.	0 - 16#FFF#	16#000#
iomask	MASK field of the AHB BAR1 defining I/O address space	0 - 16#FFF#	16#FFF#
ddrbits	Data bus width of external DDR memory	16, 32, 64	16
MHz	DDR clock input frequency in MHz.	10 - 200	100
clkmul, clkdiv	The DDR input clock is multiplied with the clkmul generic and divided with clkdiv to create the final DDR clock	2 - 32	2
rstdel	Clock reset delay in micro-seconds.	1 - 1023	200
col	Default number of column address bits	9 - 12	9
Mbyte	Default memory chip select bank size in Mbyte	8 - 1024	16
pwron	Enable SDRAM at power-on initialization	0 - 1	0
oepol	Polarity of bdrive and vbdrive signals. 0=active low, 1=active high	0 - 1	0
ahbfreq	Frequency in MHz of the AHB clock domain	1 - 1023	50
readdly	Additional read latency cycles (used to increase calibration range)	0-3	1
TRFC	Reset value for the tRFC timing parameter in ns.	75-155	130
ddelayb0*	Input data delay for bit[7:0]	0-63	0
ddelayb1*	Input data delay for bit[15:8]	0-63	0
ddelayb2*	Input data delay for bit[23:16]	0-63	0
ddelayb3*	Input data delay for bit[31:24]	0-63	0
ddelayb4*	Input data delay for bit[39:32]	0-63	0
ddelayb5*	Input data delay for bit[47:40]	0-63	0
ddelayb6*	Input data delay for bit[55:48]	0-63	0
ddelayb7*	Input data delay for bit[63:56]	0-63	0
cbdelayb0*	Input data delay for checkbit[7:0]	0-63	0
cbdelayb1*	Input data delay for checkbit[15:8]	0-63	0
cbdelayb2*	Input data delay for checkbit[23:16]	0-63	0
cbdelayb3*	Input data delay for checkbit[31:24]	0-63	0

*Table 245.*Configuration options

Generic	Function	Allowed range	Default
numidelctrl*	Number of IDELAYCTRL the core will instantiate	-	4
norefclk*	Set to 1 if no 200 MHz reference clock is connected to clkref200 input.	0-1	0
odten	Enable odt: 0 = Disabled, 1 = 75Ohm, 2 =150Ohm, 3 = 50Ohm	0-3	0
rskew**	Set the phase relationship between the DDR controller clock and the input data sampling clock. Sets the phase in ps.	0 - 9999	0
octen**	Enable on chip termination: 1 = enabled, 0 = disabled	0 - 1	0
dqsgating***	Enable gating of DQS signals when doing reads. 1 = enable, 0 = disable	0 - 1	0
nosync	Disable insertion of synchronization registers between AHB clock domain and DDR clock domain. This can be done if the AHB clock's rising edges always are in phase with a rising edge on the DDR clock. If this generic is set to 1 the clkmul and clkdiv generics should be equal. Otherwise the DDR controller may scale the incoming clock and loose the clocks' edge alignment in the process.	0 - 1	0
eightbanks	Enables address generation for DDR2 chips with eight banks. The DDR_BA is extended to 3 bits if set to 1.	0 - 1	0
dqsse	Single-ended DQS. The value of this generic is written to bit 10 in the memory's Extended Mode register. If this bit is 1 DQS is used in a single-ended mode. Currently this bit should only, and must be, set to 1 when the Stratix2 DDR2 PHY is used. This is the only PHY that supports single ended DQS without modification.	0 - 1	0
burstlen	DDR access burst length in 32-bit words	8,16,32,..,256	8
ahbbits	AHB bus width	32,64,128,256	AHBDW
ft	Enable fault-tolerant version	0 - 1	0
ftbits	Extra DDR data bits used for checkbits	0,8,16,32	0
bigmem	Big memory support, changes the range of supported total memory bank sizes from 8MB-1GB to 32MB-4GB	0 - 1	0
raspipe	Enables an extra pipeline stage in the address decoding to improve timing at the cost of one DDR-cycle latency	0 - 1	0
* only available in Virtex4/5 implementation. ** only available in Altera and Spartan3 implementations. *** only available on Nextreme/eASIC implementations			

25.8   Implementation

25.8.1   Technology mapping

The core has two technology mapping VHDL generics: *memtech* and *fabtech*. The VHDL generic *memtech* controls the technology used for memory cell implementation. The VHDL generic *fabtech* controls the technology used in the PHY implementation. See the GRLIB Users's Manual for available settings.

25.8.2   FPGA support

Complete PHY:s for a number of FPGA technologies are included in the distribution, see table below. Unless otherwise noted these have been only functionally tested on evaluation board in lab environment and detailed timing analysis has not been performed. Note also that some of the FPGA phy:s use

GRIP
Apr 2024, Version 2024.1

225

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

simplified sampling approaches which may require the memory timing to be better than the JEDEC standard specifies.

Scripts for post-layout static timing analysis are not included. Because these PHY:s are based on dedicated hard macros with fixed placement in the FPGA:s pad structure, just a minimal set of constraints are normally neccessary for synthesis purposes.

Some PHY:s support instantiation without built-in pads, to separate the pads from the PHY the internal ddr2spax entity and the phy must be instantiated manually.

*Table 246.*FPGA DDR2 PHYs included in GRLIB

Technology	fabtech	Read clock method	Built-in pads
Stratix 2	stratix2	Tech intrinsics (DQS based)	Yes
Stratix 3	stratix3	Tunable static shift	Yes
Spartan 3	spartan3	Clock feedback loop + static shift	Yes
Virtex4,5,6	virtex4, virtex5, virtex6	Fixed clock, DQ shifted using IDELAY	Yes or No
Spartan6	spartan6	Fixed clock, DQ shifted using IDELAY	Yes or No

25.8.3 RAM usage

The FIFOs in the core are implemented with the *syncram_2p* (with separate clock for each port) component found in the technology mapping library (TECHMAP). The number of RAMs used for the FIFO implementation depends om the DDR data width, set by the *ddrbits* VHDL generic, and the AHB bus width in the system.

The RAM block usage is tabulated below for the default burst length of 8 words. If the burst length is doubled, the depths for all the RAMs double as well but the count and width remain the same.

*Table 247.*Block-RAM usage for default burst length

DDR width	AHB width	Write FIFO block-RAM usage			Read-FIFO block-RAM usage			Total RAM count
		Count	Depth	Width	Count	Depth	Width	
16	32	1	16	32	1	8	32	2
16	64	2	8	32	2	4	32	4
16	128	4	4	32	4	2	32	8
16	256	8	2	32	8	1	32	16
32	32	2	8	32	1	4	64	3
32	64	2	8	32	1	4	64	3
32	128	4	4	32	2	2	64	6
32	256	8	2	32	4	1	64	12
64	32	4	4	32	1	2	128	5
64	64	4	4	32	1	2	128	5
64	128	4	4	32	1	2	128	5
64	256	8	2	32	2	1	128	10

25.8.4 Xilinx Virtex-specific issues

The Xilinx tools require one IDELAYCTRL macro to be instantiated in every region where the IDELAY feature is used. Since the DDR2 PHY uses the IDELAY on every data (DQ) pin, this affects the DDR2 core. For this purpose, the core has a numidelctrl generic, controlling how many IDELAYCTRL's get instantiated in the PHY.

GRIP

Apr 2024, Version 2024.1

226

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The tools allow for two ways to do this instantiation:

- Instantiate the same number of IDELAYCTRL as the number of clock regions containing DQ pins and place the instances manually using UCF LOC constraints.
- Instantiate just one IDELAYCTRL, which the ISE tools will then replicate over all regions.

The second solution is the simplest, since you just need to set the numidelctrl to 1 and no extra constraints are needed. However, this approach will not work if IDELAY is used anywhere else in the FPGA design.

For more information on IDELAYCTRL, see Xilinx Virtex4/5 User's Guide.

25.8.5 Design tools

To run the design in Altera Quartus 7.2 you have to uncomment the lines in the .qsf file that assigns the MEMORY_INTERFACE_DATA_PIN_GROUP for the DDR2 interface. These group assignments result in error when Altera Quartus 8.0 is used.

25.9   Signal descriptions

Table 248 shows the interface signals of the core (VHDL ports).

Table 248. Signal descriptions

Signal name	Type	Function	Active
RST_DDR	Input	Reset input for the DDR PHY	Low
RST_AHB	Input	Reset input for AHB clock domain	Low
CLK_DDR	Input	DDR input Clock	-
CLK_AHB	Input	AHB clock	-
CLKREF200	Input	200 MHz reference clock	-
LOCK	Output	DDR clock generator locked	High
CLKDDRO		Internal DDR clock output after clock multiplication	
CLKDDRI		Clock input for the internal DDR clock domain. Must be connected to CLKDDRO.	
AHBSI	Input	AHB slave input signals	-
AHBSO	Output	AHB slave output signals	-
DDR_CLK[2:0]	Output	DDR memory clocks (positive)	High
DDR_CLKB[2:0]	Output	DDR memory clocks (negative)	Low
DDR_CLK_FB_OUT	Output	DDR data synchronization clock, connect this to a signal path with equal length of the DDR_CLK trace + DDR_DQS trace	-
DDR_CLK_FB	Input	DDR data synchronization clock, connect this to the other end of the signal path connected to DDR_CLK_FB_OUT	-
DDR_CKE[1:0]	Output	DDR memory clock enable	High
DDR_CSB[1:0]	Output	DDR memory chip select	Low
DDR_WEB	Output	DDR memory write enable	Low
DDR_RASB	Output	DDR memory row address strobe	Low
DDR_CASB	Output	DDR memory column address strobe	Low
DDR_DM[(DDRBITS+FTBITS)/8-1:0]	Output	DDR memory data mask	Low
DDR_DQS[(DDRBITS+FTBITS)/8-1:0]	Bidir	DDR memory data strobe	Low
DDR_DQSN[(DDRBITS+FTBITS)/8-1:0]	Bidir	DDR memory data strobe (inverted)	High
DDR_AD[13:0]	Output	DDR memory address bus	Low
DDR_BA[2 or 1:0] [3]	Output	DDR memory bank address	Low
DDR_DQ[DDRBITS+FTBITS-1:0]	BiDir	DDR memory data bus	-
DDR_ODT[1:0]	Output	DDR memory odt	Low

1) see GRLIB IP Library User's Manual
2) Polarity selected with the oepol generic
3) DDR_BA[2:0] if the eightbanks generic is set to 1 else DDR_BA[1:0]
4) Only used on Virtex4/5
5) Only used on Spartan3

26 DIV32 - Signed/unsigned 64/32 divider module

26.1 Overview

The divider module performs signed/unsigned 64-bit by 32-bit division. It implements the radix-2 non-restoring iterative division algorithm. The division operation takes 36 clock cycles. The divider leaves no remainder. The result is rounded towards zero. Negative result, zero result and overflow (according to the overflow detection method B of SPARC V8 Architecture manual) are detected.

26.2 Operation

The division is started when '1' is samples on DIVI.START on positive clock edge. Operands are latched externally and provided on inputs DIVI.Y, DIVI.OP1 and DIVI.OP2 during the whole operation. The result appears on the outputs during the clock cycle following the clock cycle after the DIVO.READY was asserted. Asserting the HOLD input at any time will freeze the operation, until HOLDN is de-asserted.

26.3 Implementation

26.3.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers if the GRLIB config package setting *grlib_async_reset_enable* is set.

26.4 Configurations options

Core has only one VHDL generic, scantest, that should be set to 1 if GRLIB has been configured to use asynchronous reset.

27   DSU3 - LEON3 Hardware Debug Support Unit

27.1   Overview

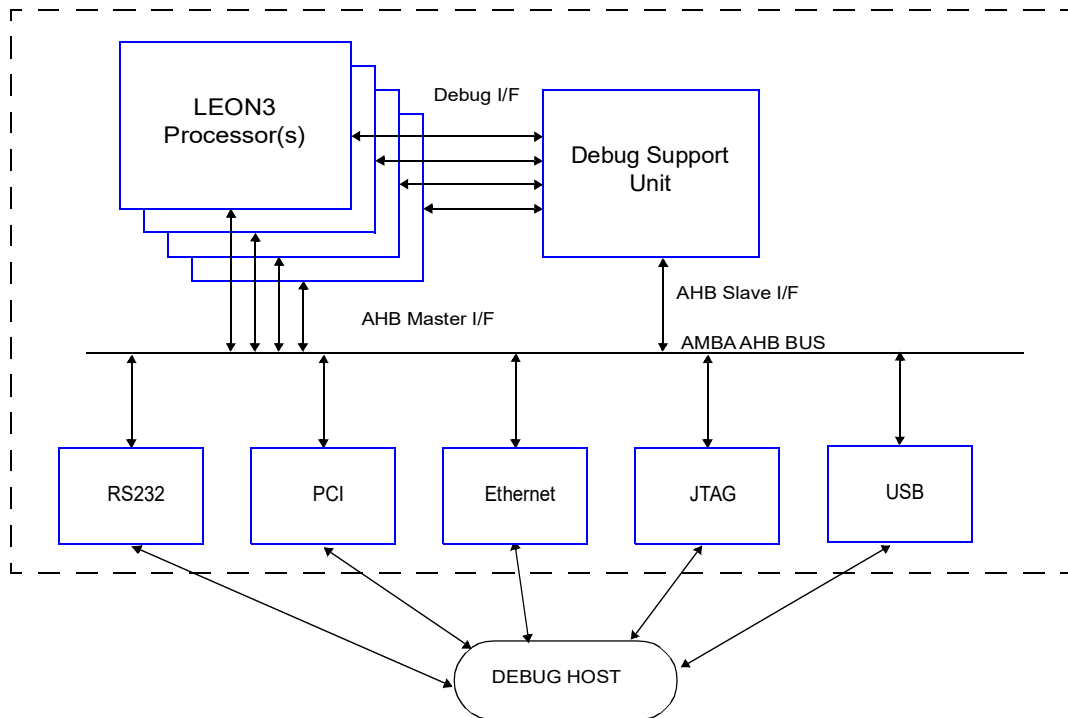
To simplify debugging on target hardware, the LEON3 processor implements a debug mode during which the pipeline is idle and the processor is controlled through a special debug interface. The LEON3 Debug Support Unit (DSU) is used to control the processor during debug mode. The DSU acts as an AHB slave and can be accessed by any AHB master. An external debug host can therefore access the DSU through several different interfaces. Such an interface can be a serial UART (RS232), JTAG, PCI, USB or Ethernet. The DSU supports multi-processor systems and can handle up to 16 processors.


Figure 60. LEON3/DSU Connection

27.2   Operation

Through the DSU AHB slave interface, any AHB master can access the processor registers and the contents of the instruction trace buffer. The DSU control registers can be accessed at any time, while the processor registers and caches can only be accessed when the processor has entered debug mode. In debug mode, the processor pipeline is held and the processor state can be accessed by the DSU. Entering the debug mode can occur on the following events:

*   executing a breakpoint instruction (ta 1)

*   integer unit hardware breakpoint/watchpoint hit (trap 0xb)

*   rising edge of the external break signal (DSUBRE)

*   setting the break-now (BN) bit in the DSU control register

*   a trap that would cause the processor to enter error mode

*   occurrence of any, or a selection of traps as defined in the DSU control register

*   after a single-step operation

*   one of the processors in a multiprocessor system has entered the debug mode

*   DSU AHB breakpoint or watchpoint hit

GRIP

Apr 2024, Version 2024.1   234   Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The debug mode can only be entered when the debug support unit is enabled through an external sig-nal (DSUEN). For DSU break (DSUBRE), and the break-now BN bit, to have effect the Break-on-IU-watchpoint (BW) bit must be set in the DSU control register. This bit is set when DSUBRE is active after reset and should also be set by debug monitor software when initializing the DSU. When the debug mode is entered, the following actions are taken:

• PC and nPC are saved in temporary registers (accessible by the debug unit)

• an output signal (DSUACT) is asserted to indicate the debug state

• the timer unit is (optionally) stopped to freeze the LEON timers and watchdog

The instruction that caused the processor to enter debug mode is not executed, and the processor state is kept unmodified. Execution is resumed by clearing the BN bit in the DSU control register or by de-asserting DSUEN. The timer unit will be re-enabled and execution will continue from the saved PC and nPC. Debug mode can also be entered after the processor has entered error mode, for instance when an application has terminated and halted the processor. The error mode can be reset and the pro-cessor restarted at any address.

When a processor is in the debug mode, an access to ASI diagnostic area is forwarded to the IU which performs access with ASI equal to value in the DSU ASI register and address consisting of 20 LSB bits of the original address.

27.3   AHB trace buffer

The AHB trace buffer consists of a circular buffer that stores AHB data transfers, the monitored AHB bus is either the same bus as the DSU AHB slave interface is connected to, or a completely separate bus. The address, data and various control signals of the AHB bus are stored and can be read out for later analysis. The trace buffer is 128, 160 or 224 bits wide, depending on the AHB bus width. Note that for systems with a 256 bit wide AHB bus, the DSU3 can be used but will only save the lower 128 bits of the AHB data bus. The way information stored is indicated in the table below:

Table 252. AHB Trace buffer data allocation

Bits	Name	Definition
223:160	Load/Store data	AHB HRDATA/HWDATA(127:64)
159:129	Load/Store data	AHB HRDATA/HWDATA(63:32)
127	AHB breakpoint hit	Set to '1' if a DSU AHB breakpoint hit occurred.
126	-	Not used
125:96	Time tag	DSU time tag counter
95:80	-	Not used
79	Hwrite	AHB HWRITE
78:77	Htrans	AHB HTRANS
76:74	Hsize	AHB HSIZE
73:71	Hburst	AHB HBURST
70:67	Hmaster	AHB HMASTER
66	Hmastlock	AHB HMASTLOCK
65:64	Hresp	AHB HRESP
63:32	Load/Store data	AHB HRDATA/HWDATA(31:0)
31:0	Load/Store address	AHB HADDR

In addition to the AHB signals, the DSU time tag counter is also stored in the trace.

The trace buffer is enabled by setting the enable bit (EN) in the trace control register. Each AHB transfer is then stored in the buffer in a circular manner. The address to which the next transfer is writ-

ten is held in the trace buffer index register, and is automatically incremented after each transfer. Tracing is stopped when the EN bit is reset, or when a AHB breakpoint is hit. Tracing is temporarily suspended when the processor enters debug mode, unless the trace force bit (TF) in the trace control register is set. If the trace force bit is set, the trace buffer is activated as long as the enable bit is set. The force bit is reset if an AHB breakpoint is hit and can also be cleared by software. Note that neither the trace buffer memory nor the breakpoint registers (see below) can be read/written by software when the trace buffer is enabled.

The DSU has an internal time tag counter and this counter is frozen when the processor enters debug mode. When AHB tracing is performed in debug mode (using the trace force bit) it may be desirable to also enable the time tag counter. This can be done using the timer enable bit (TE). Note that the time tag is also used for the instruction trace buffer and the timer enable bit should only be set when using the DSU as an AHB trace buffer only, and not when performing profiling or software debugging. The timer enable bit is reset on the same events as the trace force bit.

27.3.1 AHB trace buffer filters

The DSU can be implemented with filters that can be applied to the AHB trace buffer, breakpoints and watchpoints. If implemented, these filters are controlled via the AHB trace buffer filter control and AHB trace buffer filter mask registers. The fields in these registers allows masking access characteristics such as master, slave, read, write and address range so that accesses that correspond to the specified mask are not written into the trace buffer. Address range masking is done using the second AHB breakpoint register set. The values of the LD and ST fields of this register has no effect on filtering.

27.3.2 AHB statistics

The DSU can be implemented to generate statistics from the traced AHB bus. When statistics collection is enabled the DSU will assert outputs that are suitable to connect to a LEON3 statistics unit (L3STAT). The statistical outputs can be filtered by the AHB trace buffer filters, this is controlled by the Performance counter Filter bit (PF) in the AHB trace buffer filter control register. The DSU can collect data for the events listed in table 253 below.

Table 253. AHB events

Event	Description	Note
idle	HTRANS=IDLE	Active when HTRANS IDLE is driven on the AHB slave inputs and slave has asserted HREADY.
busy	HTRANS=BUSY	Active when HTRANS BUSY is driven on the AHB slave inputs and slave has asserted HREADY.
nseq	HTRANS=NONSEQ	Active when HTRANS NONSEQ is driven on the AHB slave inputs and slave has asserted HREADY.
seq	HTRANS=SEQ	Active when HTRANS SEQUENTIAL is driven on the AHB slave inputs and slave has asserted HREADY.
read	Read access	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and the HWRITE input is low.
write	Write access	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and the HWRITE input is high.
hsize[5:0]	Transfer size	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and HSIZE is BYTE (hsize[0]), HWORD (HSIZE[1]), WORD (hsize[2]), DWORD (hsize[3]), 4WORD hsize[4], or 8WORD (hsize[5]).
ws	Wait state	Active when HREADY input to AHB slaves is low and AMBA response is OKAY.
retry	RETRY response	Active when master receives RETRY response
split	SPLIT response	Active when master receives SPLIT response

GRIP

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 253.*AHB events

Event	Description	Note
spdel	SPLIT delay	Active during the time a master waits to be granted access to the bus after reception of a SPLIT response. The core will only keep track of one master at a time. This means that when a SPLIT response is detected, the core will save the master index. This event will then be active until the same master is re-allowed into bus arbitration and is granted access to the bus. This also means that the delay measured will include the time for re-arbitration, delays from other ongoing transfers and delays resulting from other masters being granted access to the bus before the SPLIT:ed master is granted again after receiving SPLIT complete. If another master receives a SPLIT response while this event is active, the SPLIT delay for the second master will not be measured.
locked	Locked access	Active while the HMASTLOCK signal is asserted on the AHB slave inputs.

27.4 Instruction trace buffer

The instruction trace buffer consists of a circular buffer that stores executed instructions. The instruction trace buffer is located in the processor, and read out via the DSU. The trace buffer is 128 bits wide, the information stored is indicated in the table below:

*Table 254.*Instruction trace buffer data allocation

Bits	Name	Definition
127	-	Unused
126	Multi-cycle instruction	Set to '1' on the second and third instance of a multi-cycle instruction (LDD, ST or FPOP)
125:96	Time tag	The value of the DSU time tag counter
95:64	Load/Store parameters	Instruction result, Store address or Store data
63:34	Program counter	Program counter (2 lsb bits removed since they are always zero)
33	Instruction trap	Set to '1' if traced instruction trapped
32	Processor error mode	Set to '1' if the traced instruction caused processor error mode
31:0	Opcode	Instruction opcode

During tracing, one instruction is stored per line in the trace buffer with the exception of multi-cycle instructions. Multi-cycle instructions are entered two or three times in the trace buffer. For store instructions, bits [95:64] correspond to the store address on the first entry and to the stored data on the second entry (and third in case of STD). Bit 126 is set on the second and third entry to indicate this. A double load (LDD) is entered twice in the trace buffer, with bits [95:64] containing the loaded data. Bit 126 is set for the second entry.

When the processor enters debug mode, tracing is suspended. The trace buffer and the trace buffer control register can be read and written while the processor is in the debug mode. During the instruction tracing (processor in normal mode) the trace buffer and trace buffer control register 0 can not be written. If the two-port trace buffer is enabled (refer to the *tbuf* generic in section 95.16), then the trace buffer can be read contextually to the instruction tracing (processor in normal mode). The traced instructions can optionally be filtered on instruction types. Which instructions are traced is defined in the instruction trace register [31:28], as defined in the table below:

GRIP

Table 255. Trace filter operation

Trace filter	Instructions traced
0x0	All instructions
0x1	SPARC Fomat 2 instructions
0x2	Control-flow changes. All Call, branch and trap instructions including branch targets
0x4	SPARC Format 1 instructions (CALL)
0x8	SPARC Format 3 instructions except LOAD or STORE
0xC	SPARC Format 3 LOAD or STORE instructions
0xD	SPARC Format 3 LOAD or STORE instructions to alternate space
0xE	SPARC Format 3 LOAD or STORE instructions to alternate space 0x80 - 0xFF with ASI last digit base filtering

It is also possible to filter traced instructions based on the program counter value. This option is combined with the filtering option if an additional filtering mechanism is activated from Table 255. Refer to section 27.6.13 for detailed information.

27.5   DSU memory map

The DSU memory map can be seen in table 256 below. In a multiprocessor systems, the register map is duplicated and address bits 27 - 24 are used to index the processor.

Note: The DSU memory interface is intended to be accessed by a debug monitor. Software running on the LEON processors should not access the DSU interface. Registers, such as ASR registers, may not have all fields available via the DSU interface

Table 256. DSU memory map

Address offset	Register
0x000000	DSU control register
0x000008	Time tag counter
0x000020	Break and Single Step register
0x000024	Debug Mode Mask register
0x000040	AHB trace buffer control register
0x000044	AHB trace buffer index register
0x000048	AHB trace buffer filter control register
0x00004c	AHB trace buffer filter mask register
0x000050	AHB breakpoint address 1
0x000054	AHB mask register 1
0x000058	AHB breakpoint address 2
0x00005c	AHB mask register 2
0x100000 - 0x10FFFF	Instruction trace buffer (..0: Trace bits 127 - 96, ..4: Trace bits 95 - 64, ..8: Trace bits 63 - 32, ..C : Trace bits 31 - 0)
0x110000	Instruction Trace buffer control register 0
0x110004	Instruction Trace buffer control register 1
0x200000 - 0x210000	AHB trace buffer (..0: Trace bits 127 - 96, ..4: Trace bits 95 - 64, ..8: Trace bits 63 - 32, ..C : Trace bits 31 - 0)
0x300000 - 0x3007FC	IU register file, port1 (%asr16.dpsel = 0) IU register file, port 2 (%asr16.dpsel = 1)
0x300800 - 0x300FFC	IU register file check bits (LEON3FT only)

0x400018	FSR register
0x40001C	CPSR register
0x400020	DSU trap register
0x400024	DSU ASI register
0x400040 - 0x40007C	ASR16 - ASR31 (when implemented)
0x700000 - 0x7FFFFC	ASI diagnostic access (ASI = value in DSU ASI register, address = address[19:0]) ASI = 0x9 : Local instruction RAM, ASI = 0xB : Local data RAM ASI = 0xC : Instruction cache tags, ASI = 0xD : Instruction cache data ASI = 0xE : Data cache tags, ASI = 0xF : Data cache data ASI = 0x1E : Separate snoop tags

The addresses of the IU registers depends on how many register windows has been implemented:

- %on : 0x300000 + (((psr.cwp * 64) + 32 + n*4) mod (NWINDOWS*64))

- %ln : 0x300000 + (((psr.cwp * 64) + 64 + n*4) mod (NWINDOWS*64))

- %in : 0x300000 + (((psr.cwp * 64) + 96 + n*4) mod (NWINDOWS*64))

- %gn : 0x300000 + (NWINDOWS*64) + n*4

- %fn : 0x301000 + n*4

27.6 DSU registers

27.6.1 DSU control register

The DSU is controlled by the DSU control register:

*Table 257.*0x000000 - CTRL - DSU control register

31		12	11	10	9	8	7	6	5	4	3	2	1	0
RESERVED			PW	HL	PE	EB	EE	DM	BZ	BX	BS	BW	BE	TE
0			0	0	0	*	*		*	*	*	*	*	*
r			r	rw	rw	r	r	r	rw	rw	rw	rw	rw	rw

31: 12   Reserved

11   Power down (PW) - Returns '1' when processor is in power-down mode.

10   Processor halt (HL) - Returns '1' on read when processor is halted. If the processor is in debug mode, setting this bit will put the processor in halt mode.

9   Processor error mode (PE) - returns '1' on read when processor is in error mode, else '0'. If written with '1', it will clear the error and halt mode.

8   External Break (EB) - Value of the external DSUBRE signal (read-only)

7   External Enable (EE) - Value of the external DSUEN signal (read-only)

6   Debug mode (DM) - Indicates when the processor has entered debug mode (read-only).

5   Break on error traps (BZ) - if set, will force the processor into debug mode on all *except* the following traps: priviledged_instruction, fpu_disabled, window_overflow, window_underflow, asynchronous_interrupt, ticc_trap.

*Table 257.*0x000000 - CTRL - DSU control register

4	Break on trap (BX) - if set, will force the processor into debug mode when any trap occurs.
3	Break on S/W breakpoint (BS) - if set, debug mode will be forced when an breakpoint instruction (ta 1) is executed.
2	Break on IU watchpoint (BW) - if set, debug mode will be forced on a IU watchpoint (trap 0xb).
1	Break on error (BE) - if set, will force the processor to debug mode when the processor would have entered error condition (trap in trap).
0	Trace enable (TE) - Enables instruction tracing. If set the instructions will be stored in the trace buffer. Remains set when then processor enters debug or error mode

27.6.2 DSU Break and Single Step register

This register is used to break or single step the processor(s). This register controls all processors in a multi-processor system, and is only accessible in the DSU memory map of processor 0.

*Table 258.*0x000020 - BRSS - BRSS - DSU Break and Single Step register

31	16	15	0
SS[15:0]		BN[15:0]	

31: 16	Single step (SSx) - if set, the processor x will execute one instruction and return to debug mode. The bit remains set after the processor goes into the debug mode. As an exception, if the instruction is a branch with the annul bit set, and if the delay instruction is effectively annulled, the processor will execute the branch, the annulled delay instruction and the instruction thereafter before returning to debug mode.
15: 0	Break now (BNx) -Force processor x into debug mode if the Break on watchpoint (BW) bit in the processors DSU control register is set. If cleared, the processor x will resume execution.

27.6.3 DSU Debug Mode Mask Register

When one of the processors in a multiprocessor LEON3 system enters the debug mode the value of the DSU Debug Mode Mask register determines if the other processors are forced in the debug mode. This register controls all processors in a multi-processor system, and is only accessible in the DSU memory map of processor 0.

*Table 259.*0x000024 - DBGM - DSU Debug Mode Mask register

31	16	15	0
DM[15:0]		ED[15:0]	

31: 16	Debug mode mask (DMx) - If set, the corresponding processor will not be able to force running processors into debug mode even if it enters debug mode.
15: 0	Enter debug mode (EDx) - Force processor x into debug mode if any of processors in a multiprocessor system enters the debug mode. If 0, the processor x will not enter the debug mode.

27.6.4 DSU trap register

The DSU trap register is a read-only register that indicates which SPARC trap type that caused the processor to enter debug mode. When debug mode is force by setting the BN bit in the DSU control register, the trap type will be 0xb (hardware watchpoint trap).

*Table 260.*0x400020 - DTR - DSU Trap register

31	13	12	11	4	3	0
RESERVED		EM	TRAPTYPE		R	

31: 13	RESERVED
12	Error mode (EM) - Set if the trap would have cause the processor to enter error mode.
11: 4	Trap type (TRAPTYPE) - 8-bit SPARC trap type
3: 0	Read as 0x0

27.6.5 DSU time tag counter

The trace buffer time tag counter is incremented each clock as long as the processor is running. The counter is stopped when the processor enters debug mode and when the DSU is disabled (unless the timer enable bit in the AHB trace buffer control register is set), and restarted when execution is resumed.

*Table 261.*0x000008 - DTTC - DSU time tag counter

31	0
TIMETAG	
0	
rw	

31: 0	DSU Time Tag Value (TIMETAG)

The value is used as time tag in the instruction and AHB trace buffer.

The width of the timer is configurable at implementation time.

27.6.6 DSU ASI register

The DSU can perform diagnostic accesses to different ASI areas. The value in the ASI diagnostic access register is used as ASI while the address is supplied from the DSU.

*Table 262.*0x400024 - DASI - ASI diagnostic access register

31	8	7	0
RESERVED		ASI	
0		NR	
r		rw	

31: 8	RESERVED
7: 0	ASI (ASI) - ASI to be used on diagnostic ASI access

27.6.7 AHB Trace buffer control register

The AHB trace buffer is controlled by the AHB trace buffer control register:

*Table 263.*0x000040 - ATBC - AHB trace buffer control register

Table 263.0x000040 - ATBC - AHB trace buffer control register

0		0		0	0	0	0		0		0	0	0
rw		r		rw	rw	rw	rw		r		rw	rw	rw

31: 16	Trace buffer delay counter (DCNT) - Note that the number of bits actually implemented depends on the size of the trace buffer.
15: 9	RESERVED
8	Enable Debug Mode Timer Freeze (DF) - The time tag counter keeps counting in debug mode when at least one of the processors has the internal timer enabled. If this bit is set to '1' then the time tag counter is frozen when the processors have entered debug mode.
7	Sample Force (SF) - If this bit is written to '1' it will have the same effect on the AHB trace buffer as if HREADY was asserted on the bus at the same time as a sequential or non-sequential transfer is made. This means that setting this bit to '1' will cause the values in the trace buffer's sample registers to be written into the trace buffer, and new values will be sampled into the registers. This bit will automatically be cleared after one clock cycle.
	Writing to the trace buffer still requires that the trace buffer is enabled (EN bit set to '1') and that the CPU is not in debug mode or that tracing is forced (TF bit set to '1'). This functionality is primarily of interest when the trace buffer is tracing a separate bus and the traced bus appears to have frozen.
6	Timer enable (TE) - Activates time tag counter also in debug mode.
5	Trace force (TF) - Activates trace buffer also in debug mode. Note that the trace buffer must be disabled when reading out trace buffer data via the core's register interface.
4: 3	Bus width (BW) - This value corresponds to log2(Supported bus width / 32)
2	Break (BR) - If set, the processor will be put in debug mode when AHB trace buffer stops due to AHB breakpoint hit.
1	Delay counter mode (DM) - Indicates that the trace buffer is in delay counter mode.
0	Trace enable (EN) - Enables the trace buffer.

27.6.8 AHB trace buffer index register

The AHB trace buffer index register contains the address of the next trace line to be written.

Table 264.0x000044 - ATBI - AHB trace buffer index register

31	4 3	0
INDEX		R
NR		0
rw		r

31: 4	Trace buffer index counter (INDEX) - Note that the number of bits actually implemented depends on the size of the trace buffer.
3: 0	Read as 0x0

27.6.9 AHB trace buffer filter control register

The trace buffer filter control register is only available if the core has been implemented with support for AHB trace buffer filtering.

+46 31 7758650 | frontgrade.com/gaisler

Table 265.0x000048 - ATBFC - AHB trace buffer filter control register

13: 12	AHB watchpoint filtering (WPF) - Bit 13 of this field applies to AHB watchpoint 2 and bit 12 applies to AHB watchpoint 1. If the WPF bit for a watchpoint is set to '1' then the watchpoint will not trigger unless the access also passes through the filter. This functionality can be used to, for instance, set a AHB watchpoint that only triggers if a specified master performs an access to a specified slave.
11: 10	RESERVED
9: 8	AHB breakpoint filtering (BPF) - Bit 9 of this field applies to AHB breakpoint 2 and bit 8 applies to AHB breakpoint 1. If the BPF bit for a breakpoint is set to '1' then the breakpoint will not trigger unless the access also passes through the filter. This functionality can be used to, for instance, set a AHB breakpoint that only triggers if a specified master performs an access to a specified slave.
7: 4	RESERVED
3	Performance counter Filter (PF) - If this bit is set to '1', the cores performance counter (statistical) outputs will be filtered using the same filter settings as used for the trace buffer. If a filter inhibits a write to the trace buffer, setting this bit to '1' will cause the same filter setting to inhibit the pulse on the statistical output.
2	Address Filter (AF) - If this bit is set to '1', only the address range defined by AHB trace buffer breakpoint 2's address and mask will be included in the trace buffer.
1	Filter Reads (FR) - If this bit is set to '1', read accesses will not be included in the trace buffer.
0	Filter Writes (FW) - If this bit is set to '1', write accesses will not be included in the trace buffer.

27.6.10 AHB trace buffer filter mask register

The trace buffer filter mask register is only available if the core has been implemented with support for AHB trace buffer filtering.

Table 266.0x00004C - ATBFM - AHB trace buffer filter mask register

31	16	15	0
SMASK[15:0]		MMASK[15:0]	
0		0	
rw		rw	

31: 16	Slave Mask (SMASK) - If SMASK[n] is set to '1', the trace buffer will not save accesses performed to slave n.
15: 0	Master Mask (MMASK) - If MMASK[n] is set to '1', the trace buffer will not save accesses performed by master n.

27.6.11 AHB trace buffer breakpoint registers

The DSU contains two breakpoint registers for matching AHB addresses. A breakpoint hit is used to freeze the trace buffer by automatically clearing the enable bit. Freezing can be delayed by programming the DCNT field in the trace buffer control register to a non-zero value. In this case, the DCNT value will be decremented for each additional trace until it reaches zero, after which the trace buffer is frozen. A mask register is associated with each breakpoint, allowing breaking on a block of addresses. Only address bits with the corresponding mask bit set to '1' are compared during breakpoint detection. To break on AHB load or store accesses, the LD and/or ST bits should be set.

Table 267.0x000050, 0x000058 - ATBBA - AHB trace buffer break address register

27: 16	RESERVED
15: 0	Instruction trace pointer (ITPOINTER) - Note that the number of bits actually implemented depends on the size of the trace buffer

27.6.13 Instruction trace control register 1

The instruction trace control register 1 contains settings used for trace buffer overflow detection, in addition it includes settings used for some of the instruction trace buffer filtering options. This register can be written while the processor is running.

Bits [31:28] is used to enable or disable Instruction Trace Buffer Address based Filtering (ITBAF). ITBAF is intended to allow the available hardware watch-point (HWP) registers to be used as instruction trace buffer filters when they are not used for breakpoint operation. If a bit is set to '1' in ITBAF, the corresponding address and mask information in the HWP register will be used to filter instruction trace entries based on the program counter (PC) value. Bits[31:28] corresponds to HWP[3:0] respectively. ITBAF can only be used if the corresponding HWP register exist in the hardware. Instruction Trace Buffer Address based Filtering Option (ITBAFO, Bits[19:16]) determines the type of filtering for the corresponding ITBAF entry. If an ITBAFO entry is set to '0' only the PC value(s) that match the address and mask option in the corresponding HWP register will be logged in the instruction trace buffer (ITB). If a bit is set to '1' only the PC value(s) that does not match the address and mask option in the corresponding HWP register will be logged in the ITB. Bits[19:16] corresponds to the option for ITBAF[3:0] respectively. If there is more than one address filtering operation is enabled, the corresponding filtering operations will be combined together.

Bits[15:0] corresponds to ASI last digit based filtering mask (ASIFMASK). ASIFMASK is in effect when the trace filter configuration is set to 0xE (SPARC Format 3 LOAD or STORE instructions to alternate space 0x80 - 0xFF with ASI last digit base filtering). Bits[15:0] corresponds to digits [0xF:0x0] respectively. If a bit is set to '0' in the ASIFMASK, the load and store instructions which have an ASI between the range of 0x80-0xFF and have the corresponding last digit are logged in the instruction trace buffer. For example if only the bit0 and bit2 of the ASIFMASK are '0' then only the load and store instructions with ASIs 0x80, 0x82, 0x90, 0x92, 0xA0, 0xA2, 0xB0, 0xB2, 0xC0, 0xC2, 0xD0, 0xD2, 0xE0, 0xE2, 0xF0, 0xF2 are tracked in the ITB. After the reset of processor all the bits

27.7 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x017. For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

27.8 Implementation

27.8.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

27.8.2 Technology mapping

DSU3 has one technology mapping generic, *tech*. This generic controls the implementation of which technology that will be used to implement the trace buffer memories. The AHB trace buffer will use two identical SYNCRAM64 blocks to implement the buffer memory (SYNCRAM64 may then result in two 32-bit wide memories on the target technology, depending on the technology map), with one additional 32-bit wide SYNCRAM if the system's AMBA data bus width is 64-bits, and also one additional 64-bit wide SYNCRAM if the system's AMBA data bus width exceeds 64 bits.

The depth of the RAMs depends on the KBYTES generic. If KBYTES = 1 (1 Kbyte), then the depth will be 64. If KBYTES = 2, then the RAM depth will be 128 and so on.

27.9 Configuration options

Table 271 shows the configuration options of the core (VHDL generics).

*Table 271.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	0 - NAHBSLV-1	0
haddr	AHB slave address (AHB[31:20])	0 - 16#FFF#	16#900#
hmask	AHB slave address mask	0 - 16#FFF#	16#F00#
ncpu	Number of attached processors	1 - 16	1
tbits	Number of bits in the time tag counter	2 - 63	30
tech	Memory technology for trace buffer RAM	0 - NTECH-1	0 (inferred)
kbytes	Size of trace buffer memory in Kbytes. A value of 0 will disable the trace buffer function.	0 - 64	0 (disabled)
clk2x	Support for LEON3 double-clocking (this generic is only available on dsu3x entity), see next section.	0 - 1	0 (disabled)
testen	Scan test support enable	0 - 1	0
bwidth	Traced AHB bus width	32, 64, 128	32
ahbpf	AHB performance counters and filtering. If *ahbpf* is non-zero the core will support AHB trace buffer filtering. If *ahbpf* is larger than 1 then the core's statistical outputs will be enabled.	0 - 2	0

27.10 Signal descriptions

Table 272 shows the interface signals of the core (VHDL ports). There are several top-level entities available for the DSU3. The dsu3x entity contains all signals and settings. The other entities are wrappers around dsu3x. The available entities are:

- dsu3 - Entity without support for double clocking. AHB trace of same bus as DSU AHB slave interface is connected to.

- dsu3_2x - Entity with support for LEON3 double-clocking. AHB trace of same bus as DSU AHB slave interface is connected to.

- dsu3_mb - Entity with support for AHB tracing of separate bus

- dsu3x - Entity with support for all features (double-clocking and tracing of separate bus)

27.11   Signal definitions and reset values

Table 272. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	CPU and bus clock, on dsu3 and dsu3_mb entites	-

 irqi(i), irqo(i), dbgi(i), dbgo(i));
    irqi(i) <= leon3o(i).irq; leon3i(i).irq <= irqo(i);
end generate;

dsu0 : dsu3-- LEON3 Debug Support Unit
    generic map (ahbndx => 2, ncpu => NCPU, tech => memtech, kbytes => 2)
    port map (rstn, clkm, ahbmi, ahbsi, ahbso(2), dbgo, dbgi, dsui, dsuo);
dsui.enable <= dsuen; dsui.break <= dsubre; dsuact <= dsuo.active;
```

28 DSU4 - LEON4 Hardware Debug Support Unit

28.1 Overview

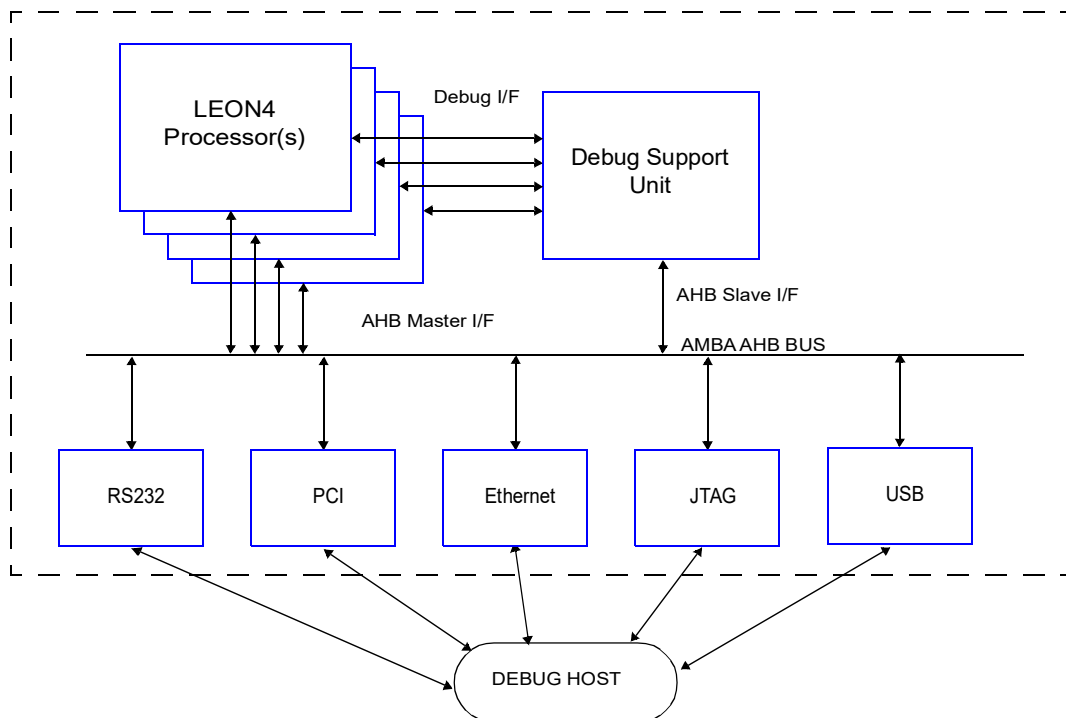
To simplify debugging on target hardware, the LEON4 processor implements a debug mode during which the pipeline is idle and the processor is controlled through a special debug interface. The LEON4 Debug Support Unit (DSU) is used to control the processor during debug mode. The DSU acts as an AHB slave and can be accessed by any AHB master. An external debug host can therefore access the DSU through several different interfaces. Such an interface can be a serial UART (RS232), JTAG, PCI, USB or Ethernet. The DSU supports multi-processor systems and can handle up to 16 processors.


Figure 62. LEON4/DSU Connection

28.2 Operation

Through the DSU AHB slave interface, any AHB master can access the processor registers and the contents of the instruction trace buffer. The DSU control registers can be accessed at any time, while the processor registers and caches can only be accessed when the processor has entered debug mode. In debug mode, the processor pipeline is held and the processor state can be accessed by the DSU. Entering the debug mode can occur on the following events:

- executing a breakpoint instruction (ta 1)

- integer unit hardware breakpoint/watchpoint hit (trap 0xb)

- rising edge of the external break signal (DSUBRE)

- setting the break-now (BN) bit in the DSU control register

- a trap that would cause the processor to enter error mode

- occurrence of any, or a selection of traps as defined in the DSU control register

- after a single-step operation

- one of the processors in a multiprocessor system has entered the debug mode

- DSU AHB breakpoint or watchpoint hit

GRIP

Apr 2024, Version 2024.1

250

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The debug mode can only be entered when the debug support unit is enabled through an external signal (DSUEN). For DSU break, and the break-now BN bit, to have effect the Break-on-IU-watchpoint (BW) bit must be set in the DSU control register. This bit is set when DSUBRE is active after reset and should also be set by debug monitor software when initializing the DSU. When the debug mode is entered, the following actions are taken:

- PC and nPC are saved in temporary registers (accessible by the debug unit)

- an output signal (DSUACT) is asserted to indicate the debug state

- the timer unit is (optionally) stopped to freeze the LEON timers and watchdog

The instruction that caused the processor to enter debug mode is not executed, and the processor state is kept unmodified. Execution is resumed by clearing the BN bit in the DSU control register or by de-asserting DSUEN. The timer unit will be re-enabled and execution will continue from the saved PC and nPC. Debug mode can also be entered after the processor has entered error mode, for instance when an application has terminated and halted the processor. The error mode can be reset and the processor restarted at any address.

When a processor is in the debug mode, an access to ASI diagnostic area is forwarded to the IU which performs access with ASI equal to value in the DSU ASI register and address consisting of 20 LSB bits of the original address.

28.3   AHB trace buffer

The AHB trace buffer consists of a circular buffer that stores AHB data transfers, the monitored AHB bus is either the same bus as the DSU AHB slave interface is connected to, or a completely separate bus. The address, data and various control signals of the AHB bus are stored and can be read out for later analysis. The trace buffer is 128, 160 or 224 bits wide, depending on the AHB bus width. Note that for systems with a 256 bit wide AHB bus, the DSU3 can be used but will only save the lower 128 bits of the AHB data bus. The way information stored is indicated in the table below:

Table 276. AHB Trace buffer data allocation

Bits	Name	Definition
223:160	Load/Store data	AHB HRDATA/HWDATA(127:64)
159:129	Load/Store data	AHB HRDATA/HWDATA(63:32)
127	AHB breakpoint hit	Set to '1' if a DSU AHB breakpoint hit occurred.
126	-	Not used
125:96	Time tag	DSU time tag counter
95:80	-	Not used
79	Hwrite	AHB HWRITE
78:77	Htrans	AHB HTRANS
76:74	Hsize	AHB HSIZE
73:71	Hburst	AHB HBURST
70:67	Hmaster	AHB HMASTER
66	Hmastlock	AHB HMASTLOCK
65:64	Hresp	AHB HRESP
63:32	Load/Store data	AHB HRDATA/HWDATA(31:0)
31:0	Load/Store address	AHB HADDR

In addition to the AHB signals, the DSU time tag counter is also stored in the trace.

The trace buffer is enabled by setting the enable bit (EN) in the trace control register. Each AHB transfer is then stored in the buffer in a circular manner. The address to which the next transfer is writ-

GRIP
Apr 2024, Version 2024.1

251

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

ten is held in the trace buffer index register, and is automatically incremented after each transfer. Tracing is stopped when the EN bit is reset, or when a AHB breakpoint is hit. Tracing is temporarily suspended when the processor enters debug mode, unless the trace force bit (TF) in the trace control register is set. If the trace force bit is set, the trace buffer is activated as long as the enable bit is set. The force bit is reset if an AHB breakpoint is hit and can also be cleared by software. Note that neither the trace buffer memory nor the breakpoint registers (see below) can be read/written by software when the trace buffer is enabled.

The DSU has an internal time tag counter and this counter is frozen when the processor enters debug mode. When AHB tracing is performed in debug mode (using the trace force bit) it may be desirable to also enable the time tag counter. This can be done using the timer enable bit (TE). Note that the time tag is also used for the instruction trace buffer and the timer enable bit should only be set when using the DSU as an AHB trace buffer only, and not when performing profiling or software debugging. The timer enable bit is reset on the same events as the trace force bit.

28.3.1   AHB trace buffer filters

The DSU can be implemented with filters that can be applied to the AHB trace buffer, breakpoints and watchpoints. If implemented, these filters are controlled via the AHB trace buffer filter control and AHB trace buffer filter mask registers. The fields in these registers allows masking access characteristics such as master, slave, read, write and address range so that accesses that correspond to the specified mask are not written into the trace buffer. Address range masking is done using the second AHB breakpoint register set. The values of the LD and ST fields of this register has no effect on filtering.

28.3.2   AHB statistics

The DSU can be implemented to generate statistics from the traced AHB bus. When statistics collection is enabled the DSU will assert outputs that are suitable to connect to a LEON4 statistics unit (L4STAT). The statistical outputs can be filtered by the AHB trace buffer filters, this is controlled by the Performance counter Filter bit (PF) in the AHB trace buffer filter control register. The DSU can collect data for the events listed in table 277 below.

Table 277. AHB events

Event	Description	Note
idle	HTRANS=IDLE	Active when HTRANS IDLE is driven on the AHB slave inputs and slave has asserted HREADY.
busy	HTRANS=BUSY	Active when HTRANS BUSY is driven on the AHB slave inputs and slave has asserted HREADY.
nseq	HTRANS=NONSEQ	Active when HTRANS NONSEQ is driven on the AHB slave inputs and slave has asserted HREADY.
seq	HTRANS=SEQ	Active when HTRANS SEQUENTIAL is driven on the AHB slave inputs and slave has asserted HREADY.
read	Read access	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and the HWRITE input is low.
write	Write access	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and the HWRITE input is high.
hsize[5:0]	Transfer size	Active when HTRANS is SEQUENTIAL or NON-SEQUENTIAL, slave has asserted HREADY and HSIZE is BYTE (hsize[0]), HWORD (HSIZE[1]), WORD (hsize[2]), DWORD (hsize[3]), 4WORD hsize[4], or 8WORD (hsize[5]).
ws	Wait state	Active when HREADY input to AHB slaves is low and AMBA response is OKAY.
retry	RETRY response	Active when master receives RETRY response
split	SPLIT response	Active when master receives SPLIT response

Apr 2024, Version 2024.1

252

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

Table 277. AHB events

Event	Description	Note
spdel	SPLIT delay	Active during the time a master waits to be granted access to the bus after reception of a SPLIT response. The core will only keep track of one master at a time. This means that when a SPLIT response is detected, the core will save the master index. This event will then be active until the same master is re-allowed into bus arbitration and is granted access to the bus. This also means that the delay measured will include the time for re-arbitration, delays from other ongoing transfers and delays resulting from other masters being granted access to the bus before the SPLIT:ed master is granted again after receiving SPLIT complete. If another master receives a SPLIT response while this event is active, the SPLIT delay for the second master will not be measured.
locked	Locked access	Active while the HMASTLOCK signal is asserted on the AHB slave inputs.

28.4 Instruction trace buffer

The instruction trace buffer consists of a circular buffer that stores executed instructions. The instruction trace buffer is located in the processor, and read out via the DSU. The trace buffer is 128 bits wide, the information stored is indicated in the table below:

Table 278. Instruction trace buffer data allocation

Bits	Name	Definition
126	Multi-cycle instruction	Set to '1' on the second instance of a multi-cycle instruction
125:96	Time tag	The value of the DSU time tag counter
95:64	Result or Store address/data	Instruction result, Store address or Store data
63:34	Program counter	Program counter (2 lsb bits removed since they are always zero)
33	Instruction trap	Set to '1' if traced instruction trapped
32	Processor error mode	Set to '1' if the traced instruction caused processor error mode
31:0	Opcode	Instruction opcode

During tracing, one instruction is stored per line in the trace buffer with the exception of atomic load/store instructions, which are entered twice (one for the load and one for the store operation). Bits [95:64] in the buffer correspond to the store address and the loaded data for load instructions. Bit 126 is set for the second entry.

When the processor enters debug mode, tracing is suspended. The trace buffer and the trace buffer control register can be read and written while the processor is in the debug mode. During the instruction tracing (processor in normal mode) the trace buffer and trace buffer control register 0 can not be written. If the two-port trace buffer is enabled (refer to the *tbuf* generic in section 96.15), then the trace buffer can be read contextually to the instruction tracing (processor in normal mode). The traced instructions can optionally be filtered on instruction types. Which instructions are traced is defined in the instruction trace register [31:28], as defined in the table below:

GRIP

Table 279. Trace filter operation

Trace filter	Instructions traced
0x0	All instructions
0x1	SPARC Format 2 instructions
0x2	Control-flow changes. All Call, branch and trap instructions including branch targets
0x4	SPARC Format 1 instructions (CALL)
0x8	SPARC Format 3 instructions except LOAD or STORE
0xC	SPARC Format 3 LOAD or STORE instructions
0xD	SPARC Format 3 LOAD or STORE instructions to alternate space
0xE	SPARC Format 3 LOAD or STORE instructions to alternate space 0x80 - 0xFF with ASI last digit base filtering

It is also possible to filter traced instructions based on the program counter value. This option is combined with the filtering option if an additional filtering mechanism is activated from Table 279. Refer to section 28.6.13 for detailed information.

28.5 DSU memory map

The DSU memory map can be seen in table 280 below. In a multiprocessor systems, the register map is duplicated and address bits 27 - 24 are used to index the processor.

Note: The DSU memory interface is intended to be accessed by a debug monitor. Software running on the LEON processors should not access the DSU interface. Registers, such as ASR registers, may not have all fields available via the DSU interface.

Table 280. DSU memory map

Address offset	Register
0x000000	DSU control register
0x000008	Time tag counter

28.6   DSU registers

28.6.1   DSU control register

The DSU is controlled by the DSU control register:

*Table 281.*0x000000 - CTRL - DSU control register

31	12	11	10	9	8	7	6	5	4	3	2	1	0
RESERVED		PW	HL	PE	EB	EE	DM	BZ	BX	BS	BW	BE	TE
0		0	0	0	*	*		*	*	0	*	*	*
r		r	rw	uc	r	r	r	rw	rw	rw	rw	rw	rw

31: 12   Reserved

11   Power down (PW) - Returns '1' when processor is in power-down mode.

10   Processor halt (HL) - Returns '1' on read when processor is halted. If the processor is in debug mode, setting this bit will put the processor in halt mode.

Table 281.0x000000 - CTRL - DSU control register

9	Processor error mode (PE) - returns '1' on read when processor is in error mode, else '0'. If written with '1', it will clear the error and halt mode.
8	External Break (EB) - Value of the external DSUBRE signal (read-only)
7	External Enable (EE) - Value of the external DSUEN signal (read-only)
6	Debug mode (DM) - Indicates when the processor has entered debug mode (read-only).
5	Break on error traps (BZ) - if set, will force the processor into debug mode on all *except* the following traps: priviledged_instruction, fpu_disabled, window_overflow, window_underflow, asynchronous_interrupt, ticc_trap.
4	Break on trap (BX) - if set, will force the processor into debug mode when any trap occurs.
3	Break on S/W breakpoint (BS) - if set, debug mode will be forced when an breakpoint instruction (ta 1) is executed.
2	Break on IU watchpoint (BW) - if set, debug mode will be forced on a IU watchpoint (trap 0xb).
1	Break on error (BE) - if set, will force the processor to debug mode when the processor would have entered error condition (trap in trap).
0	Trace enable (TE) - Enables instruction tracing. If set the instructions will be stored in the trace buffer. Remains set when then processor enters debug or error mode

28.6.2 DSU Break and Single Step register

This register is used to break or single step the processor(s). This register controls all processors in a multi-processor system, and is only accessible in the DSU memory map of processor 0.

Table 282.0x000020 - BRSS - DSU Break and Single Step register

31	16	15	0
SS[15:0]		BN[15:0]	
0		0	
rw		rw	

31: 16	Single step (SSx) - if set, the processor x will execute one instruction and return to debug mode. The bit remains set after the processor goes into the debug mode. As an exception, if the instruction is a branch with the annul bit set, and if the delay instruction is effectively annulled, the processor will execute the branch, the annulled delay instruction and the instruction thereafter before returning to debug mode.
15: 0	Break now (BNx) -Force processor x into debug mode if the Break on watchpoint (BW) bit in the processors DSU control register is set. If cleared, the processor x will resume execution.

28.6.3 DSU Debug Mode Mask Register

When one of the processors in a multiprocessor LEON4 system enters the debug mode the value of the DSU Debug Mode Mask register determines if the other processors are forced in the debug mode. This register controls all processors in a multi-processor system, and is only accessible in the DSU memory map of processor 0.

Table 283.0x000024 - DBGM - DSU Debug Mode Mask register

31	16	15	0
DM[15:0]		ED[15:0]	
0		0	
rw		rw	

31: 16	Debug mode mask (DMx) - If set, the corresponding processor will not be able to force running processors into debug mode even if it enters debug mode.
15: 0	Enter debug mode (EDx) - Force processor x into debug mode if any of processors in a multiprocessor system enters the debug mode. If 0, the processor x will not enter the debug mode.

28.6.4 DSU trap register

The DSU trap register is a read-only register that indicates which SPARC trap type that caused the processor to enter debug mode. When debug mode is force by setting the BN bit in the DSU control register, the trap type will be 0xb (hardware watchpoint trap).

Table 284.0x400020 - DTR - DSU Trap register

31	13	12	11	4	3	0
RESERVED		EM	TRAPTYPE		R	
0		NR	NR		0	
r		r	r		r	

31: 13	RESERVED
12	Error mode (EM) - Set if the trap would have cause the processor to enter error mode.
11: 4	Trap type (TRAPTYPE) - 8-bit SPARC trap type
3: 0	Read as 0x0

28.6.5 DSU time tag counter

The trace buffer time tag counter is incremented each clock as long as the processor is running. The counter is stopped when the processor enters debug mode and when the DSU is disabled (unless the timer enable bit in the AHB trace buffer control register is set), and restarted when execution is resumed.

Table 285.0x000008 - DTTL - DSU time tag counter

31	0
TIMETAG	
0	
rw	

31: 0	DSU Time Tag Value (TIMETAG)

The value is used as time tag in the instruction and AHB trace buffer.

The width of the timer is configurable at implementation time.

28.6.6 DSU ASI register

The DSU can perform diagnostic accesses to different ASI areas. The value in the ASI diagnostic access register is used as ASI while the address is supplied from the DSU.

Table 286.0x400024 -DASI - ASI diagnostic access register

31	8	7	0

28.6.7 AHB Trace buffer control register

The AHB trace buffer is controlled by the AHB trace buffer control register:

Table 287.0x000040 - ATBC - AHB trace buffer control register

31 ... 16	15 ... 9	8	7	6	5	4 ... 3	2	1	0
DCNT	RESERVED	DF	SF	TE	TF	BW	BR	DM	EN
0	0	0	0	0	0	*	0	0	*
rw	r	rw	rw	rw	rw	r	rw	rw	rw

31: 16	Trace buffer delay counter (DCNT) - Note that the number of bits actually implemented depends on the size of the trace buffer.
15: 9	RESERVED
8	Enable Debug Mode Timer Freeze (DF) - The time tag counter keeps counting in debug mode when at least one of the processors has the internal timer enabled. If this bit is set to '1' then the time tag counter is frozen when the processors have entered debug mode.
7	Sample Force (SF) - If this bit is written to '1' it will have the same effect on the AHB trace buffer as if HREADY was asserted on the bus at the same time as a sequential or non-sequential transfer is made. This means that setting this bit to '1' will cause the values in the trace buffer's sample registers to be written into the trace buffer, and new values will be sampled into the registers. This bit will automatically be cleared after one clock cycle.
	Writing to the trace buffer still requires that the trace buffer is enabled (EN bit set to '1') and that the CPU is not in debug mode or that tracing is forced (TF bit set to '1'). This functionality is primarily of interest when the trace buffer is tracing a separate bus and the traced bus appears to have frozen.
6	Timer enable (TE) - Activates time tag counter also in debug mode.
5	Trace force (TF) - Activates trace buffer also in debug mode. Note that the trace buffer must be disabled when reading out trace buffer data via the core's register interface.
4: 3	Bus width (BW) - This value corresponds to log2(Supported bus width / 32)
2	Break (BR) - If set, the processor will be put in debug mode when AHB trace buffer stops due to AHB breakpoint hit.
1	Delay counter mode (DM) - Indicates that the trace buffer is in delay counter mode.
0	Trace enable (EN) - Enables the trace buffer.

28.6.8 AHB trace buffer index register

The AHB trace buffer index register contains the address of the next trace line to be written.

Table 288.0x000044 - ATBI - AHB trace buffer index register

31 ... 4	3 ... 0
INDEX	R
NR	0
rw	r

31: 4	Trace buffer index counter (INDEX) - Note that the number of bits actually implemented depends on the size of the trace buffer.
3: 0	Read as 0x0

28.6.9 AHB trace buffer filter control register

The trace buffer filter control register is only available if the core has been implemented with support for AHB trace buffer filtering.

Table 289.0x000048 - ATBFC - AHB trace buffer filter control register

31 ... 14	13 12	11 10	9 8	7 ... 4	3	2	1	0
RESERVED	WPF	R	BPF	RESERVED	PF	AF	FR	FW
0	0	0	0	0	0	0	0	0
r	rw	r	rw	r	rw	rw	rw	rw

*Table 289.*0x000048 - ATBFC - AHB trace buffer filter control register

31: 14	RESERVED
13: 12	AHB watchpoint filtering (WPF) - Bit 13 of this field applies to AHB watchpoint 2 and bit 12 applies to AHB watchpoint 1. If the WPF bit for a watchpoint is set to '1' then the watchpoint will not trigger unless the access also passes through the filter. This functionality can be used to, for instance, set a AHB watchpoint that only triggers if a specified master performs an access to a specified slave.
11: 10	RESERVED
9: 8	AHB breakpoint filtering (BPF) - Bit 9 of this field applies to AHB breakpoint 2 and bit 8 applies to AHB breakpoint 1. If the BPF bit for a breakpoint is set to '1' then the breakpoint will not trigger unless the access also passes through the filter. This functionality can be used to, for instance, set a AHB breakpoint that only triggers if a specified master performs an access to a specified slave. Note that if a AHB breakpoint is coupled with an AHB watchpoint then the setting of the corresponding bit in this field has no effect.
7: 4	RESERVED
3	Performance counter Filter (PF) - If this bit is set to '1', the cores performance counter (statistical) outputs will be filtered using the same filter settings as used for the trace buffer. If a filter inhibits a write to the trace buffer, setting this bit to '1' will cause the same filter setting to inhibit the pulse on the statistical output.
2	Address Filter (AF) - If this bit is set to '1', only the address range defined by AHB trace buffer breakpoint 2's address and mask will be included in the trace buffer.
1	Filter Reads (FR) - If this bit is set to '1', read accesses will not be included in the trace buffer.
0	Filter Writes (FW) - If this bit is set to '1', write accesses will not be included in the trace buffer.

28.6.10 AHB trace buffer filter mask register

The trace buffer filter mask register is only available if the core has been implemented with support for AHB trace buffer filtering.

*Table 290.*0x00004C - ATBFM - AHB trace buffer filter mask register

31	16	15	0
SMASK[15:0]		MMASK[15:0]	
0		0	
rw		rw	

31: 16	Slave Mask (SMASK) - If SMASK[n] is set to '1', the trace buffer will not save accesses performed to slave n.
15: 0	Master Mask (MMASK) - If MMASK[n] is set to '1', the trace buffer will not save accesses performed by master n.

28.6.11 AHB trace buffer breakpoint registers

The DSU contains two breakpoint registers for matching AHB addresses. A breakpoint hit is used to freeze the trace buffer by automatically clearing the enable bit. Freezing can be delayed by programming the DCNT field in the trace buffer control register to a non-zero value. In this case, the DCNT value will be decremented for each additional trace until it reaches zero, after which the trace buffer is frozen. A mask register is associated with each breakpoint, allowing breaking on a block of addresses. Only address bits with the corresponding mask bit set to '1' are compared during breakpoint detection. To break on AHB load or store accesses, the LD and/or ST bits should be set.

*Table 291.*0x000050, 0x000058 - ATBBA - AHB trace buffer break address register

28.6.12 Instruction trace control register 0

The instruction trace control register 0 contains a pointer that indicates the next line of the instruction trace buffer to be written.

Table 293.0x110000 - ITBCO - Instruction trace control register 0

31	28	27	16	15	0
TFILT		RESERVED		ITPOINTER	
0		0		0	
rw		r		rw	

31: 28	Trace filter configuration
27: 16	RESERVED
15: 0	Instruction trace pointer (ITPOINTER) - Note that the number of bits actually implemented depends on the size of the trace buffer

28.6.13 Instruction trace control register 1

The instruction trace control register 1 contains settings used for trace buffer overflow detection, in addition it includes settings used for some of the instruction trace buffer filtering options. This register can be written while the processor is running.

Bits [31:28] is used to enable or disable Instruction Trace Buffer Address based Filtering (ITBAF). ITBAF is intended to allow the available hardware watch-point (HWP) registers to be used as instruction trace buffer filters when they are not used for breakpoint operation. If a bit is set to '1' in ITBAF, the corresponding address and mask information in the HWP register will be used to filter instruction trace entries based on the program counter (PC) value. Bits[31:28] corresponds to HWP[3:0] respectively. ITBAF can only be used if the corresponding HWP register exist in the hardware. Instruction Trace Buffer Address based Filtering Option (ITBAFO, Bits[19:16]) determines the type of filtering for the corresponding ITBAF entry. If an ITBAFO entry is set to '0' only the PC value(s) that match the address and mask option in the corresponding HWP register will be logged in the instruction trace buffer (ITB). If a bit is set to '1' only the PC value(s) that does not match the address and mask option in the corresponding HWP register will be logged in the ITB. Bits[19:16] corresponds to the option for ITBAF[3:0] respectively. If there is more than one address filtering operation is enabled, the corresponding filtering operations will be combined together.

Bits[15:0] corresponds to ASI last digit based filtering mask (ASIFMASK). ASIFMASK is in effect when the trace filter configuration is set to 0xE (SPARC Format 3 LOAD or STORE instructions to alternate space 0x80 - 0xFF with ASI last digit base filtering). Bits[15:0] corresponds to digits [0xF:0x0] respectively. If a bit is set to '0' in the ASIFMASK, the load and store instructions which have an ASI between the range of 0x80-0xFF and have the corresponding last digit are logged in the instruction trace buffer. For example if only the bit0 and bit2 of the ASIFMASK is set then only the load and store instructions with ASIs 0x80, 0x82, 0x90, 0x92, 0xA0, 0xA2, 0xB0, 0xB2, 0xC0, 0xC2,

31: 28	Instruction Trace Buffer Address based Filtering (ITBAF) (see text)
27	Watchpoint on overflow (WO) - If this bit is set, and Break on iu watchpoint (BW) is enabled in the DSU control register, then a watchpoint will be inserted when a trace overflow is detected (TOV field in this register gets set).
26: 24	Trace Limit (TLIM) - TLIM is compared with the top bits of ITPOINTER in Instruction trace control register 0 to generate the value in the TOV field below.
23	Trace Overflow (TOV) - Gets set to '1' when the DSU detects that TLIM equals the top three bits of ITPOINTER.
22: 20	RESERVED
19: 16	Instruction Trace Buffer Address based Filtering Option (ITBAFO) (see text)
15: 0	ASI last digit based filtering mask (ASIFMASK) (see text)

28.6.14 Instruction count register

The DSU contains an instruction count register to allow profiling of application, or generation of debug mode after a certain clocks or instructions. The instruction count register consists of a 29-bit down-counter, which is decremented on either each clock (IC=0) or on each executed instruction (IC=1). In profiling mode (PE=1), the counter will set to all ones after an underflow without generating a processor break. In this mode, the counter can be periodically polled and statistics can be formed on CPI (clocks per instructions). In non-profiling mode (PE=0), the processor will be put in debug mode when the counter underflows. This allows a debug tool such as GRMON to execute a defined number of instructions, or for a defined number of clocks.

*Table 295.*0x000070 - ICNT - Instruction count register

31	30	29	28	0
CE	IC	PE	ICOUNT[28:0]	
0	0	0	NR

31	Counter Enable (CE) - Counter enable
30	Instruction Count (IC) - Instruction (1) or clock (0) counting
29	Profiling Enable (PE) - Profiling enable
28: 0	Instruction count (ICOUNT) - Instruction count

28.6.15 AHB watchpoint control register

The DSU has two AHB watchpoints that can be used to freeze the AHB tracebuffer, or put the processor in debug mode, when a specified data pattern occurs on the AMBA bus. These watchpoints can also be coupled with the two AHB breakpoints so that a watchpoint will not trigger unless the AHB breakpoint is triggered. This also means that when a watchpoint is coupled with an AHB breakpoint,

GRIP

Apr 2024, Version 2024.1

261

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

the breakpoint will not cause an AHB tracebuffer freeze, or put the processor(s), in debug mode unless also the watchpoint is triggered.

*Table 296.*0x000080 - AHBWPC - AHB watchpoint control register

31				7	6	5	4	3	2	1	0

r					rw	rw	rw	r	rw	rw	rw

31: 7	RESERVED
6	Invert (IN) - Invert AHB watchpoint 2. If this bit is set the watchpoint will trigger if data on the AHB bus does NOT match the specified data pattern (typically only usable if the watchpoint has been coupled with an address by setting the CP field).
5	Couple (CP) - Couple AHB watchpoint 2 with AHB breakpoint 2
4	Enable (EN) - Enable AHB watchpoint 2
3	RESERVED
2	Invert (IN) - Invert AHB watchpoint 1. If this bit is set the watchpoint will trigger if data on the AHB bus does NOT match the specified data pattern (typically only usable if the watchpoint has been coupled with an address by setting the CP field).
1	Couple (CP) - Couple AHB watchpoint 1 with AHB breakpoint 1
0	Enable (EN) - Enable AHB watchpoint 1

28.6.16 AHB watchpoint data and mask registers

The AHB watchpoint data and mask registers specify the data pattern for an AHB watchpoint. A watchpoint hit is used to freeze the trace buffer by automatically clearing the enable bit. A watchpoint hit can also be used to force the processor(s) to debug mode.

A mask register is associated with each data register. Only data bits with the corresponding mask bit set to '1' are compared during watchpoint detection.

*Table 297.*0x000040 to 0x00004C - 0x0000B0 to 0x0000BC - AHBWPPO-7 - AHB watchpoint data register

31	0
DATA[127-n*32 : 96-n*32]	
NR	
rw	

31: 0	AHB watchpoint data (DATA) - Specifies the data pattern of one word for an AHB watchpoint. The lower part of the register address specifies with part of the bus that the register value will be compared against: Offset 0x0 specifies the data value for AHB bus bits 127:96, 0x4 for bits 95:64, 0x8 for 63:32 and offset 0xC for bits 31:0.

*Table 298.*0x0000A0 - 0x0000AC - 0x0000C0 to 0x0000CC - AHBWPMO-7 - AHB watchpoint mask register

31	0
MASK[127-n*32 : 96-n*32]	
NR	
rw	

31: 0	AHB watchpoint mask (MASK) - Specifies the mask to select bits for comparison out of one word for an AHB watchpoint. The lower part of the register address specifies with part of the bus that the register value will be compared against: Offset 0x0 specifies the data value for AHB bus bits 127:96, 0x4 for bits 95:64, 0x8 for 63:32 and offset 0xC for bits 31:0.

In a system with 64-bit bus width only half of the data and mask registers must be written. For AHB watchpoint 1, a data value with 64-bits would be written to the AHB watchpoint data registers at offsets 0x98 and 0x9C. The corresponding mask bits would be set in mask registers at offsets 0xA8 and 0xAC.

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

In most GRLIB systems with wide AMBA buses, the data for an access size that is less than the full bus width will be replicated over the full bus. For instance, a 32-bit write access from a LEON processor on a 64-bit bus will place the same data on bus bits 64:32 and 31:0.

28.7 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x017. For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

28.8 Implementation

28.8.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

28.8.2 Technology mapping

DSU4 has one technology mapping generic, *tech*. This generic controls the implementation of which technology that will be used to implement the trace buffer memories. The AHB trace buffer will use two identical SYNCRAM64 blocks to implement the buffer memory (SYNCRAM64 may then result in two 32-bit wide memories on the target technology, depending on the technology map), with one additional 32-bit wide SYNCRAM if the system's AMBA data bus width is 64-bits, and also one additional 64-bit wide SYNCRAM if the system's AMBA data bus width exceeds 64 bits.

The depth of the RAMs depends on the KBYTES generic. If KBYTES = 1 (1 Kbyte), then the depth will be 64. If KBYTES = 2, then the RAM depth will be 128 and so on.

28.9 Configuration options

Table 299 shows the configuration options of the core (VHDL generics).

*Table 299.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	0 - NAHBSLV-1	0
haddr	AHB slave address (AHB[31:20])	0 - 16#FFF#	16#900#
hmask	AHB slave address mask	0 - 16#FFF#	16#F00#
ncpu	Number of attached processors	1 - 16	1
tbits	Number of bits in the time tag counter	2 - 63	30
tech	Memory technology for trace buffer RAM	0 - NTECH-1	0 (inferred)
kbytes	Size of trace buffer memory in KiB. A value of 0 will disable the trace buffer function.	0 - 64	0 (disabled)
clk2x	Enable LEON4 double-clocking (generic is only available on dsu4_2x and dsu4x entities, see next section)	0 - 1	0
bwidth	Traced AHB bus width	32, 64, 128	64
ahbpf	AHB performance counters and filtering. If *ahbpf* is non-zero the core will support AHB trace buffer filtering. If *ahbpf* is larger than 1 then the core's statistical outputs will be enabled.	0 - 2	0
ahbwp	AHB watchpoint enable. If *ahbwp* is non-zero (default) then the core will support AHB watchpoints (also referred to as AHB data breakpoints). Pipeline registers will be added when *ahbwp* is set to 2 (default value), one register for each bit on the AMBA data bus. This setting is recommended in order to improve timing but has a cost in area. The pipeline registers will also lead to the AHB watchpoint being triggered one cycle later. It is recommended to leave this functionality enabled. However, the added logic can create critical timing paths from the AMBA data vectors and so AHB watchpoints can be completely disabled by setting this generic to 0.	0 - 2	2
scantest	Scan test support enable	0 - 1	0
pipedbg	Add pipeline registers on signals from LEON4. If critical timing paths show between, or through, the DSU4 and LEON4 then this value can be set to 1 to add pipeline registers on the dbgi input vector. This adds one additional wait state on some DSU register accesses.	0 - 1	0
pipeahbt	Add pipeline registers on AMBA signals to AHB trace buffer. If there are critical timing paths between the AMBA AHB bus and the DSU AHB trace buffer memory then this value can be set to 1 to add one stage of pipelining between the AHB bus and the trace buffer RAM.	0 - 1	0

28.10 Signal descriptions

Table 300 shows the interface signals of the core (VHDL ports). There are several top-level entities available for the DSU4. The dsu4x entity contains all signals and settings. The other entities are wrappers around dsu4x. The available entities are:

dsui.enable <= dsuen; dsui.break <= dsubre; dsuact <= dsuo.active;
```

29 FTADDR - Autonomous DDR2/DDR3 Controller with EDAC

29.1 Overview

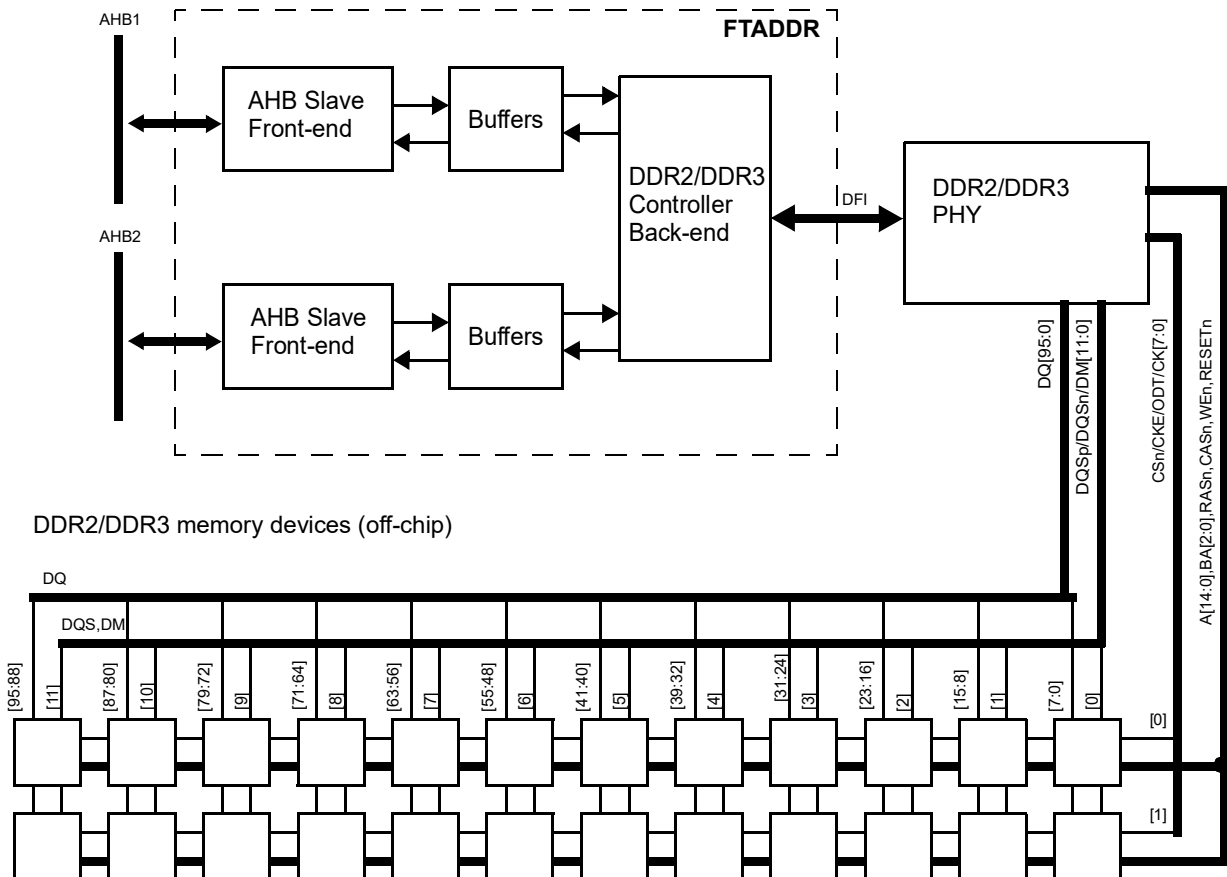
FTADDR is a memory controller for DDR2 and DDR3 type of SDRAM memory devices. On the memory side, it presents a DFI interface for connection to an on-chip physical layer (PHY) that manages the low-level timing and data recovery and then provides the I/O buffers. Towards the system-on-chip, it presents the memory through an AMBA AHB slave interface.


Figure 64. Block diagram of FTADDR Memory controller with two ports and two external banks of 96 bit wide DDR2/DDR3 x8 RAM devices.

Internally, the controller is composed of one part clocked by the AMBA clock which manages the user interface, one part clocked by the DFI clock to manage DDR command scheduling and initialization, and FIFOs to communicate between these two parts.

The controller is designed to interface 96-bit wide banks of memory, made out of individual memory devices of width x8 or x4, and then uses a strong error correction code to achieve double-device correction capability. This allows it to deliver correct data despite one full device failure and random SEU-induced errors on the other devices. Up to 8 parallel banks (chip selects) are supported by the controller. Reduced configurations are possible for reduced pin count.

The controller can be used in a multi-ported configuration to support concurrent accesses to different memory banks.

The controller provides configuration registers accessed through a separate address area in the AHB slave. The controller is designed to support processor-less configurations and therefore can operate autonomously with the desired configuration settings supplied as input data at system reset. An interface for direct control of DDR commands and diagnostic reading of data and checkbits is also provided.

29.2 Operation

29.2.1 Memory bank configurations

Single DDR2/DDR3 SDRAM chips are typically 4,8 or 16 data bits wide. By putting multiple identical chips side by side, wider SDRAM memory banks can be built. Since the command signals are common for all chips, the memories behave as one single wide memory chip, called an external bank or rank. This memory controller supports up to eight identical such memory banks.

Three error detection/correction configurations are supported by the controller: EDAC, parity and none. The controller can be set into two width settings, full width and half width. The controller can interface banks of x8 or x4 devices. This combined creates 12 possible configurations, listed below.

Devices of width x16 behave exactly as two x8 devices in terms of protocol and is therefore functionally compatible with the controller, however as one device error may affect up to 16 bits, it is not compatible with the EDAC schemes employed by the controller.

Note that the x4 mode is intended for use with PHYs designed with 8 data bits per DQS pair using only the lowest nibble of each byte lane, if the PHY can manage 4 data bits per DQS and present that as a full DFI data bus then the regular x8 mode can be used.

Table 304. List of memory bank configurations supported by the FTADDR Memory controller

Configuration #	Controller setting			External bank layout		# DQ bits	Device-wide error correction	
	enx4	eccen	hwidth	Device type	# of devices	Data+Check	# Corrected	# Detected
1	0 (x8)	10 (EDAC)	0	x8	12	64+32	2	2
2			1		6	32+16	1	1
3		01 (Parity)	0		9	64+8	0	1
4			1		5	32+8	0	1

29.2.2 Configurable timing parameters

To provide optimum access cycles for different DDR2/DDR3 devices (and at different frequencies), seven timing parameters can be programmed through the memory configuration registers. The value of these fields affects the memory timing as described in table 305. Note that if the CAS latency setting is changed after initialization, this change needs also to be programmed into the memory chips by executing the Load Mode Register command.

*Table 305.*FTADDR programmable DDR2/DDR3 command timings

DDR2/DDR3 SDRAM timing parameter	Register fields used	Minimum timing (clocks) as function of field values	Formula for field value from timing parameters
CAS latency, CL	DDRT, CASLAT	DDR2: CASLAT DDR3: CASLAT+4	DDR2: CASLAT=CL DDR3: CASLAT=CL-4
CAS write latency, CWL (for DDR2, CWL is fixed to (CL-1))	DDRT, CASLAT, WLAT	DDR2: CASLAT-1 DDR3: WLAT+5	DDR2: WLAT=0 (unused) DDR3: WLAT=CWL-5
Activate to read/write command (t_{RCD})	DRCD	DRCD+2	DRCD=ceil(t_{RCD}/t_{CK})-2
Read to precharge (t_{RTP})[2]	DRTP	DDR2: DRTP+0 DDR3: DRTP+2	DDR2: DRTP=min(ceil(t_{RTP}/t_{CK}), 2) DDR3: DRTP=min(ceil(t_{RTP}/t_{CK})-2, 2)
Write recovery time (t_{WR})	DWR, DDRT, CASLAT, WLAT	DDR2: DWR-CASLAT-1 DDR3: DWR-WLAT-7	DWR=ceil(t_{WR}/t_{CK})+CWL+2
Precharge to activate (t_{RP})	DRP	DRP+3	DRP=ceil(t_{RP}/t_{CK})-3
Activate to precharge (t_{RAS})	DRAS	DRAS+3	DRAS=ceil(t_{RAS}/t_{CK})-3
Auto-refresh command period (t_{RFC})	DRFC	DRFC+3	DRFC=ceil(t_{RFC}/t_{CK})-3
Activate to activate command period (t_{RRD})	DRRD	DRRD+2	DRRD=ceil(t_{RRD}/t_{CK})-2
Four activate window (t_{FAW})	DFAW	DFAW+DRAS+4	DFAW=max (0, ceil((t_{FAW}-t_{RAS})/t_{CK})-1)
Write to read command delay (t_{WTR})	DWTR, CASLAT, WLAT	DDR2: DWTR-CASLAT-1 DDR3: DWTR-WLAT-7	DWTR=ceil(t_{WTR}/t_{CK})+CWL+2
DDR3 mode register set command update delay (t_{MOD})[1]	DMOD	DMOD+3	DMOD=t_{MOD} - 3

[1] tMOD also exists with a different definition on DDR2, this does not require the DMOD field to be set

[2] Note that tRTP is defined differently for DDR2 (with BL8) and DDR3, leading to the 2 cycle difference shown here.

If the fields in table 305 are programmed such that the memory specifications are fulfilled, and periodic refresh is correctly setup, then the remaining SDRAM command timing parameters will also be met by design. Table 306 derives example register value for some of the standard speed bins.

29.2.3 Registered SDRAM

Registered memory modules (RDIMM:s) have one cycle extra latency on the control signals due to the external register. They can be supported with this core by setting the REG control register bit. When set this shifts the internal latency used by the controller one cycle relative to the latency programmed to the memory, which compensates for the delay.

This should not be confused with Fully-Buffered DDR2/DDR3 memory, which uses a different protocol and is not supported by this controller.

GRIP

271

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

29.2.4 On-die termination management

At the memory device side, for each chip select the controller can be set up to program different values of on-die termination (Rtt, and for DDR3 also Rtt_wr) and output inpedance setting into the mode register.

To control the on-die termination in the memory devices (via the ODT control signal), the configuration registers of the controller contain an ODT enable matrix deciding which of the ODT signals are enabled when a specific chip select is being read and written. There is also a default ODT configuration set when neither reading nor writing. By default ODT is always off.

The timing of the ODT signal enabling relative to the read and write command is programmable. The earliest supported switching of the ODT signals are one cycle after the command. For low-latency DDR2 writes this may not be fast enough to switch on the ODT in time, in which case the default ODT configuration should be set to the write configuration instead so that it is set already when the command is given.

A similar configuration is available to enable the controller-side termination on reads, if such termination exist in the PHY.

For DDR3 memory, the Rtt setting and ODT enable state desired during write leveling can be selected separately from the setting used during functional mode. Note that the JEDEC standard allows only a subset of the Rtt settings during write leveling.

29.2.5 Setup

The controller is designed to be configurable using two possible means:

- Setting up all configuration register's reset values using external signals, then using the controller directly. The external signals can be either tied to fixed values at higher level in the design, tied to top-level inputs or driven by other logic at the top level of the design
- Configuring parameters over the on-chip bus from processor or other SoC resource

The type of memory (DDR2 or DDR3) and the external bank configuration (see section 29.2.1) must be set up before starting up the controller and must remain at the same setting, while other settings can be modified at any time. For correct operation, the timing and size parameters must be set to match the device used, see sections 29.2.2 and 29.2.8.

29.2.6 Memory device initialization and management

Assuming the controller is setup correctly, the controller will manage initialization, refresh and other housekeeping functions. For details on initialization and low-level DDR handling, see section 29.3

29.2.7 Data access

Data accesses to the AHB slave ports are translated to DDR memory accesses by the controller, towards the rest of the system-on-chip the DDR memory will appear as a flat memory space. On the DDR side, all accesses are bursts of length 8, while on the AHB side any length is supported and will be mapped to the necessary number of bursts.

In the multi-ported configuration, each slave port maps to a separate fraction of the available memory. This is done by mapping different ports to different internal banks. Having a fixed mapping all the way from front-end ports minimizes the timing interference between the ports, since accesses on different ports can never map to the same memory row. Accesses can always be done overlapping and therefore the worst case interference becomes only the sum of the maximum data burst length of the other ports rather than one full row open-close cycle for each other port.

For example, with DDR3-800 memory, burst length 8, four ports, the worst case interference becomes 3 ports*(4 cycles burst + 2 cycles turnaround) = 18 DDR cycles = 45 ns, while with a any-to-any mapping the worst case interference would be (all writing to different rows in same internal bank) 3 ports

GRIP
Apr 2024, Version 2024.1
272
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

* 25 cycles = 75 cycles = 187.5 ns. The difference gets worse with increasing DDR memory clock rate.

29.2.8 Logical address to memory address mapping

The controller uses a linear address mapping scheme between on-chip bus addresses and external memory addresses. From the least significant bits upward the bits are interpreted as:

- Byte lane on DDR bus. Depending on external bank configuration (see section 29.2.1) the data width is 16,32 or 64 bits making this field take up the lowest 2-4 bits of the address.

- Column address. Width of this field depends on the number of columns in the external memory devices, between 9-12 bits

- Row address. Width of this field depends on the number of rows in the external memory, between 12-16 bits

- Internal bank. In multi-port configurations the least significant bits of the bank number is implied by which port is accessed and is therefore not included in the address translation. Number of banks can be either 4 or 8 for DDR2, and is always 8 for DDR3. This leads to between 0-3 address bits.

- External bank/chip select. Up to 8 are supported, leading to 3 address bits for this field.

To achieve a correct address translation without holes or aliases, the AHB address decode register fields need to be set up to match the external memory devices. The algorithm to do this is as follows:

1. Set COLBASE to match the width of the data bus (not including ECC bits).

2. Set ROWBASE so that (9+ROWBASE-COLBASE) matches the number of column address bits on the DDR memories (bits actually used for addressing the column, not counting that A(10) and A(12) are used for auto-precharge and burst-chop indication).

3. Set BANKBASE so that (10+BANKBASE-ROWBASE) matches the number of row address bits on the DDR memories.

4. Set CSBASE so that ($2^{\wedge}$(CSBASE-BANKBASE)+NPORTS) matches the number of internal banks (4 or 8) or the DDR memories.

5. If the resulting CSBASE value from step 4 became 11 or higher then subtract (CSBASE-10) from both CSBASE and BANKBASE

29.3 Back-end functional description

29.3.1 Controller back-end states

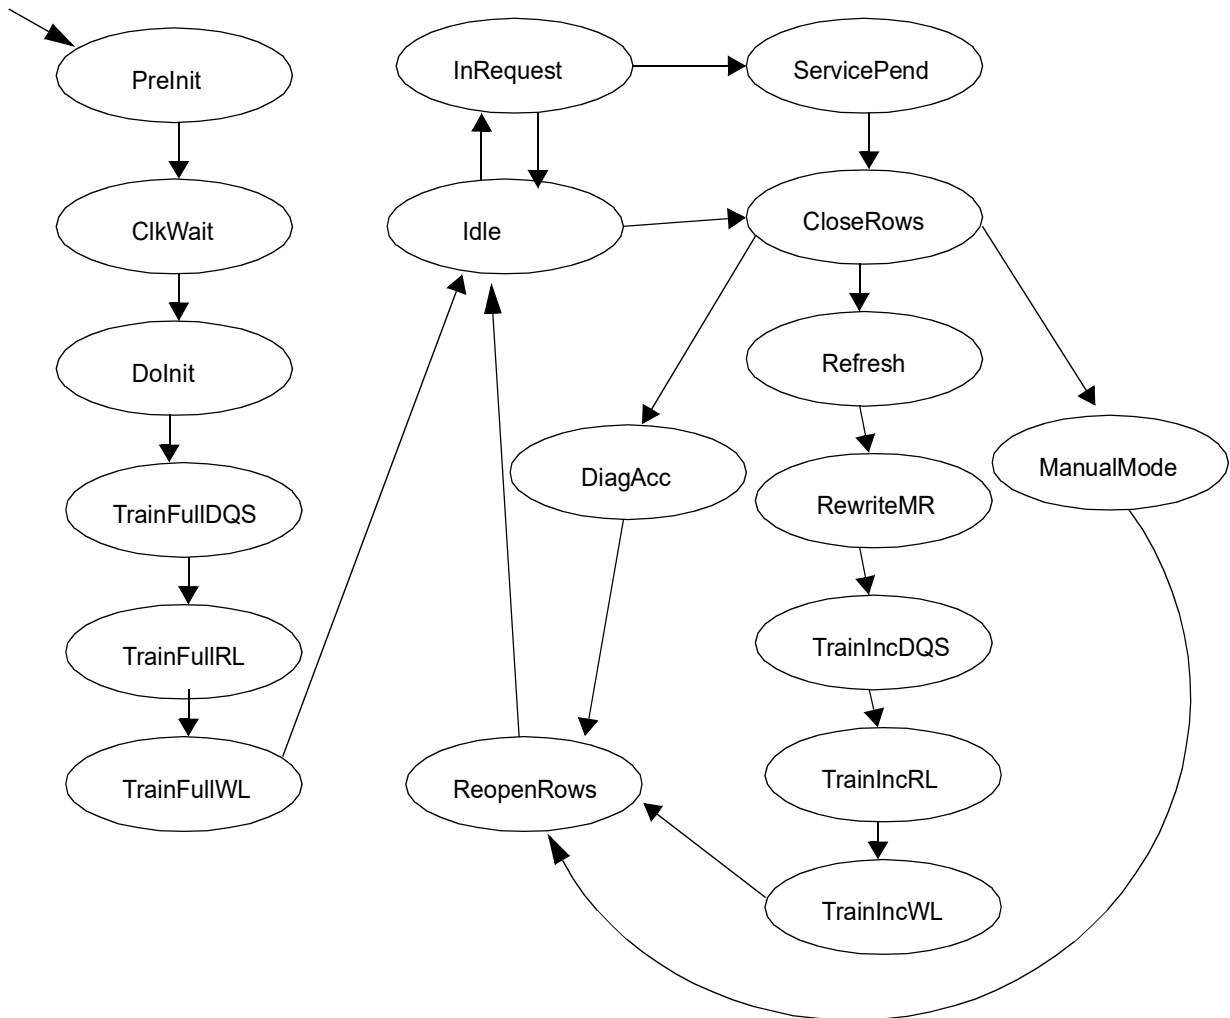
From a usage perspective, the DDR side of the controller follows the simplified state diagram shown in figure 65.


Figure 65. Simplified state diagram of DDR2/DDR3 controller back-end

PreInit - the controller waits for the configuration settings to be set and the pwron bit to be set in the controller. Note that if pwron is set high by the signal interface then this state will be left immediately after reset.

ClkWait - wait until the minimum time has passed from power-on reset before starting the initialization sequence as required by the JEDEC standard. This can be skipped for testing/simulation purposes by writing into the training time counter register while in this state.

DoInit - Initialization sequence according to the selected memory standard.

TrainFullDQS - Training of DQS gate timing

TrainFullRL - Training of read data leveling (DDR3 only)

TrainFullWL - Training of write data leveling (DDR3 only)

Idle - Waiting for incoming request or service interval timer

InRequest - Serving one or more read/write requests. Can start additional requests to other banks in parallel as decided by internal scheduler and timers.

ServicePend - Serving one or more read/write requests, the service interval timer has expired. New requests are not accepted.

CloseRows - At start of service interval, if any rows are then send a close all rows command to all chip selects. Wait for any tRP delay timers to expire.

Refresh - Send auto-refresh command to all memory devices, if configured to do so at this service interval.

TrainIncDQS - Performing periodic incremental DQS gate delay adjustment, if configured to do so at this service interval.

TrainIncRL - Performing periodic incremental read data leveling (DDR3 only), if configured to do so at this service interval.

TrainIncWL - Performing periodic incremental write data leveling (DDR3 only), if configured to do so at this service interval.

ReopenRows - Re-open any of the open rows that were closed at the beginning of the service interval. If the controller can see that the next command coming in on a port will result in closing the row (a row close command, or a row open command to a different row), then the row will not be re-opened.

DiagAcc - Perform diagnostic access requested by user.

ManualMode - Performing manual or diagnostic command requested by user (AHB frontend)

29.3.2 Data transfers

The controller contains four bank tracking units to keep track of ongoing data transfers and currently opened rows in the external memory. Each tracking unit has a fixed mapping to a specific set of internal banks in the memory devices, based on the two least significant bits of the internal bank number. At most one opened row at a time can be tracked by each bank tracking unit.

A command scheduler module looks at the state of the bank tracking units, and schedules commands to the DDR command bus as they are ready and can be issued without causing data bus collisions with other ongoing commands. In case more than one bank tracker has a command ready the same cycle, the scheduler will use a round-robin arbiter as a tie-breaker.

The front-end ports are mapped to the bank tracking units in a fixed 1:4, 1:2, or 1:1 mapping depending on how many front-end ports are implemented in the controller, so each front-end port will map to a separate slice of the external memory.

29.3.3 Service intervals

There are several functions in the controller that need to be done periodically, and that require the memory devices to be in idle state so can not be done in parallel with regular data transfers. To handle this efficiently, these are handled in common service intervals. The number of cycles per interval is can be set through configuration registers.

You do not need to do every function at every service interval. For each of the functions (refresh, incremental training, mode register reprogramming), you can configure the frequency as an integer multiple of service intervals. For example, you can set refresh to be done every service interval and incremental training every third interval. Service intervals where nothing is to be done are optimized away so there is no blocking of transfers in that case.

Within each service iteration, all currently opened rows are closed, the pending operations are performed, and the rows are then re-opened to resume operation. To avoid unnecessary re-opening of rows just in order to close them shortly after, the controller peeks at the following command in the command FIFOs, and if that is a row-close or row-open command, the re-opening is skipped for that bank machine. This optimization can be disabled with the FREOP configuration register bit.

GRIP

It is possible to postpone service iterations using the SHOLD configuration bit. The pending bits and the time counting will still proceed normally. Since there is only a single pending bit for each refresh (or other action), suspending the service iteration for longer than the refresh interval can result in losing a pending refresh command leading to lower refresh rate than expected. Therefore when using the SHOLD function, the user either has to ensure the time is shorter than the refresh interval or the user needs to manually trigger additional refreshes to compensate for the lost refresh commands.

29.3.4 Refresh

The controller contains a refresh function that during a service interval issues an AUTO-REFRESH command to all SDRAM banks. Depending on SDRAM type, the required average period is typically 7.8 us.

29.3.5 ZQ calibration

For DDR3 memories, the controller can be programmed to issue ZQ calibration short (ZQCS) commands periodically at service intervals in order to prevent the input/output drivers on the memory devices from drifting out of specification. ZQ calibration short (ZQCS) and ZQ calibration long (ZQCL) commands can also be manually commanded through the command register. One ZQCL command is always issued during initialization as this is required by the JEDEC standard.

29.3.6 Periodic mode register reprogramming

The controller can be set up to reprogram the memory device's mode registers periodically during service intervals to ensure they are set to correct values.

29.3.7 Delay training

Depending on the PHY design and of the speed of the DDR interface, training of delays may be required. The controller has been designed to support such training.

If the PHY uses MC evaluation mode (DFI mode 01), the training is implemented in a custom sub-block of the controller with an algorithm designed for the specific PHY. For a new PHY that requires this a new phyimpl constant must be defined to the controller which instantiates the new sub-block.

In other training modes (PHY evaluation, PHY independent, and None), the calibration is implemented inside the PHY and the controller only provides some supporting services. This is supported in the generic DFI implementation of the controller without any custom logic.

Incremental training can be done periodically within service intervals to track changes in delays. At each incremental training, a fine adjustment of DQS delays and write leveling is performed. The controller can also be setup to re-do the full training with some interval.

29.3.8 User specified commands

The user can force a refresh or mode register load by writing to command register bits. The controller will schedule the requested command as soon as possible, letting any pending data transfers complete, and ensure the memory timing parameters are respected.

29.3.9 Diagnostic access

The controller has a diagnostic interface where you can command a read or write from a specific location via the register interface. The diagnostic interface can be used safely while the core is running normally.

The procedure for performing a diagnostic access is:

1. Write to the Diagnostic access control register 1, set the DIAGCS,DIAGBANK,DIAGROW fields with the desired location

GRIP
Apr 2024, Version 2024.1

276

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

2. If it's a write, set up the diagnostic checkbit and data registers with the desired data

3. Write to the Diagnostic access control register 2, DIAGCOL field with the desired column, DODG=1, DGWR=1/0 depending on if it's a read or write

4. Poll the diagnostic access status register until the DDONE field is 1.

5. If it was a read, the diagnostic checkbit and data registers hold the read data

The diagnostic access is handled similar to service iterations, current accesses complete, all rows are closed, the diagnostic access is performed, and rows are then re-opened.

The unit of the diagnostic access is always a 64-bit word with the corresponding checkbits. When reading with EDAC enabled, the EDAC decoder error outputs can be seen in the diagnostic status register after the access, however the data that is stored in the diagnostic data/checkbit registers is always uncorrected.

In half-width mode, each diagnostic access will read or write two columns to get a complete EDAC codeword. The column that is addressed should always be even in this mode. Otherwise the diagnostic register interface behaves exactly the same towards the user.

The diagnostic interface ignores the x4 mode setting, and will handle it like the x8 mode. The user has to ignore the top nibbles of the data and checkbits, and mask the corresponding correctable error bits, when using diagnostic accesses in x4 mode.

29.3.10 Manual mode

A raw interface allows to manually perform arbitrary DDR commands such as mode register write, auto refresh, activate, RAS, read/write, and precharge. Note that these manual commands are not managed by the bank tracker and it's the responsibility of the user to not violate the SDRAM protocol. While manual mode is activated, normal accesses will be blocked. Also, no refresh or other service commands will be performed during that time

To activate the manual mode, the user writes 1 to the MANE configuration register field, and then polls the Backend status register until the back-end has entered the manual mode. To return back to normal mode, write 0 to the MANE register field.

In manual mode, the address lines are continuously driven with the value of the DIAGROW field, the bank address lines are driven with the value of the DIAGBANK field. The chip select lines are normally driven high but can be asserted for one cycle by writing into the MANUAL_CSN field.

It is possible to command a read or write command and transfer data with proper DQS strobe generation. This is done by asserting the MRDC or MWDC fields at the same time as giving the CAS command. The data transfer is handled in a similar way as for a diagnostic access, and will use the diagnostic data and checkbit registers (however the diagnostic status register is not modified).

29.3.11 Frequency ratio operation

Frequency ratio operation is only available in the GRLIB integrated version of the controller, not in the stand-alone version.

Besides interfacing PHYs with a frequency ratio of 1:1 (the DFI frequency matching the external memory clock frequency), the controller can support interfacing PHYs with a frequency ratio of 1:2 ("half-rate") or 1:4 ("quarter rate"). The functionality is the same when used in half-rate/quarter-rate configuration and all timing register settings in the controller are still set as if the controller was running at 1:1 rate. The selection of frequency ratio between the controller and PHY is intended to be an internal detail that normally does not need to be a concern for the user.

In half rate configuration, the controller will only issue one command per DFI clock cycle, resulting in one command every two memory clock cycles. Depending on the 2T timing setting, either slot 0 or slot 1 will be used for the command (with slot 0 used in 2T mode to setup the address/control lines

one cycle ahead of the command). The command selected on any DFI cycle will be arbitrated between the bank machine in the same way as in full-rate operation (see section 29.3.2).

In quarter-rate operation, the controller can issue up to two commands each cycle, one read/write command and one row-open/precharge command. Depending on the 2T setting, either slots 0 and 2 are used for the two commands, or slots 1 and 3 (with slots 0 and 2 used in 2T mode to setup the address/control lines with chip select deasserted one cycle ahead of the command). If only one command is scheduled, the earlier slot (0 or 1) is always used. If two commands are issued the same cycle, the read/write command is scheduled on the earlier slot (0 or 1)and the row open/close command is scheduled on the later slot (2 or 3). Due to the constraints on slots used for commands in frequency ratio operation, some delays will get "rounded up" to multiples of 2 or 4 compared to when operating in full-rate mode.

29.3.12 PHY-specific support

The controller has a phyimpl configuration option specifying if a specific kind of PHY is used. The back-end adapts the default control signal timing (via the timing masks) and may also adjust to other 'quirks' in the specific PHY. Some PHY implementations also provide dedicated configuration or status registers that can be accessed via the PHY indirect address and data registers, those are listed in table 314.

Currently the PHYs in table 307 are implemented.

*Table 307.*FTADDR back-end PHY implementations supported

Value	Name	PHY-specific registers	Description
0	Generic	No	Generic DFI PHY interface
1	Reserved		
2	Altera UniPhy/AFI interface	No	For Altera FPGAs. Can interface a full-rate, half-rate or quarter-rate PHY generated by the Quartus UniPhy MegaWizard
3	Reserved		
4	Xilinx Ultrascale	Yes	For Xilinx Ultrascale FPGAs, interfaces a Xilinx LogiCORE DDR3 IP in Phy-only mode.

29.3.13 Memory reboot support

The controller has features to support resetting and possibly also power cycling of individual byte lanes of memory, in order to recover from permanent SEFI errors. While rebooting one byte lane, the other memories are held in self refresh mode to preserve their contents, and the rebooted byte lane's contents can be recovered using the EDAC.

Using the reboot feature requires special support both on the DDR PHY, system design and on the board level. Instead of a separate RESET and CKE signal per rank, there needs to be a separate RESET and CKE signal per byte slice but shared over all ranks. These are output from the controller on the xdfi_bl_resetn and xdfi_bl_cke signals with the same timings as the regular DFI dfi_reset_n and dfi_cke signals. In addition, there needs to be support for either driving both clk_p and clk_n low, or tristating them, this is activated through the additional xdfi_clk_zero signal. An additional output signal xdfi_bl_pdn signals when the memory should be power cycled, this needs to propagate out to the board level.

If the reboot support is not required, the added signals can be ignored and the standard DFI signals used instead. Using the reboot function will then not have any useful effect, it will just put the memories into self-refresh mode, and then after some time leave self-refresh mode and go back into normal operation.

29.3.14 Internal assertion error flags

There are internal assertion error flags in the back-end status register, that are set when an internally inconsistent state is detected. These are intended mainly for use as assertions in development (for checking after tests) and for debugging malfunctioning systems. The conditions for these flags should never occur under correct operation, and if one of the conditions have occurred then a full system reset is required to get back to a known good state. A brief description of each flag is provided in table 308 below.

*Table 308.*Internal assertion error flags for back-end

Bit	Description summary
5	Back-end asserted write into status FIFO when FIFO signaled full
4	Back-end asserted write into prefetch data FIFO when FIFO signaled full.
3	Back-end asserted write into read data FIFO when FIFO signaled full
2	Write command received from front-end but expected amount of write data not in write data FIFO.
1	Read data valid received from PHY when no read data has been requested.
0	Currently unused (always zero)

29.4 Front-end functional description

29.4.1 AHB slave ports

Each port implements an AMBA 2.0 AHB compliant slave interface. The AHB interface can have either 32, 64 or 128 bits width on the data bus, selected through the ahbbits VHDL generic.

The GRLIB version of the controller wraps the AHB interface into the GRLIB AMBA record format and also includes the additional sideband signals used for the GRLIB plug-n-play extension to AMBA.

The memory mapped area supports all types of accesses, however some result in suboptimal performance due to read-modify-write cycles or emulating bursts using single cycle accesses or shorter bursts internally. For optimum performance, the following rules should be followed:

- Accesses should be made using the full width of the AHB data bus as HSIZE.

- Wrapping bursts should not be used.

29.4.2 Response patterns

The slave port will respond with wait states using the HREADY signal whenever needed. Retry and split responses are never used.

ERROR responses are used when accessing outside the available memory range, and also in case of EDAC uncorrectable error. The error responses can be disabled using configuration register bits.

29.4.3 Memory read and write

When reading from the memory, the slave port will give wait states until the data is available and then deliver the data streamed out of the internal FIFO as soon as it is ready. The master should be prepared to handle wait states issued at any time within the burst.

When writing to memory, the controller will normally accept the write (single or burst) without wait-states, however if the command FIFO is full then it will issue wait states.

When EDAC is enabled, writes smaller than the codeword size will result in read-modify-write cycles. These are queued internally and will not cause wait states unless the internal FIFOs are full. If the read part of the RMW cycle detects an uncorrectable error, the memory location will be left unmodified and the error will be logged in the core's register and an interrupt will be issued.

GRIP
Apr 2024, Version 2024.1
279
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

29.4.4   Write buffering

Normally any number of writes up to the capacity of the internal buffer can be accepted, however through a configuration register, a maximum limit can be set on the number of queued writes in the buffer, where further accesses will cause wait states. At a minimum, the limit can be set to allow only one buffered write.

The amount of buffering should not be more than needed to mask the latency through the controller and to cover AHB bus timing jitter (unrelated accesses causing gaps in the write stream). Increasing the buffering beyond this will only result in degrading worst-case read latency without improving throughput.

29.4.5   Read pre-fetching

To better support masters streaming long packets of data without requiring very long burst lengths, the AHB slave port supports a read pre-fetching feature. When a read burst is made, the port will queue up one or more additional number of bursts of the same length to the back-end and store these in a prefetch buffer when the data arrives. When the same master comes back and requests the following data, it will then serve this from the prefetch buffer and instead request an additional read burst after the currently prefetched point.

The controller has separate tracking registers for each master in order to detect when prefetching should be activated. The prefetching is activated when the same master makes three read bursts that are back-to-back in terms of address. A prefetch master mask configuration register allows to limit which masters can activate the pre-fetching logic so that random access masters such as caches can be prevented from activating it.

Only one prefetching stream can be ongoing at the same time on each AHB port. The current prefetch is cancelled when the currently prefetching master makes an access which does not match the continued stream, or when a prefetch time-out counter expires without the master coming in and requesting data from the next address in the stream. If a write to the same row as is being prefetched is performed on the same AHB port by any master then the prefetch data is discarded in order to prevent serving out-of-date data.

The prefetching continues only to the end of the row and does not cross across row boundaries. It will need to be re-activated on the following row in the same way as described above.

The number of additional read bursts to prefetch is controlled through a configuration register.

29.4.6   Configuration area

Each slave port provides two separate memory areas, one memory mapped area for regular access and one register area for configuration register access.

In the stand-alone version, the ahb_hsel_reg signal selects if memory or registers are accessed. This signal is only considered when the ahb_hsel signal is also asserted on the same cycle. In the GRLIB version, the two AHB areas to two different BARs of the slave similar to other memory controller IP in the library.

The configuration register area must always only be accessed using 32-bit wide accesses, however both single accesses and bursts are permitted.

Any port can access all of the configuration registers, and the register interface is internally arbitrated between the ports.

29.4.7   Multi-ported configuration

In multi-ported configuration, multiple AHB slave ports will be presented. The slave ports are logically separated so they can be either tied to the same bus, or to different AHB buses.

29.5 Error detection and correction features

29.5.1 Overview

The memory controller can be configured to support bit-error tolerant operation by choosing a suitable external memory configuration (see section 29.2.1). In this mode, the DDR data bus is widened and the extra bits are used to store 32 checkbits corresponding to each 64 bit data word.

When writing, the controller generates the checkbits and stores them along with the data on the added part of the data bus. When reading, the controller will transparently correct any correctable bit errors and provide the corrected data on the AHB bus. An extra corrected error output signal is asserted when a correctable read error occurs, at the same cycle as the corrected data is delivered. This can be connected to an interrupt input or to a memory scrubber.

A scrubber function is built into the core that periodically reads from incrementing addresses and writes the data back in case a correctable error is detected. The rate of the scrubbing is programmable and it can also be disabled. The core can also be configured to automatically write back to memory any correctable error that is detected on read.

When performing a write smaller than the codeword size of 64 bits, the controller will automatically perform a read-correct-modify-write cycle to correctly update the checkbits.

29.5.2 Correctable error handling

The intent is for error correction to be transparent to the application, and the controller delivers corrected data with the same timing as uncorrected data. There is no automatic write-back on correctable errors, the controller instead provides a periodic scrubbing function that should be used to prevent error build-up.

A separate ahb_ce output signal is asserted in parallel with the data, this can be used for handling externally to the controller. An internal register holds the address of the correctable error, and an optional interrupt can also be used if desired by the application. All of these features are optional and the controller will work properly even if they are not used.

29.5.3 Uncorrectable error handling

Uncorrectable errors occur when reading a data and checkbit combination that does not match any possible data with any possible combination of errors. To trigger an uncorrectable error, three bytes or more of the data bus must be incorrect (in the default configuration, see table 304 for other configurations). Note that the design intent of the controller with features such as strong EDAC, scrubbing, and SEFI handling is to make the risk of uncorrectable errors occurring as low as possible.

In case of uncorrectable error, this is by default signaled by giving an AHB error response to the master. This behavior can be disabled by configuration and the core will in that case "respond in form" with the corrupted data. A separate sideband signal for uncorrectable errors is also available for custom handling at the SoC level. An uncorrectable error register is included in the core where software can see where the last (if any) uncorrectable error occurred, for diagnosis.

In case of an uncorrectable error detected during a read-modify-write cycle, the modify-write part is cancelled and the original contents of the address (containing error) is left untouched, to be found later by the scrubber or a read access.

29.5.4 EDAC details

The implemented EDAC is based on a Reed-Solomon code implemented over the $GF2^4$ Galois field, with the capability to correct two symbol errors, one symbol corresponding to four binary bits of data. The code has theoretically 11 data symbols and 4 check symbols, however it is shortened to 8 data symbols and 4 check symbols.

GRIP

Apr 2024, Version 2024.1

281

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The field generating polynomial for the Galois field is a^4+a+1, and each nibble of data in and out of the controller is interpreted as powers of alpha, so $\{b3,b2,b1,b0\} = b3*a^3+b2*a^2+b1*a^1+b0$. The Reed-Solomon code in this field is defined by the generating polynomial $(x+a^6)(x+a^7)(x+a^8)(x+a^9)$.

To support correction of byte-wide errors, the code is interleaved by a factor of two, resulting in a code with 2*8 data symbols * 4 bit = 64 data bits and 2*4 check symbols * 4 bits/symbol = 32 check bits. The interleaved code can then correct two different byte-wide errors in the data.

29.5.5 Internal self-checking

The external memory EDAC contains an internal self-check function where the data after decoding is re-encoded and compared with the original read-in data and checkbits. If they differ in some other location than one where an error was corrected, then the EDAC will signal an internal consistency error.

The core can be configured to automatically retry the read transfer when this happens. If the retry is disabled, or if there is another consistency error when the retry is made, this will be treated as an uncorrectable error (section 29.5.3) and in addition a consistency error IRQ is signaled.

29.5.6 Diagnostic interface

The controller supports a diagnostic interface where the checkbits and data bits can be read and written separately with the EDAC bypassed to allow error injection. Accesses to the diagnostic area can be freely mixed with normal memory access which simplifies many test scenarios. Further details are in the back-end description, section 29.3.9.

29.5.7 Initialization

When EDAC is used, the memory must be initialized with correct checkbits. An initialization function that clears the entire memory is implemented in the front-end. This can be set up to initialize with a custom pattern, or to initialize each address with the row/column number of that address.

The controller can be set up to perform a read back immediately after the initialization to verify that the expected data is returned.

29.5.8 Scrubbing

The controller has a built-in scrubber implemented in the front-end side. This reads through all of the memory at a programmable rate, and if any correctable errors are detected, then the corrected data is written back to the same address. The scrubber is also used as the basis for the SEFI handling functionality.

29.5.9 Correctable error counting

There are two separate sets of counters that count statistics on correctable errors, the byte lane error counters, and the address error counters. Both of these will be updated whenever the scrubber finds a correctable error. Note that these are only updated by scrubber accesses and not updated when a regular access triggers a correctable error. The reason for that is to avoid large up-counts if the same error location is read multiple times, which could interfere with the statistics and falsely trigger the SEFI detection logic.

29.5.10 Byte lane error counters

The controller has 12 wrapping counters that track the number of correctable errors that the scrubber finds in each byte of the DDR data bus, plus an additional counter called the watermark that tracks the value of the slowest moving counter. These counters are combined to implement a statistical SEFI

GRIP

Apr 2024, Version 2024.1

282

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

detection scheme, which triggers when the byte lane with the most correctable errors has 64 errors more than the byte lane with the least amount of correctable errors.

The watermark is implemented simply by starting at zero after reset like the other counters, and each cycle checking if it is equal to any of the 12 byte lane counters. If the watermark is not equal to any of the counters, then the slowest moving counter must have incremented and the watermark is also incremented to track it.

If one byte lane has a much higher frequency of errors than the others, then that byte lane's error counter will eventually wrap around and count up to the watermark value. That is used as an indication that a SEFI has occurred on that byte lane, which is managed by the SEFI handling state machine.

An equivalent scheme would be to have byte lane counters where you subtract one from each counter once all counters are non-zero and trigger when one counter reaches 64. Each counter minus the watermark (modulo 64) can be viewed as such a counter.

Note that these counters only count errors found by the scrubber, in order to guarantee proportional checking of errors across the whole address space, as otherwise repeated reads of one address with a correctable error could quickly increment a specific counter.

29.5.11 SEFI handling

A special state machine is implemented to attempt SEFI recovery when detected by the byte lane error counters. Note that due to the powerful EDAC and other features implemented in the controller, a single SEFI plus additional SEUs in parallel can be handled implicitly by the controller, the purpose of the SEFI recovery features is to achieve a faster repair in case of recoverable SEFI. The SEFI recovery actions can be disabled in the controller if unwanted, and the SEFI detection logic can then be used in a passive mode for diagnostic purposes instead.

When a SEFI is detected using the byte lane error counters, the SEFI handler it will first request a recalibration of the memory, and a re-write of the memory mode registers from the controller back-end. When this is complete, the scrubber will be setup to perform an accelerated scrub run over the whole memory range in order to quickly regenerate the check bits in case the SEFI was temporary.

After the regeneration, the scrubber will again run in the normal pace. If a full cycle (from start adddress to end address) of the scrubber is performed without the SEFI detection triggering on the byte lane that had the SEFI, then it is considered to be 'healed' from the SEFI. If the SEFI detection again triggered, it is considered to have a permanent SEFI. When that happens, the controller will issue a permanent SEFI interrupt. and can also optionally be configured to disable the output drivers for that byte-lane in the backend. The controller will continue tracking errors in the byte lane and may find it to have healed at a later stage.

29.5.12 PHY-based SEFI detection

The controller supports an optional sideband signal from the PHY indicating that it had a read failure on a byte lane, if available in the implementation then this can be used to trigger the SEFI handling functionality independently of the error counting. A dedicated interrupt also exists for this condition (back-end error signaled by PHY).

29.5.13 Address error counters

A second set of correctable error counters updated by the scrubber are also provided. These are saturating signed counters that will increase or decrease depending on which address the error occurred on. One counter is implemented for each address bit in the memory address space (CS/bank/row/column). If a correctable error is found where the corresponding address bit is 0, that counter is decremented, while if the address bit was 1, that counter is incremented. As long as errors are occurring randomly over the address space, these counters will vary randomly around zero, but if more errors happens when an address bit has one value, the corresponding counter will tend towards its maximum or minimum value.

GRIP

Apr 2024, Version 2024.1

283

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The main purpose of these counters are for identifying the likely address when a SEFI is detected, and also to collect statistics over time to detect if some parts of memory are weaker than others.

29.6 Front-end to back-end interface implementation

29.6.1 Command FIFO format

Each port of the front-end sends commands to the back-end using a FIFO. The command words of the FIFO have been designed to match closely (but not exactly) with the commands going out to the memory.

The command words containing the following fields:

- Command ID (4-bit tag)
- 3-bit command word, similar to the (RASn,CASn,WEn) signals of the DDR memory interface
- Chip-select ID (number of bits depending on number of CS supported)
- Bank address bits not implied by port ID
- Address bits (16 bits)
- A special read-modify-write flag (1 bit)
- Prefetch flag (1 bit)

29.6.2 Commands

In normal operation, the commands row-open (011), read (101), write (100), and row-close (010) are issued.

The row-open command opens a specific CS, bank and row. Note that each port can only have one row open. If a new row-open command comes in when a port is open, the other open row will first be closed by the back-end.

The read command causes a read burst to be performed by the back-end. A row must have been selected already using the row-open command. The read out data is normally written into the read-data FIFO, unless the RMW flag or the prefetch flag is set. Note that the CS and bank fields are ignored for this command (these fields have special use for precharging, see below)

The write command performs a write burst to memory, analogous to the read command. The write data must have been placed in the write data FIFO before sending this command.

The row close command will close the currently opened row for the port, if no port is opened it will have no effect. Note that since the back-end does not require this between row-open commands, this is only needed when the port is idle to ensure that the row is not kept opened indefinitely. This also gives the front-end responsibility to manage the row-open policy of the controller.

Having a separate command to select/open the row has some benefits for performance. The front-end can be optimized to transfer the CS,bank,row immediately, and other work such as determining the exact column and transferring write data into the FIFO can be done in parallel with the back-end opning the row.

29.6.3 Response FIFO format

The response FIFO provides a response word for each command. This consists of:

- Command ID (4-bit)
- Result code (3-bit)
- Correctable error byte lane mask (12-bit)

The result code can be one of: OK (000), uncorrectable error (001), EDAC consistency error (010), TBD (011,100,101,110), internal fault detected (111)

+46 31 7758650 | frontgrade.com/gaisler

29.6.4 Read-data FIFO format

The read-data FIFO words consists of:

- Data word 128-bit
- Correctable error mask (48-bit)
- Uncorrectable error indicator (2-bit)
- Last of burst indicator (1 bit)

Note that the data word is always 128 bits regardless of the width setting of the DDR memory, therefore each read burst will generate 2 or 4 words in the FIFO.

Which byte lanes had the correctable errors can be seen in the response word.

29.6.5 Write-data FIFO format

The write-data FIFO words consists of:

- Data word 128-bit
- Data byte valid 16-bit

The data word is always 128 bits wide regardless of the width setting of the DDR memory, therefore each write command must have 2 or 4 words in this FIFO corresponding to the data. The front-end must always pad data to full bursts by adding words with all valid bits set to 0.

29.6.6 Read-modify-write accesses

The controller allows read-modify-write accesses (8/16/32-bit writes) to be queued up internally without stalling the AHB bus. They are performed without doing round-trips up to the AHB front-end which allows them to be done much more efficiently.

Read-modify-write accesses are commanded by:

1. in the command FIFO, put a row-open command to the command FIFO (unless the desired row is already open)

2. in the command FIFO, put a read command for the desired column with the RMW flag bit set to 1. This will make the back-end store the first word of the read burst into an internal buffer.

3. in the write data FIFO, store the partial codeword with corresponding mask as the first word of the write burst, and then pad with additional words with all bytes masked to make a full burst. (this can be done in parallel with steps 1 and 2)

4. in the command FIFO, put a write command to the same column with RMW flag set to 0.

5. once the RMW is completed a result word will be put into the response FIFO

29.6.7 Prefetching

In order to command a prefetch, set the prefetch bit to 1 in the commmand word. The read out data will not be stored in the read data FIFO but in a separate two-port prefetch buffer RAM. The RAM might hold multiple bursts, CS,Bank and the top bits of the address part of the read command word that are otherwise ignored are used as address bits into the prefetch buffer in this case.

29.6.8 Register interface

The configuration registers in the back-end are accessed using a simple handshaked interface, allowing one write or one read at a time. Only one register interface is implemented and is internally multiplexed in the front-end between the user ports and the SEFI handler state machine.

29.7 Implementation

29.7.1 Code structure

The top level of the GRLIB version of the controller is named ftaddr_gr.

The main part of the controller logic is contained in the entities ftaddr_fe_ahb (AHB-clocked part), ftaddr_be (DFI-clocked part), ftaddr_edac (EDAC sub-block of ftaddr_be) and the package ftaddr_int.

29.7.2 Clocking and reset

The controller takes two clocks as input, one AHB clock used to clock the front-end ports, and one DFI clock used to clock the controller back-end. The inputs and output signals of the core all belong to one of these two clock domains.

The core has two synchronous reset inputs, one for each clock domain. The two should both be asserted for a number of cycles in both domains, long enough to reset each domain and then to allow all synchronization registers to stabilize. After that the resets can be raised in any order.

A dynsync signal is included in the controller that allows skipping a synchronization stage if the clock domains are synchronous to each other and if the FIFOs support this function. Note that this should not change during operation. Note also that using dynsync requires synchronous constraining between the clock domains.

29.7.3 Buffer memories

Each AMBA port has five FIFOs, all implemented using the syncfifo_2p entity from the GRLIB techmap library. Typically a suitable configuration is that the write and prefetch FIFOs are mapped to RAM blocks, and the command, response, and read data FIFOs are mapped to flip flops.

Using the generic fifoinfmask, it can be controlled per FIFO type if the technology of the FIFO is set to the same as the top level, or to inferred. Using the generic fifoftmask, it can be selected whether EDAC is enabled on the FIFO or not.

Table 309. Buffer memories instantiated inside the top-level entity

Buffer	Depth	Width (excluding ECC)	infmask / ftmask mask bit	Tech on syncfifo_2p		FT on syncfifo_2p		fwft
				infmask=0	infmask=1	ftmask=0	ftmask=1	
Command	8	26-31	0	tech	inferred	0	1	2
Response	8	18	1	tech	inferred	0	1	1
Write data	32	144	2	tech	inferred	0	4	1
Read data	4	179	3	tech	inferred	0	4	2
Prefetch data	32	179	4	tech	inferred	0	4	1

The FIFOs must be of the first-word-fall-through type, where data and valid come out on the same cycle, therefore fwft is set on all the FIFO instantiations. Since command and read data FIFO latency will affect the read access latency of the controller, the fwft generic has been set to 2 to activate a minimum-latency FIFO where that is available. The dynsync signal is passed on into the syncfifo_2p instantiation to allow bypassing synchronization when supported.

29.7.4 EDAC pipelining

The EDAC has been implemented with one full cycle for decoding, and one full cycle for encoding. The decoder has been designed to allow automatic retiming by synthesis tools, to use up any slack before or after the decoder stage.

GRIP

286

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Extra EDAC pipeline stages are currently not supported, as the pipelining currerntly implemented satisfies the performance requirements. However the controller has been designed to allow for expanding this in the future without major redesign effort.

29.7.5 Clock gating

The IP core is designed with a design style that allows for automatic clock gate insertion by the synthesis tool.

29.7.6 Performance and area

Trial synthesis of the controller was done to C65SPACE using DC Topo with configuration 4 ports, 128 bits AHB, stand-alone version with all features included, black boxed SRAMs. This met timing at 400 MHz frequency on both AHB and DDR domains and produced a standard cell area (not including the SRAM) of 0.46 mm^2, and at 550 MHz frequency with an area of 0.51 mm^2

The controller has also been built with all features including EDAC, for an Altera Stratix4 FPGA with AHB clock 100 MHz and AFI/DDR clock 125 MHz.

29.7.7 Stand-alone version

A separate toplevel called ftaddr_sa is available for building the controller without the surrounding GRLIB infrastructure. When building the stand-alone top-level together with the pure-RTL fifo with flip flops, the IP core has no external dependencies, except for the standard IEEE VHDL libraries.

The stand-alone top level instantiates a block called ftaddr_sa_fifo to implement the FIFOs, instead of going through the GRLIB techmap. The ftaddr_sa_fifo entity can either implement a FIFO based on flip flops or on RAM blocks. When RAM blocks are selected then those are instantiated from the ftaddr_sa_techspec_fifobuf entity, which needs to be provided for the target technology.

Guard gates to prevent glitches propagating between the clock domains are implemented with the ftaddr_sa_cdcguard, in turn depending on the ftaddr_sa_nand2 block, which is a two-input NAND model. In order to avoid this from being optimized out, the command "set_boundary_optimization [get_designs ftaddr_sa_nand2] false" can be used in Design Compiler.

An additional wrapper also exists called ftaddr_sawrap, this takes the stand-alone version and gives it the same interface as the GRLIB version. The main purpose is to allow the stand-alone version to be tested inside a test bench designed to use the GRLIB version.

29.8 PHY specific implementation characteristics

29.8.1 Generic DFI implementation

The generic DFI implementation is intended to interface a DFI2.1.1 compliant DDR2/DDR3 PHY with the following limitations:

- The PHY must use a 1:1, 1:2, or 1:4 frequency ratio DFI interface

- The PHY does not use "MC evaluation" mode for training. Note that it is impossible to implement a generic MC evaluation calibration algorithm since the meaning of the delays are not defined in DFI. For using MC evaluation mode, a PHY specific implementation is required.

- The DFI timing parameters are compatible. The timing parameters for the controller are listed in table 311.

The trden, twrlat and twrdata timings that the PHY supports are supplied to the controller through VHDL generics (genphy_trden, genphy_twrlat, and genphy_twrdata). The timings can be set either absolute or relative to the CAS latency depending on what the PHY requires so that they will always be correctly set when updating the CAS latency. The timings can also be overridden from software at run time through the PHY timing registers.

GRIP

Apr 2024, Version 2024.1

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The update interfaces (both MC initiated and PHY initiated) are supported by the controller. The MC update request is asserted while waiting for periodic refresh command to finish.

Note that the DFI parity buses are not used, the regular data bus is used also for ECC/parity bits.

The controller offers some optional extra signals that may be used if the PHY supports it, or may be ignored otherwise:

- xdfi_term_en - Usable to enable local termination on the controller side during reads. Active high, default not used (always 0). The timing and usage of this signal is controlled via the ODT internal timing register.

- xdfi_rderr - Indicate that data on a specific byte lane was not received. Tie to all-0 if not used.

- xdfi_softrst - Active high "soft-reset" to reset the state machines of the PHY to idle state while idle.

- xdfi_phyctrl - Generic control signals tied to PHY generic control signal register.

If desired and supported by the PHY, the control and address signal buses may be duplicated through the ctrldup and csdup generics.

Note that for frequency ratio operation, instead of creating additional signals for the different phases, the DFI signals are widened with a factor corresponding to the frequency ratio with the first phase is stored in the lowest numbered bits. If a signal is N bits wide in full-rate operation, bits (N-1):0 will correspond to phase 0, (2N-1):N corresponds to phase 1, (3N-1):2N corresponds to phase 2, and so on.

In frequency ratio operation, the controller will re-align the write data so that it is delivered in the correct phase relative to the command and the wrdata_en signals for the PHY. For read, the controller requires the data to be delivered from the PHY phase aligned to the phases as mandated by DFI, with the first read data on phase 0, second read data item on phase 1, and so on. Since the controller always issues bursts of length 8, the data for each burst will always be delivered with the first data item starting on phase 0.

29.8.2 Altera UniPhy implementation

The Altera implementation is intended for FPGA prototyping. It has been tested on Stratix4 with DDR2 memory.

The PHY is built using the Quartus II "DDR2 SDRAM Controller with UniPHY" MegaWizard flow, with the "Generate PHY only" option. The burst length must be set to 8.

Some specific precautions need to be taken with this PHY:

- The controller should not reprogram the mode registers, and in particular not change the CAS latency. All period mode register reprogramming functions must be disabled, and the CAS latency setting in the controller must be set to the same as set up when building the PHY.

- Accessing a non-implemented rank will result in the PHY locking up. This is avoided by setting up the NCS field properly in the AHB address decode register and enabling out-of-range AHB error.

The interface used is AFI which is very similar to DFI. Two dedicated ports are added to the controller to support this PHY, afi_dqs_burst and afi_wlat.

29.8.3 Xilinx Ultrascale implementation

The Xilinx Ultrascale implementation is intended to interface Xilinx's DDR3 PHY that is included with the Vivado tool suite. The PHY operates in 1:4 frequency ratio.

As this PHY is not DFI compliant, several minor custom adaptations have been made in the controller:

- The ordering of the data bits of the read and write data buses and data mask are slightly unusual, the controller will internally shuffle the bits of these buses to match so that they can be directly tied to the PHY.

- The PHY requires every bit of the control signals to be duplicated to DDR format, this is not managed in the controller so it has to be done externally between the controller and PHY.

- The PHY only allows read/write commands in slots 0 or 2, to match up with that requirement that reason the 2T mode is forced to disabled in the controller which will make the regular 1:4 command scheduling (see section 29.3.11) to always use slot 0 for read/write commands.

- The PHY requires some custom signals to indicate when reading and writing that have been added to the controller.

- The PHY does not use a fixed delay between the write comand and the write data, instead it uses a signal wrdataen from the PHY to indicate when write data should be sent.

The PHY uses a custom scheme to track voltage/tracking variations which the controller supports. Once every microsecond, the gtrdy signal is asserted. In each time window between gtrdy assertions, there should be at least one read command and three cycles in a row without read commands. To support the read command requirement, the controller has a programmable time threshold where a dummy read is inserted if there has not already been a read since the last gtrdy assertion. Because the read can not always be done immediately, for example due to an ongoing refresh command, the time threshold has to be set high enough to allow such commands to complete. There is a status register bit indicating if the read requirement was missed and a field indicating the lowest number of cycles left observed for a read that can be used for verifying that the threshold setting is high enough.

There is a convenience wrapper for the controller and PHY called ftaddr_xilus_ddr3 toghether with a script to extract the timings from the generated PHY and set the reset values of the controller to match.

29.9 DFI Spec Sheet

Below is a specification sheet of the controller in the same format as section 7.0 of the DFI specification. (note that version 2.1.1 of the specification has an error where min and max have been swapped).

Table 311. DFI Settings specification for FTADDR controller

Terms	Min	Max	Comment
DFI clock frequency	N/A		Synchronous logic, max frequency depends on implementation technology.
DFI Address width	16	16	
DFI Bank Width	3	3	
DFI Control Width	1	1	
DFI Chip Select Width	1	8	Selected via numcs generic
DFI Data Width	64	256	Selected via ddrbits generic (times 2). Since maximum 2*96 bits are used, additional data bits are padded with zero/ignored.
DFI Data Enable Width	1	-	Set via numrwen generic, all bits driven to same value.
DFI Read Data Valid Width	1	-	Set via numrwen generic, only bit 0 is used.
DFI Read Leveling Delay Width	1	-	Set via rdblvlbits generic.
DFI Read Leveling Gate Delay Width	1	-	Set via rdglvlbits generic
DFI Read Leveling MC IF Width	1	-	Set via numrdlvlmc generic
DFI Read Leveling PHY IF Width	1	-	Set via numrdlvlphy generic
DFI Read Leveling Response Width	32	96	Selected via ddrbits generic (always same width as data bus)
DFI Write Leveling Delay Width	1	-	Set via wrlvlbits generic
DFI Write Leveling MC IF Width	1	-	Set via numwrlvlmc generic
DFI Write LEveling PHY IF Width	1	-	Set via numwrlvlphy generic
DFI Write Leveling Response Width	32	96	Selected via ddrbits generic (always same width as data bus)

Table 312. Timing parameter settings for FTADDR controller

Parameter	Min	Max	Comment
t_{ctrl_delay}	0	5	
t_{phy_wrdata}	0	11-tphy_wrlat	Set via genphy_twrdata generic

29.10 Registers

The controller provides a 1024 byte memory-mapped register area. This is split into two halves, the first for configuration registers residing in the back-end, and the second for configuration registers residing in the front-end. For forward compatibility, reserved fields should be written either with 0 or with the last read-out value, and reserved registers should not be accessed at all.

Table 313. Configuration registers for FTADDR controller

Register address offset	Name	R/W	Reset value (dynrst=0)	Notes

29.10.9 PHY timing register 1

Table 323. 0x020 - FTADDR PHY timing register 1

31	30		16
PTOR	RESERVED		
0	0		
rr	r		

15	12	11	0
RESERVED		RDEN_MASK	
0		*	
r		rw	

31		PHY timing register override (PTOR)
		This is set to 1 to allow manual configuration of the fields in PHY timing register 1 and 2, otherwise they are set up automatically.
30 : 12		Reserved
11 : 0		Read-enable timing mask. This controls when the read-enable signal to the PHY (dfi_rddata_enable) is sent out relative to the read command. If bit 0 is set, the read-enable signal is asserted the same time as the command, if bit 1 is set then the read-enable is asserted one cycle after, and so on.
		Only one bit in the mask should be set for DFI compliant operation, however it may in some cases be useful for debugging to set multiple bits to stretch the dfi_rddata_enable longer than the actual burst.
		By default (if PTOR is not set) this will be set automatically to an expected good value based on CAS latency values and which PHY implementation is used.

29.10.10 PHY timing register 2

Table 324. 0x024 - FTADDR PHY timing register 2

31	21	20	16

29.10.20Command register

Table 334. 0x068 - FTADDR command register

31										20	19	18	17	16
SET BYTE LANE DISABLE											RES	MREB	DOZQL	DOZQS
0											0	0	0	0
ws											r	ws	ws	ws

15	14		11	10	9	8	7	6	5	4	3	2	1	0
SPRST	TRLANE			BLTR	BLTG	BLTW	INCTR	INCTG	INCTW	FTRR	FTRG	FTRW	DOMR	DOREF
0	r0			0	0	0	0	0	0	0	0	0	0	0
ws	rw			ws	ws	ws	ws	ws	ws	ws	ws	ws	ws	ws

31 : 20	Disable byte lane. Writing 1 to one of the bits in this field sets the corresponding bit in the byte lane disable register in memory configuration register 4 (see 29.10.6). Reading returns a copy of the byte lane disable register.
19	Reserved
18	Write 1 to trigger memory reboot of single byte lane selected by bits 14:11, if supported by controller. The read value of this field will be 1 after writing it until the action has been performed.
17	Write 1 to trigger a single DDR3 ZQ Calibration long command. The read value of this field will be 1 after writing it until the action has been performed.
16	Write 1 to trigger a single DDR3 ZQ Calibration short command. The read value of this field will be 1 after writing it until the action has been performed.
15	Write 1 to this bit to trigger a soft reset of the PHY (if supported). The read value of this field will be 1 after writing it until the action has been performed.
14 : 11	Selects which byte lane to target for byte lane re-training or memory reboot:
	0=bits 7:0, 1=bits 15:8, ..., 11 = bits 95:88, 12-15 = reserved
	This field is only written when one or more of the bits 10:8 or 18 is also written with 1. The field needs to have its value kept until the re-training and re-boot actions have completed.
10	Write 1 to trigger read data eye training on single byte lane selected by bits 14:11. The read value of this field will be 1 after writing it until the action has been performed.
9	Write 1 to trigger gate training on single byte lane selected by bits 14:11. The read value of this field will be 1 after writing it until the action has been performed.
8	Write 1 to trigger write leveling on single byte lane selected by bits 14:11. The read value of this field will be 1 after writing it until the action has been performed.
7	Write 1 to trigger full read data eye training. The read value of this field will be 1 after writing it until the action has been performed.
6	Write 1 to trigger full gate training. The read value of this field will be 1 after writing it until the action has been performed.
5	Write 1 to trigger full write leveling. The read value of this field will be 1 after writing it until the action has been performed.
4	Write 1 to trigger incremental read data eye training. The read value of this field will be 1 after writing it until the action has been performed.
3	Write 1 to trigger incremental gate training. The read value of this field will be 1 after writing it until the action has been performed.
2	Write 1 to trigger incremental write leveling. The read value of this field will be 1 after writing it until the action has been performed.
1	Write 1 to trigger a mode register reprogramming. The read value of this field will be 1 after writing it until the action has been performed.
0	Write 1 to trigger an auto-refresh. The read value of this field will be 1 after writing it until the action has been performed.

29.10.21Sleep mode configuration register

Table 335. 0x06C - FTADDR sleep mode configuration register

31			16
RESERVED			
0			
r			

15		4	3	1	0
RESERVED			SREFTHRES		ASRFE
0			000		0
r			rw		rw

31 : 4	Reserved
3 : 1	Self refresh threshold (SREFTHRES). Number of idle refresh periods needed in order to trigger going to self-refresh mode, minus one. Only used if SLPEN is set.
0	Automatic self-refresh enable. If set to 1 the controller will automatically put memories in self-refresh mode when idle for a longer time.

29.10.22EDAC configuration register

Table 336. 0x070 - FTADDR backend EDAC and FIFO error counter register

31	30	29	28	27	26		16
ECCMODE		ERET	RDEEN	DRMW	RESERVED		
10		0	0	0	0		
rw		rw	rw	rw	r		

15		4	3		0
RESERVED			RETTEST		
0			0000		
r			rw		

31 : 30	Error Correction Code Mode
	10 = full EDAC, 01 = parity, 00 = none
29	Automatic retry on EDAC internal errors
28	Enable read-error signal from PHY (if supported by PHY) to trigger byte lane failure messages to the front-end.
27	Disable read-modify-write and perform partially masked writes instead. Should only be used when EDAC is disabled (ECCMODE=00)
26 : 4	Reserved
3 : 0	Retry test. Writing a 1 to bit 3 and a count of 1-7 to bits 2:0 will trigger an EDAC internal error flag once in order to test the automatic retry feature enabled by bit 29. The count determines how many read data words from the PHY are received before the test is triggered. Writing 0 to bit 3 or writing 0 to bits 2:0 will have no effect and the field gets cleared.

29.10.23 Service time counter register

This register provides access to the internal running counters of the back-end that trigger the periodic service functions. Writing to this register is mainly intended for testability purposes (for example to produce a specific timing corner case for testing) and is not expected to be used in a typical application.

Table 337. 0x074 - FTADDR service time counter register

31	29	28	27		20	19	16
RESERVED		SITICK	MRREPCTR			REFCTR(7:4)	
0		0	00000000			0000

rw		rw		rw		rw		rw	

31	Out-of-range AHB error.
	Set to 1 to trigger an AHB error response if an address above the amount of installed memory is made (determined based on CSBASE and NCS).
30 : 16	Reserved
15 : 13	Number of chip selects (ranks / external banks) installed, minus one. Used for out-of-range detection and for the scrubber.
12 : 9	AHB address bits used to determine chip select (CSBASE)
	0: HADDR(24 : 22), (nports*4) MiB data/rank
	1: HADDR(25 : 23), (nports*8) MiB data/rank
	...
	9: HADDR(31 : 31), (nports * 2) GiB data/rank (only two ranks used)
	10: All addresses map to first chip select, (nports * 4) GiB data/rank
	11-15: Reserved
	See section 29.2.8 for guidance on setting up this field
8 : 5	AHB address bits used to determine internal bank index (BANKBASE)
	Same range as CSBASE.
	Note: If no address bits are needed to determine internal bank (number of ports on controller equals number of internal banks on memory), this should be set equal to CSBASE.
	See section 29.2.8 for guidance on setting up this field
4 : 2	AHB address bits used to determine row (ROWBASE)
	0: HADDR(..: 10), 1 KiB/row (over whole data bus)
	1: HADDR(.. : 11), 2 KiB/row (over whole data bus)
	...
	5: HADDR(.. : 15), 32 KiB/row (over whole data bus)
	6-7: Reserved
	See section 29.2.8 for guidance on setting up this field
1 : 0	AHB address bits used to determine column (COLBASE)
	0: HADDR(N:1), 16 data bits/column (hwidth=1, enx4=1)
	1: HADDR(N:2), 32 data bits/column (hwidth=1,enx4=0 or hwidth=0,enx4=1)
	2: HADDR(N:3), 64 data bits/column (hwidth=0, enx4=0)
	3: Reserved
	Note this field must be set corresponding to the backend hwidth/enx4 configuration for correct controller operation.

29.10.30 AHB access configuration register

Table 344. 0x204 - FTADDR AHB access configuration register

31		28	27		24	23		19	18		16
PRELIMHI			PREFLIMLO			RESERVED			WQUEUEMAX		
0100			0010			r			000		
rw			rw			0			rw		

15		13	12			5	4	3	2	1	0
ROWIDLECNT			ROWOTM				ROWOPOL		UEERR	UESIG	CESIG
000			00000000				01		1	1	1
rw			rw				rw		rw	rw	rw

31 : 28	High prefetch threshold, controls how many read commands, plus 1, should be issued ahead of time by the prefetcher. Must not be set higher than the capacity of the prefetch buffer. Only used if prefetching is enabled in the prefetch configuration register.
27 : 24	Low prefetch threshold, controls at what fill level of the prefetch buffer the prefetcher will fetch more data. If set to 0 the prefetcher will not fetch more data until the prefetch buffer is empty, setting it higher will allow the prefetching latency to be masked by remaining data already in the prefetch buffer. Only used if prefetching is enable the prefetch configuration register.
23 : 19	Reserved
18 : 16	Maximum writes allowed to be queued up inside the controller before giving wait states.
	Setting the field to 0 disables the maximum, and it is then limited only by FIFO depth.
15 : 13	Row idle cycle count. This allows, in addition to other row policy settings in this register, to controls the minimum number of AHB cycles, plus 1, the AHB port will stay in idle state with a row opened before sending a row-close hint to the back-end.
12 : 5	Row open cycle count. This allows, in addition to the other row policy settings in this register, to set a minimum number of AHB cycles between opening a row and sending a row-close hint to the back-end. This can be matched to the tRAS configured in the back-end.
4 : 3	Front-end row close policy:
	00 = aggressive, send row-close hint as early as possible. (for reads, before even receiving data) 01 = standard, send row-close hint whenever AHB port is in idle state. 10 = delayed, as standard but in addition waits for writes queued up in the command FIFO to be emptied by the back-end before send. 11 = keep rows open as long as possible, do not send row-close hints to back-end
2	Enable AHB error responses on uncorrectable EDAC errors when reading
1	Enable sideband signal for uncorrectable error when reading
	This setting has no functional impact, except for masking the UE output signal
0	Enable sideband signal for correctable error when reading
	This setting has no functional impact, except for masking the CE output signal

RESERVED		RGALL	IEXD	IADR	SFCAL	BESFI	SFIDBL	SEFISTATE			SHOLD	SEFIEN	SCRUBCNT		SCREN
0		0	0	0	0	0	0	00			0	0	00		0
r		rw	rw	rw	rw	rw	rw	r			rw	rw	rw		rw

31 : 28	Initialization mode start, one bit per AHB port. When this bit is set to 1, the port will perform a full initialization run through the whole memory. The bit is cleared after completion.
	Reads 1 if currently performing initialization.
27 : 24	Read-back start, one bit per AHB port. When this bit is set to 1, the port will perform a read-back and compare with expected initialization data (corresponding to current configuration).
	This can be set to 1 at the same time as the INITEN field in order to trigger a initialization followed back-to-back with a read-back without allowing any other accesses in between.
23 : 20	Scrubber iteration pending, one bit per AHB port. This reads 1 when the periodic scrubber counter has expired, and a scrubber iteration is pending. This can be set to 1 manually by writing, and will in that case trigger a single iteration of the scrubber.
19 : 13	Reserved
12	SEFI handler regenerate all. If set to 0, regeneration will only scrub between scrubber start and scrubber end address, if set to 1 all memory will be scubbed during regeneration.
11	Initialize with existing data mode enable.
	When performing initialization (using INITEN field of SEFI handler and init register) and this field is set to 1, use read-write cycles to keep the existing data content and only update the checkbits using read-write cycles.
	Note that read-back after initialization will return errors after initializing the data in this mode, since the data contents will not match the init pattern.
10	Initialize with address mode enable.
	When set to 1, the lower bits of the initialization and read-back pattern will not be taken from the initialization pattern registers but instead be set to the current rank,bank,row and column of the address being written.
9	Perform PHY re-calibration on byte lane when a SEFI is detected on that byte lane.

31	Set to 1 when uncorrectable error was detected while scrubbing on one of the ports. Must be cleared before another error can be logged in this register.
30	Set to 1 when an error during initialization readback was detected on one of the ports. Must be cleared before another error can be logged in this register.
29 : 27	Chip select number of scrubber uncorrectable error or readback error. Only valid when SCRUE or RBERR fields in this register are set.
26 : 24	Internal bank number of scrubber uncorrectable error or readback error. Only valid when SCRUE or RBERR fields in this register are set.
23 : 8	Row number of scrubber uncorrectable error or readback error. Only valid wen SCRUE or RBERR fields in this register are set.
7 : 0	Top bits (11:4) of column number where scrubber uncorrectable error or readback error occurred. Only valid when SCRUE or RBERR fields in this register are set.

29.10.37 Scrubber CE byte lane counter register 1,2,3

Register 1 holds counters for bits 95:64 (check bits), register 2 holds counters for bits 63:32 (high part of data bits), register 3 holds counters for bits 31:0. All registers are cleared by writing to the BLCLR bit in byte lane error counter register 4.

29.10.42 Access CE/UE location register, port 0,1,2,3

For each AHB port two registers are implemented, the first holding the address of a correctable error, the second holding the address of an uncorrectable error. These are only valid if the corresponding IRQ pending bit is set, and will not be updated until the IRQ pending bit has been cleared.

Table 356. 0x240-0x25C - FTADDR AHB CE/UE location register, port 0,1,2,3

31	16
CE/UE ADDRESS (31:16)	
(nr)	
r	

15	0
CE/UE ADDRESS (15:0)	
(nr)	
r	

31 : 0	AHB address of access with error.

29.10.43 Prefetch status register, port N

Table 357. 0x260-0x26C, FTADDR prefetch status register for port #N

31	30	29 25	24 16
PFACT	PFDRN	PREF FETCH POSITION	PREF READOUT POSITION
0	0	(nr)	(nr)
r	r	r	r

15	0
PREFETCH ROW	
(nr)	
r	

31	Prefetcher activated status. 1=activated, 0=idle
30	Prefetcher draining status, 1=draining, 0=normal
	This will be set after a master accessing a different address than predicted by the prefetcher before all prefetch data in flight has been discarded
29 : 25	Current fetch position of the prefetcher, column bits 7:3. Only valid when PFACT is 1.
	The other, higher, column bits can be deducted from the read position
24 : 16	Current read position of the prefetcher, column bits 11:3. Only valid when PFACT is 1.
15 : 0	Current prefetcher row. Only valid when PFACT is 1.

Note: 1-4 separate registers with the same format is implemented, one for each AHB port. Additional bank/CS address bits are in the prefetch bank register shared between all the ports.

+46 31 7758650 | frontgrade.com/gaisler

Table 364. PHY indirect address 0 - VT Tracking configuration register

15 : 8	Dummy read threshold, when this number of cycles are left until the current VT period (one microsecond) expires and no read has been made, the controller will insert a dummy read as soon as possible. This field is expressed in controller clock cycles (1/4 of memory frequency), not memory clock cycles. The reset value is set via a generic into the core.
7 : 0	VT tracking period, controls the interval between periodic activities to track VT variations. To get the 1 us period required by the PHY, set this field to (MEMFREQ/4)-2, where MEMFREQ is the DDR memory clock frequency in MHz. The reset value is set via a generic into the core.

29.11 Vendor and device identifiers

This controller is identified with vendor ID 0x001 (Frontgrade Gaisler) and device ID 0x0AE. The version described in this document is version 0.

29.12 Implementation

29.12.1 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). Since accesses should match the bus width the core supports both big-endian and little-endian systems.

29.13 Configuration options

Tables 365 shows the configuration options (VHDL generics) of the core.

Table 365. Configuration options for FTADDR (ftaddr_gr entity)

Generic	Function	Allowed range	Default
hindex0	AHB slave index for port 0	0 - NAHBSLV-1	0
hindex1	AHB slave index for port 1	0 - NAHBSLV-1	0
hindex2	AHB slave index for port 2	0 - NAHBSLV-1	0
hindex3	AHB slave index for port 3	0 - NAHBSLV-1	0
haddr0	ADDR field of the AHB BAR0 defining the SDRAM address area on port 0.	0 - 16#FFF#	0

*Table 365.*Configuration options for FTADDR (ftaddr_gr entity)

Generic	Function	Allowed range	Default
phyimpl	PHY implementation ID. See section 29.3.12.	0 - PHY_MAX	0
genphy_trden	Specifies trddata_en parameter for generic DFI implementation. Add 100 to specify CAS latency relative delay.	0-11, 95-110	0
genphy_twrlat	Specifies tphy_wrlat parameter for generic DFI implementation. Add 100 to specify write latency relative delay.	0-11, 95-110	0
genphy_twrdata	Specifies twrdata parameter for generic DFI implementation.	0 - 11	0
fifoftmask	Bit mask specifying which syncfifo_2p instances should have the FT generic set. Sum of: 1: Command FIFOs 2: Response FIFOs 4: Write data FIFOs 8: Read data FIFOs 16: Prefetch read data FIFOs	0-31	31
fifoinfmask	Bit mask specifying which syncfifo_2p instances should have the tech generic set to inferred instead of tech value given in generic. Same encoding as fifoftmask.	0-31	0
dynrst	Enable reset values control from input signals	0 - 1	0
phyctrlbits	Number of bits implemented in generic PHY control register	0 - 32	0
xilphy_vtper	Default value of VT tracking period for Ultrascale PHY	0 - 255	73
xilphy_drthr	Default value of dummy read threshold for Ultrascale PHY	0 - 255	48

29.14 Signal descriptions

Table 366 shows the interface signals (VHDL ports) of the of the core.

*Table 366.*Signal descriptions for FTADDR (ftaddr_gr entity)

Signal name	Type	Function	Active
AHB_CLK	Input	AHB clock	Rising
AHB_RSTN	Input	Reset input for AHB clock domain	Low
AHBSI[nports-1:0]	Input	AMBA AHB signal records.	-
AHBSO[nports-1:0]	Output	Port 0 signals are contained in ahbsi[0]/ahbso[0], port 1 in ahbsi[1]/ahbso[1], and so on. All ports are clocked by the same AHB clock but are otherwise independent. The ports are not required to be on the same AHB bus. The IRQ line is driven on AHB port 0 only.	-
AHB_CE[nports-1:0]	Output	EDAC corrected error signal for each port	High
AHB_UE[nports-1:0]	Output	EDAC uncorrectable error signal for each port	High
DYNSYNC	Input	Dynamic synchronization control signal, see section 29.7.2. This is a pseudo-static signal that should only change during reset.	-
DFI_CLK	Input	DFI interface clock	Rising
DFI_RSTN	Input	Reset input for DFI clock domain	Low

Table 366. Signal descriptions for FTADDR (ftaddr_gr entity)

Signal name	Type	Function	Active
DFI_CS_N[freqratio*ctrldup*numcs-1:0]	Output	DFI interface memory control signals. Forwarded to the memory devices by the PHY. DFI_RESET_N is used for DDR3 only. If ctrldup is set higher than one, multiple identical copies of the output signals are generated.	Low
DFI_BANK[freqratio*ctrldup*3-1:0]	Output		-
DFI_ADDRESS[freqratio*ctrldup*16-1:0]	Output		-
DFI_RAS_N[freqratio*ctrldup-1:0]	Output		Low
DFI_CAS_N[freqratio*ctrldup-1:0]	Output		Low
DFI_WE_N[freqratio*ctrldup-1:0]	Output		Low
DFI_CKE[freqratio*ctrldup*numcs-1:0]	Outpu		High
DFI_ODT[freqratio*ctrldup*numcs-1:0]	Output		High
DFI_RESET_N[freqratio*ctrldup*numcs-1:0]	Output		Low
DFI_WRDATA[freqratio*2*ddrbits-1:0]	Output	DFI memory write interface. All bits of DFI_WRDATA_EN for the same phase are driven with identical values.	-
DFI_WRDATA_EN[freqratio*numrwen-1:0]	Output		High
DFI_WRDATA_MASK[freqratio*ddrbits/4-1:0]	Output		-
DFI_RDDATA_EN[freqratio*numrwen-1:0]	Output	DFI memory read interface. All bits of DFI_RDDATA_EN for the same phase are driven with identical values. Only bit 0 of DFI_RDDATA_VALID is used.	High
DFI_RDDATA[freqratio*2*ddrbits-1:0]	Input		-
DFI_RDDATA_VALID[freqratio*numrwen-1:0]	Input		High
DFI_CTRLUPD_REQ	Output	DFI update interface	High
DFI_CTRLUPD_ACK	Input		High
DFI_PHYUPD_REQ	Input		High
DFI_PHYUPD_TYPE[1:0]	Input		-
DFI_PHYUPD_ACK	Output		High
DFI_DATA_BYTE_DISABLE[ddrbits/8-1:0]	Output	DFI data byte disable signal	High
DFI_DRAM_CLK_DISABLE	Output	DFI clock output disable signal	High
DFI_INIT_COMPLETE	Input	DFI initialization complete signal from PHY	High
DFI_RDLVL_MODE[1:0]	Input	DFI read leveling (gate and eye training) interface.	-
DFI_RDLVL_REQ[numrdlvlphy-1:0]	Input		High
DFI_RDLVL_EN[numrdlvlmc-1:0]	Output		High
DFI_RDLVL_GATE_MODE[1:0]	Input		-
DFI_RDLVL_GATE_REQ[numrdlvlphy-1:0]	Input		High
DFI_RDLVL_GATE_EN[numrdlvlmc-1:0]	Output		High
DFI_RDLVL_CS_N[numcs-1:0]	Output		Low
DFI_RDLVL_EDGE[numrdlvlmc-1:0]	Output		-
DFI_RDLVL_DELAY[(ddrbits/8)*rdblvlbits-1:0]	Output		-
DFI_RDLVL_GATE_DELAY[(ddrbits/8)*rdglvlbits-1:0]	Output		
DFI_RDLVL_LOAD[numrdlvlmc-1:0]	Output		High
DFI_RDLVL_RESP[ddrbits-1:0]	Input		

Table 366. Signal descriptions for FTADDR (ftaddr_gr entity)

Signal name	Type	Function	Active
DFI_WRLVL_MODE[1:0]	Input	DFI write leveling interface	-
DFI_WRLVL_REQ[numwrlvlphy-1:0]	Input		High
DFI_WRLVL_EN[numwrlvlmc-1:0]	Output		High
DFI_WRLVL_CS_N[numcs-1;0]	Output		Low
DFI_WRLVL_DELAY[(ddrbits/8)*rdblvl-bits-1:0]	Output		-
DFI_WRLVL_LOAD[numwrlvlmc-1:0]	Output		High
DFI_WRLVL_STROBE[numwrlvlmc-1:0]	Output		High
DFI_WRLVL_RESP[ddrbits-1:0]	Input		-
XDFI_TERM_EN[freqratio-1:0]	Output	Enable for local termination on DQ bus. (PHY specific signal)	High
XDFI_RDERR[(ddrbits/8)-1:0]	Input	Byte lane error detection signal from PHY PHY-specific signal, tie low if unused	High
XDFI_SOFTRST	Output	Soft reset signal to PHY (PHY-specific signal)	High
XDFI_PHYCTRL[31:0]	Outpu	Generic PHY control register output	-
XDFI_BL_RESETN[(ddrbits/8)-1:0]	Output	RESETN and CKE signals per byte lane, to use instead of regular DFI signals when implementing a memory system with reboot support (see section 29.3.13)	Low
XDFI_BL_CKE[(ddrbits/8)-1:0]	Output		High
XDFI_BL_PDN[(ddrbits/8)-1:0]	Output	Output signal for power cycling control per byte lane, only for use when implementing a memory system with reboot support (see section 29.3.13)	Low
XDFI_CLK_ZERO	Output	Output signal for forcing clock outputs low, only for use when implementing a memory system with reboot support (see section 29.3.13)	High
AFI_DQS_BURST[freqratio-1:0]	Output	Additional control signal needed when interfacing AFI PHY	High
AFI_WLAT[5:0]	Input	AFI write latency signal, only used when interfacing AFI PHY	-
XPCLK	Input	These signals are used for a reserved PHY implementation and should not be used, tie the inputs to zero.	
XPRSTN	Input		
XPSEL	Output		
XPWRITE	Output		
XPENABLE	Output		
XPADDR[7:0]	Output		
XPWDATA[31:0]	Output		
XPREADY	Input		
XPRDATA[31:0]	Input		
XPSLVERR	Input		
XILP_RDCAS	Output	Signals used only for Ultrascale PHY implementation, connect to correspondonding signal on PHY. For other PHYs, tie inputs to constant zero.	
XILP_WRCAS	Output		
XILP_WINRANK[1:0]	Output		
XILP_WININJTXN	Output		
XILP_WRDATAEN	Input		
XILP_PERRDDONE	Input		
XILP_GTRDY	Output

*Table 366.*Signal descriptions for FTADDR (ftaddr_gr entity)

Signal name	Type	Function	Active
RSTVAL008[35:0]	Input	Reset values for configuration registers, used only if dynrst generic is set. The name corresponds to the offset in the register area of the register. Bits 31:0 are used as the reset value if dynrst is set. When bit 32 is set, and dynrst is set, this forces the register permanently to the supplied reset value and the corresponding register bits can be optimized out by the synthesis. Bit 35:33 are currently unused.	-

30 FTAHBRAM - On-chip SRAM with EDAC and AHB interface

30.1 Overview

The FTAHBRAM core is a version of the AHBRAM core with added Error Detection And Correction (EDAC). The on-chip memory is accessed via an AMBA AHB slave interface. The memory implements a configurable amount of accessible memory (configured via the *kbytes* VHDL generic). Registers are accessed via an AMB APB interface.

The on-chip memory implements volatile memory that is protected by means of Error Detection And Correction (EDAC). One error can be corrected and two errors can be detected, which is performed by using a (32, 7) BCH code or by technology specific protection provided by the target technology RAMs (implementation option, if supported by target technology). Some of the optional features available are single error counter, diagnostic reads and writes and additional pipeline registers. Configuration is performed via a configuration register.

Figure 66 shows a block diagram of the internals of the controller. The block diagram shows the technology agnostic implementation. If target technology specific protection is selected then the encoder and decoder are not implemented in the FTAHBRAM.
Figure 66. Block diagram

30.2 Operation

30.2.1 Overview

The on-chip fault tolerant memory is accessed through an AMBA AHB slave interface. The maximum AMBA access size supported is configurable through the *maccsz* VHDL generic. The controller supports all access sizes up to *maccsz* and the default value for *maccsz* is set to the maximum bus width configured for GRLIB (AHBDW constant).

The memory address range is configurable with VHDL generics. As for the standard AHB RAM, the memory technology and size is configurable through the *tech* and *kbytes* VHDL generics. The minimum size is 1 KiB and the maximum is technology dependent.

If the core is implemented without AHB pipeline registers then the EDAC functionality can be completely removed by setting the edacen VHDL generic to zero during synthesis. The APB interface is

GRIP

332

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

also removed since it is redundant without EDAC. If AHB pipeline registers are included then EDAC is always enabled and the APB interface is present.

Run-time configuration is done by writing to a configuration register accessed through an AMBA APB interface. The following can be configured during run-time: EDAC can be enabled and disabled. When it is disabled, reads and writes will behave as the standard memory. Read and write diagnostics can be controlled through separate bits. The single error counter can be reset.

30.2.2 Read and write behaviour

If EDAC is disabled (EN bit in configuration register set to 0) write data is passed directly to the memory area and read data will appear on the AHB bus immediately after it arrives from memory. If EDAC is enabled write data is passed to an encoder which outputs a 7-bit checksum. The checksum is stored together with the data in memory and the whole operation is performed without any added waitstates. This applies to word and wider stores (32-bit, 64-bit, 128-bit). If a byte or halfword store is performed, the whole word to which the byte or halfword belongs must first be read from memory (read - modify - write). A new checksum is calculated when the new data is placed in the word and both data and checksum are stored in memory. This is done with 1 - 2 additional waitstates compared to the non EDAC case.

Reads with EDAC disabled are performed with 0 or 1 waitstates while there could also be 2 waitstates when EDAC is enabled. There is no difference between wide, word and subword reads. Table 368 shows a summary of the number of waitstates for the different operations with and without EDAC.

Table 368. Summary of the number of waitstates for the different operations for the memory.

Operation	Waitstates with EDAC Disabled	Waitstates with EDAC Enabled
Read	0 - 1	0 - 2
Word, DWord, 4Word write	0	0
Subword write	0	1 - 2

When EDAC is used, the data is decoded the first cycle after it arrives from the memory and appears on the bus the next cycle if no uncorrectable error is detected. The decoding is done by comparing the stored checksum with a new one which is calculated from the stored data. This decoding is also done during the read phase for a subword write. A so-called syndrome is generated from the comparison between the checksum and it determines the number of errors that occurred. One error is automatically corrected and this situation is not visible on the bus. Two or more detected errors cannot be corrected so the operation is aborted and the required two cycle error response is given on the AHB bus (see the AMBA manual for more details). If no errors are detected data is passed through the decoder unaltered.

30.2.3 Read and write diagnostics

As mentioned earlier the memory provides read and write diagnostics when EDAC is enabled. When write diagnostics are enabled, the calculated checksum is not stored in memory during the write phase. Instead, the TCB field from the configuration register is used. In the same manner, if read diagnostics are enabled, the stored checksum from memory is stored in the TCB field during a read (and also during a subword write). This way, the EDAC functionality can be tested during run-time. Note that checkbits are stored in TCB during reads and subword writes even if a multiple error is detected. Also note that the TCB field contains the check bits for a 32-bit word. If the controller has been implemented with support for wider accesses then it is recommended to load and bypass via TCB using only word accesses. For larger write accesses, the contents of TCB will be written as the checksum for all of the words within the larger access. For wide read accesses, the TCB field will hold the check bits for the least significant word.

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

30.2.4 Error counter

An additional feature is the single error counter which can be enabled with the *errcnten* VHDL generic or by enabling AHB pipeline registers. A single error counter (SEC) field is present in the configuration register, and is incremented each time a single databit error is encountered (reads or subword writes). The number of bits of this counter is 8, set with the *cntbits* VHDL generic. It is accessed through the configuration register. Each counter bit can be reset to zero by writing a one to it. The counter saturates at the value 2^8 - 1 ($2^{cntbits}$ - 1). For each access where single errors are detected the aramo.ce signal will be driven high for one cycle. This signal should be connected to an AHB status register which stores information and generates interrupts (see the AHB Status register documentation for more information). Note that if the maximum supported access size is 32 bits then only one single error can be detected. To support wider access sizes, the core implements several EDAC protected memories with 32-bit data in parallel. This means that a 64- or 128-bit access can trigger multiple single errors. If this happens then the error counter will be incremented with one.

30.2.5 Endianness

The core is designed for big-endian systems.

30.3 Registers

The core is programmed through registers mapped into APB address space.

Table 369. FTAHBRAM registers

APB Address offset	Register
0x0	Configuration Register

Table 370. 0x00 - CFG - Configuration Register

31 30	29 28	27 24	23 21	12+8 13	12 10	9	8	7	6 0
DIAG	R	EDACEN	MEMSIZE	SEC	MEMSIZE	WB	RB	EN	TCB
0	0	*		0	*	0	0	0	NR
rw	r	r		wc	r	*	*	*	rw

27	24	Value of edacen VHDL generic.
		0: EDAC not implemented 1: Technology agnostic BCH EDAC (traditional FTAHBRAM EDAC) 2: Technology agnostic BCH EDAC, provided by SYNCRAMFT 3: Technology specific EDAC (SECDED)
23:	21	Log2 of the current memory size, bits 5:3 of value. Only used when ahbpipe VHDL generic is non-zero.
12+8:	13	Single error counter (SEC): Incremented each time a single error is corrected (includes errors on checkbits). Each bit can be set to zero by writing a one to it. This feature is only available if the errcnten VHDL generic is set.
12:	10	Log2 of the current memory size, bits 2:0 of value
9		Write Bypass (WB): When set, the TCB field is stored as check bits when a write is performed to the memory.
8		Read Bypass (RB) : When set during a read or subword write, the check bits loaded from memory are stored in the TCB field.
7		EDAC Enable (EN): When set, the EDAC is used otherwise it is bypassed during read and write operations.
		If edacen (bits 27:24 of this register) is 2 or 3 then the core always behaves as if it is enabled for write and read timing.

Table 370. 0x00 - CFG - Configuration Register

6: 0		Test Check Bits (TCB) : Used as checkbits when the WB bit is set during writes and loaded with the check bits during a read operation when the RB bit is set.

When the core makes use of technology specific EDAC then the behaviour of error injection is different. The TCB checkbits are propagated to the error injection bits of the SYNCRAMFT entity used within FTAHBRAM when the WB field is set to 1. Normally only one or two bits are used and the type of error injection supported is technology specific and described further in the SYNCRAMFT documentation. The RB field has no effect for technology specific EDAC.

Any unused most significant bits are reserved. Always read as '000...0'.

All fields except TCB are initialised at reset. The EDAC is initally disabled (EN = 0), which also applies to diagnostics fiels (RB and WB are zero).

When available, the single error counter (SEC) field is cleared to zero.

30.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x050. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

30.5 Implementation

30.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

30.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

30.6 Configuration options

Table 371 shows the configuration options of the core (VHDL generics).

*Table 371.*Configuration options

Generic	Function	Allowed range	Default
hindex	Selects which AHB select signal (HSEL) will be used to access the memory.	0 to NAHBMAX-1	0
haddr	ADDR field of the AHB BAR	0 to 16#FFF#	0
hmask	MASK field of the AHB BAR	0 to 16#FFF#	16#FFF#
tech	Memory technology	0 to NTECH	0
kbytes	SRAM size in KiB. The RAM size needs to be a power of two. Otherwise the RAM size will be rounded up to the nearest power of two. For implementations with ahbpipe=1 it is allowed to specify RAM sizes that are of the form 2^x+2^x-1. For example. Specifying a 192 KiB RAM size with ahbpipe = 0 will lead to a 256 KiB RAM area. Specifying a 192 KiB RAM size with ahbpipe = 0 allows a 192 KiB RAM to be implemented. However, specifying a 160 KiB RAM size will still lead to a 192 KiB RAM.	1 to targetdep.	1
pindex	Selects which APB select signal (PSEL) will be used to access the memory configuration registers	0 to NAPBMAX-1	0
paddr	The 12-bit MSB APB address	0 to 16#FFF#	0
pmask	The APB address mask	0 to 16#FFF#	16#FFF#
edacen	Enable and select on-chip EDAC. Must be set to 1 or larger if ahbpipe generic is set to 1. 0: Disabled 1: Technology agnostic BCH EDAC (traditional FTAH-BRAM EDAC) 2: Technology agnostic BCH EDAC, provided by SYN-CRAMFT 3: Technology specific EDAC (SECDED) Technology specific protection is further documented in the GRLIB-FT User's Manual (grlib-ft.pdf).	0 to 3	0
autoscrub	Automatically store back corrected data with new check-bits during a read when a single error is detected. Is ignored when edacen is deasserted. This generic must be set to 0 if the ahbpipe generic is set to 1.	0 to 1	0
errcnten	Enables a single error counter. This generic must be set to 1 if the ahbpipe generic is set to 1.	0 to 1	0
cntbits	number of bits in the single error counter. This generic must be set to 8 if the ahbpipe generic is set to 1.	1 to 8	1
ahbpipe	Selects to use FTAHBRAM2 architecture. Adds pipeline registers and requires edacen = 1, autoscrub = 0, errcnten = 1, cntbits = 8.	0 to 1	0
testen	Test enable	0 to 1	0
maccsz	Maximum access size supported by core	32 to 128	AHBDW

30.7   Signal descriptions

Table 372 shows the interface signals of the core (VHDL ports).

Table 372. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
AHBSI	*	Input	AHB slave input signals	-
AHBSO	*	Output	AHB slave output signals	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
ARAMO	CE	Output	Single error detected	High
MTESTI**	N/A	Input	Memory BIST input signal	-
MTESTO**	N/A	Output	Memory BIST output signal	-
MTESTCLK**	N/A	Input	Memory BIST clock	-

* see GRLIB IP Library User's Manual

** not available in FPGA releases

The aramo.ce signal is normally used to generate interrupts which starts an interrupt routine that corrects errors. Since this is not necessary when autoscrubbing is enabled, aramo.ce should not be connected to an AHB status register or the interrupt should be disabled in the interrupt controller

30.8   Library dependencies

Tabel 373 shows libraries used when instantiating the core (VHDL libraries).

Table 373. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions
GAISLER	MISC	Component	Signals and component declaration

31 FTMCTRL - 8/16/32-bit Memory Controller with EDAC

31.1 Overview

The FTMCTRL combined 8/16/32-bit memory controller provides a bridge between external memory and the AHB bus. The memory controller can handle four types of devices: PROM, asynchronous static ram (SRAM), synchronous dynamic ram (SDRAM) and memory mapped I/O devices (IO). The PROM, SRAM and SDRAM areas can be EDAC-protected using a (39,7) BCH code. The BCH code provides single-error correction and double-error detection for each 32-bit memory word.

The SDRAM area can optionally also be protected using Reed-Solomon coding. In this case a 16-bit checksum is used for each 32-bit word, and any two adjacent 4-bit (nibble) errors can be corrected.

The EDAC capability is determined through a VHDL generic.

The memory controller is configured through three configuration registers accessible via an APB bus interface. The PROM, IO, and SRAM external data bus can be configured in 8-, 16-, or 32-bit mode, depending on application requirements. The controller decodes three address spaces on the AHB bus (PROM, IO, and SRAM/SDRAM). The addresses are determined through VHDL generics. The IO area is marked as non-cacheable in the core's AMBA plug'n'play information record.

External chip-selects are provided for up to four PROM banks, one IO bank, five SRAM banks and two SDRAM banks. Figure 67 below shows how the connection to the different device types is made.

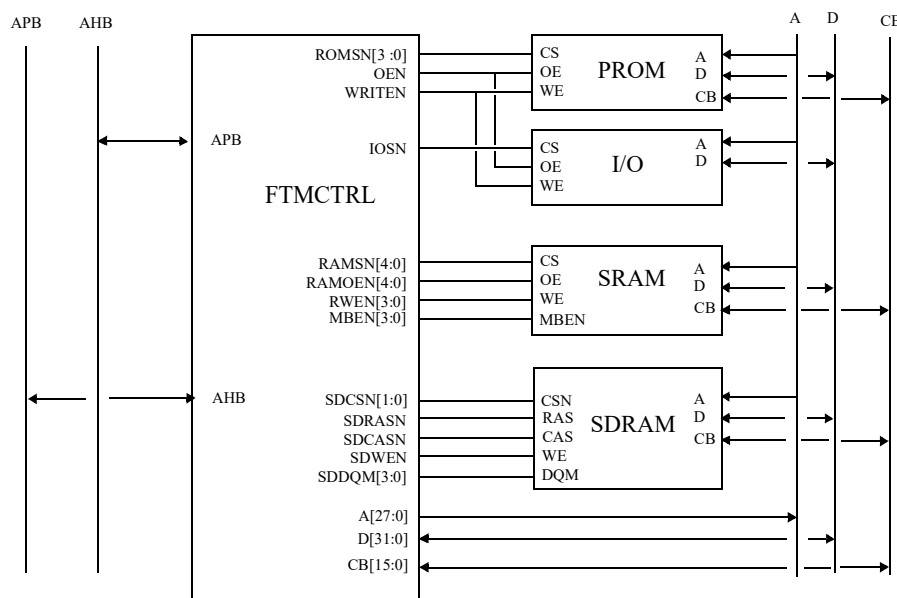
Note: The FTMCTRL AHB slave interface has a non-compliance with the AMBA 2.0 specification where the core will only assert HREADY when it is selected (via HSEL). The core functions correctly in GRLIB systems and there are no known compatibility issues caused by this behaviour. The HREADY behaviour has been, and will be, preserved to not compromise the extensive heritage of the memory controller.


Figure 67. FTMCTRL connected to different types of 32+cb-bit memory devices

31.2 PROM access

Up to four PROM chip-select signals are provided for the PROM area, ROMSN[3:0]. There are two modes: one with two chip-select signals and one with four. The size of the banks can be set in binary steps from 16KiB to 256MiB. If the AHB memory area assigned to the memory controller for PROM

GRIP

+46 31 7758650 | frontgrade.com/gaisler

accesses is larger than the combined size of the memory banks then the PROM memory area will wrap, starting with the first chip-select being asserted again when accessing addresses higher than the last decoded bank.

A read access to PROM consists of two data cycles and between 0 and 30 waitstates (in the default configuration, see *wsshift* VHDL generic documentation for details). The read data (and optional EDAC check-bits) are latched on the rising edge of the clock on the last data cycle. On non-consecutive accesses, a idle cycle is placed between the read cycles to prevent bus contention due to slow turn-off time of PROM devices. Figure 68 shows the basic read cycle waveform (zero waitstate) for non-consecutive PROM reads. Note that the address is undefined in the idle cycle. Figure 69 shows the timing for consecutive cycles (zero waitstate). Waitstates are added by extending the data2 phase. This is shown in figure 70 and applies to both consecutive and non-consecutive cycles. Only an even number of waitstates can be assigned to the PROM area.

31.3 Memory mapped IO

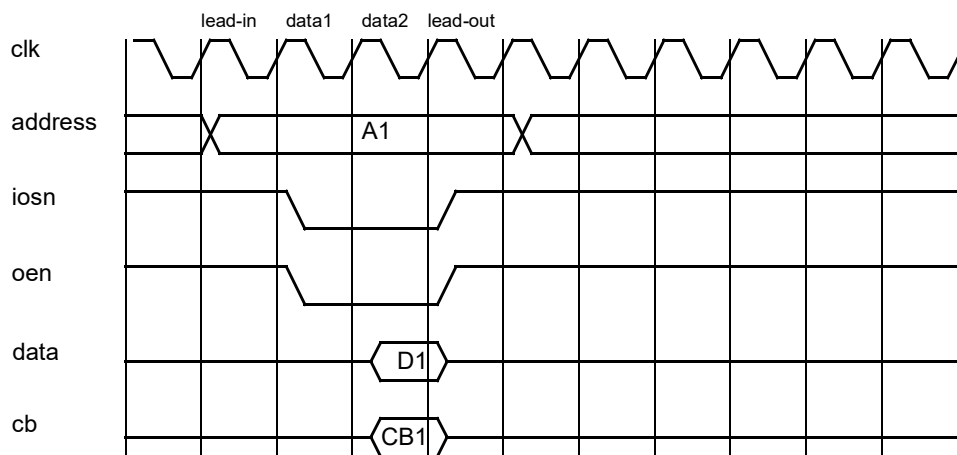
Accesses to IO have similar timing as PROM accesses. The IO select (IOSN) and output enable (OEN) signals are delayed one clock to provide stable address before IOSN is asserted. All accesses are performed as non-consecutive accesses as shown in figure 73. The data2 phase is extended when waitstates are added.


Figure 73. I/O read cycle (0-waitstates)
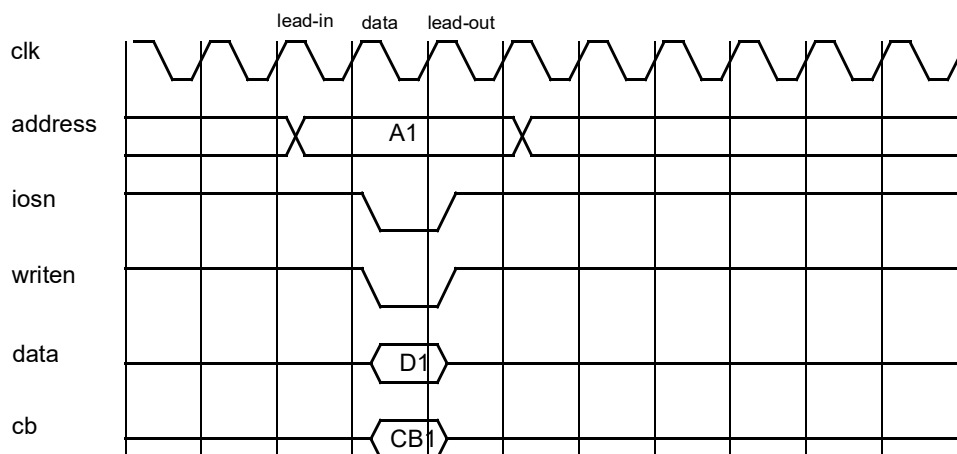

Figure 74. I/O write cycle (0-waitstates)

31.4 SRAM access

The SRAM area is divided on up to five RAM banks. The size of banks 1-4 (RAMSN[3:0]) is programmed in the RAM bank-size field (MCFG2[12:9]) and can be set in binary steps from 8KiB to 256MiB. The fifth bank (RAMSN[4]) decodes the upper 512MiB (controlled by means of the *sdrasel* VHDL generic) and cannot be used simultaneously with SDRAM memory. A read access to SRAM consists of two data cycles and between zero and three waitstates (in the default configuration, see *wsshift* VHDL generic documentation for details). The read data (and optional EDAC check-bits) are latched on the rising edge of the clock on the last data cycle. Accesses to RAMSN[4] can further be stretched by de-asserting BRDYN until the data is available. On non-consecutive accesses, a idle cycle is added after a read cycle to prevent bus contention due to slow turn-off time of memories. Fig-

GRIP

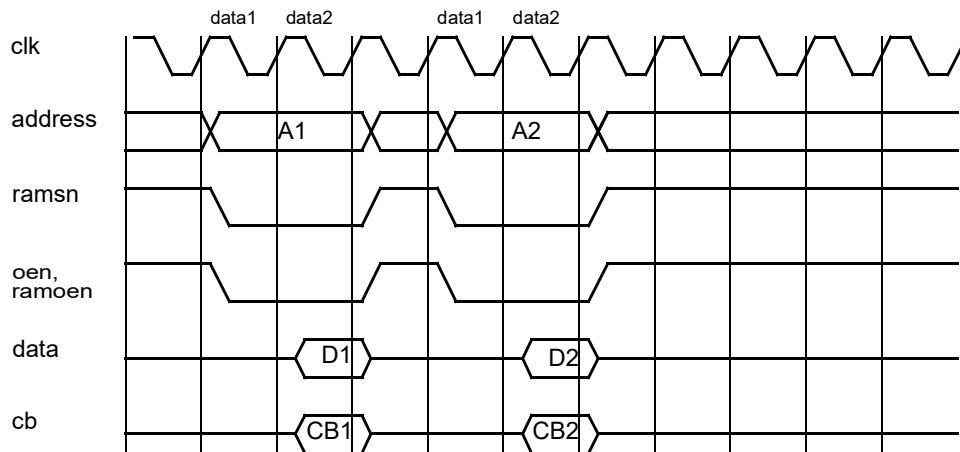
ure 75 shows the basic read cycle waveform (zero waitstate). Waitstates are added in the same way as for PROM in figure 70.


Figure 75. Sram non-consecutive read cyclecs.

For read accesses to RAMSN[4:0], a separate output enable signal (RAMOEN[n]) is provided for each RAM bank and only asserted when that bank is selected. A write access is similar to the read access but takes a minimum of three cycles. Waitstates are added in the same way as for PROM.

Each byte lane has an individual write strobe to allow efficient byte and half-word writes. If the memory uses a common write strobe for the full 16- or 32-bit data, the read-modify-write bit MCFG2 should be set to enable read-modify-write cycles for sub-word writes.

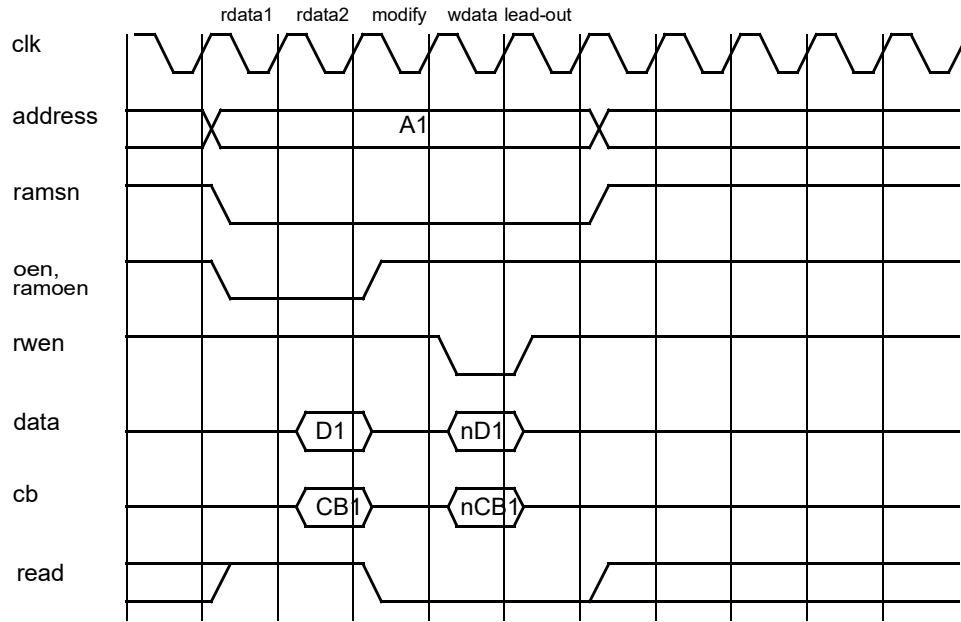

Figure 77. Sram read-modify-write cycle (0-waitstates)

31.5   8-bit and 16-bit PROM and SRAM access

To support applications with low memory and performance requirements efficiently, the SRAM and PROM areas can be individually configured for 8- or 16-bit operation by programming the ROM and RAM width fields in the memory configuration registers. Since reads to memory are always done on 32-bit word basis, read access to 8-bit memory will be transformed in a burst of four read cycles while access to 16-bit memory will generate a burst of two 16-bit reads. During writes, only the necessary bytes will be written. Figure 78 shows an interface example with 8-bit PROM and 8-bit SRAM. Figure 79 shows an example of a 16-bit memory interface.

All possible combinations of width, EDAC, and RMW are not supported. The supported combinations are given in table 374, and the behavior of setting an unsupported combination is undefined. It is not allowed to set the ROM or RAM width fields to 8-bit or 16-bit width if the core does not implement support for these widths.

*Table 374.*FTMCTRL supported SRAM and PROM configurations

PROM/SRAM bus width	RWEN resolution (SRAM)	EDAC	RMW bit (SRAM)	Core configuration
8	Bus width	None	0	8-bit support
8	Bus width	BCH	1	8-bit support, EDAC
16	Byte	None	0	16-bit support
16	Bus width	None	1	16-bit support
32	Byte	None	0	
32	Bus width	None	1	
32+7	Bus width	BCH	1	EDAC support

8-bit width support is set with *ram8* VHDL generic and 16-bit width support is set with *ram16* VHDL genericis.

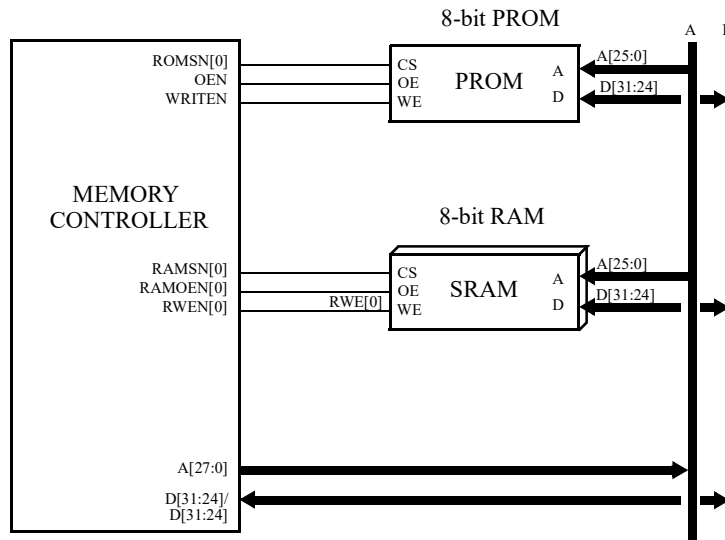
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler


Figure 78. 8-bit memory interface example
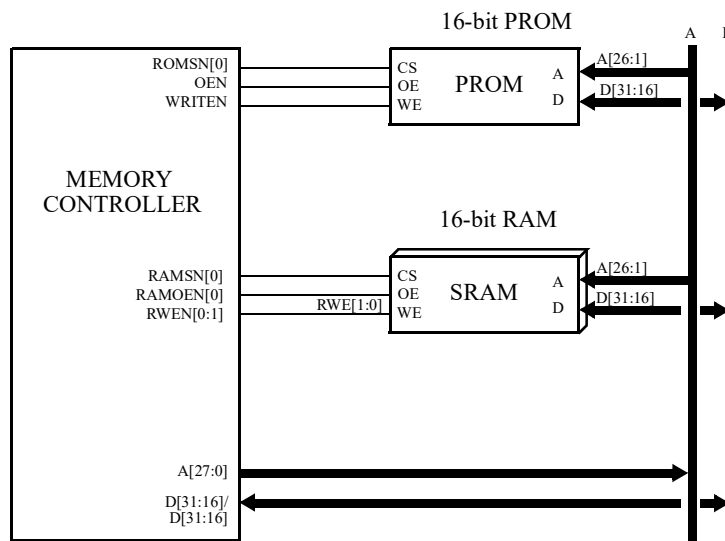

Figure 79. 16-bit memory interface example

In 8-bit mode, the PROM/SRAM devices should be connected to the MSB byte of the data bus (D[31:24]). The LSB address bus should be used for addressing (A[25:0]). In 16-bit mode, D[31:16] should be used as data bus, and A[26:1] as address bus.

31.6 8- and 16-bit I/O access

Similar to the PROM/SRAM areas, the IO area can also be configured to 8- or 16-bits mode. However, the I/O device will NOT be accessed by multiple 8/16 bits accesses as the memory areas, but only with one single access just as in 32-bit mode. To access an IO device on an 8-bit bus, only byte accesses should be used (LDUB/STB instructions for the CPU). To accesses an IO device on a 16-bit bus, only halfword accesses should be used (LDUH/STH instructions for the CPU).

To access the I/O-area in 8- or 16-bit mode, *ram8* VHDL generic or *ram16* VHDL generic must be set respectively.

31.7 Burst cycles

To improve the bandwidth of the memory bus, accesses to consecutive addresses can be performed in burst mode. Burst transfers will be generated when the memory controller is accessed using an AHB burst request. These includes instruction cache-line fills, double loads and double stores. The timing of a burst cycle is identical to the programmed basic cycle with the exception that during read cycles, the idle cycle will only occurs after the last transfer. Burst cycles will not be generated to the IO area.

Only word (HSIZE = "010") bursts of incremental type (HBURST=INCR, INCR4, INCR8 or INCR16) are supported.

31.8 SDRAM access

31.8.1 General

Synchronous dynamic RAM (SDRAM) access is supported to two banks of PC100/PC133 compatible devices. This is implemented by a special version of the SDCTRL SDRAM controller core from Frontgrade Gaisler, which is optionally instantiated as a sub-block. The SDRAM controller supports 64M, 256M and 512M devices with 8 - 12 column-address bits, and up to 13 row-address bits. The size of the two banks can be programmed in binary steps between 4MiB and 512MiB. The operation of the SDRAM controller is controlled through MCFG2 and MCFG3 (see below). Both 32- and 64-bit data bus width is supported, allowing the interface of 64-bit DIMM modules. The memory controller can be configured to use either a shared or separate bus connecting the controller and SDRAM devices.

31.8.2 Address mapping

The two SDRAM chip-select signals are decoded. SDRAM area is mapped into the upper half of the RAM area defined by BAR2 register, and cannot be used simultaneously with fifth SRAM bank (RAMSN[4]). When the SDRAM enable bit is set in MCFG2, the controller is enabled and mapped into upper half of the RAM area as long as the SRAM disable bit is not set. If the SRAM disable bit is set, all access to SRAM is disabled and the SDRAM banks are mapped into the lower half of the RAM area.

31.8.3 Initialisation

When the SDRAM controller is enabled, it automatically performs the SDRAM initialisation sequence of PRECHARGE, 8x AUTO-REFRESH and LOAD-MODE-REG on both banks simultaneously. The controller programs the SDRAM to use single location access on write. The controller programs the SDRAM to use line burst of length 8 when *pageburst* VHDL generic is 0. The controller programs the SDRAM to use page burst when *pageburst* VHDL generic is 1. The controller programs the SDRAM to use page burst or line burst of length 8, selectable via the MCFG2 register, when *pageburst* VHDL generic is 2.

31.8.4 Configurable SDRAM timing parameters

To provide optimum access cycles for different SDRAM devices (and at different frequencies), three SDRAM parameters can be programmed through memory configuration register 2 (MCFG2): TCAS, TRP and TRFCD. The value of these field affects the SDRAM timing as described in table 375.

GRIP
Apr 2024, Version 2024.1

346

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 375.*SDRAM programmable minimum timing parameters

SDRAM timing parameter	Minimum timing (clocks)
CAS latency, RAS/CAS delay (t_{CAS}, t_{RCD})	TCAS + 2
Precharge to activate (t_{RP})	TRP + 2
Auto-refresh command period (t_{RFC})	TRFC + 3
Activate to precharge (t_{RAS})	TRFC + 1
Activate to Activate (t_{RC})	TRP + TRFC + 4

If the TCAS, TRP and TRFC are programmed such that the PC100/133 specifications are fulfilled, the remaining SDRAM timing parameters will also be met. The table below shows typical settings for 100 and 133 MHz operation and the resulting SDRAM timing (in ns):

*Table 376.*SDRAM example programming

SDRAM settings	t_{CAS}	t_{RC}	t_{RP}	t_{RFC}	t_{RAS}
100 MHz, CL=2; TRP=0, TCAS=0, TRFC=4	20	80	20	70	50
100 MHz, CL=3; TRP=0, TCAS=1, TRFC=4	30	80	20	70	50
133 MHz, CL=2; TRP=1, TCAS=0, TRFC=6	15	82	22	67	52
133 MHz, CL=3; TRP=1, TCAS=1, TRFC=6	22	82	22	67	52

31.8.5 Refresh

The SDRAM controller contains a refresh function that periodically issues an AUTO-REFRESH command to both SDRAM banks. The period between the commands (in clock periods) is programmed in the refresh counter reload field in the MCFG3 register. Depending on SDRAM type, the required period is typically 7.8 or 15.6 μs (corresponding to 780 or 1560 clocks at 100 MHz). The generated refresh period is calculated as (reload value+1)/sysclk. The refresh function is enabled by setting bit 31 in MCFG2.

31.8.6 SDRAM commands

The controller can issue three SDRAM commands by writing to the SDRAM command field in MCFG2: PRE-CHARGE, AUTO-REFRESH and LOAD-MODE-REG (LMR). If the LMR command is issued, the CAS delay as programmed in MCFG2 will be used. Line burst of length 8 will be set for read when *pageburst* VHDL generic is 0. Page burst will be set for read when *pageburst* VHDL generic is 1. Page burst or line burst of length 8, selectable via the MCFG2 register will be set, when *pageburst* VHDL generic is 2. Remaining fields are fixed: single location write, sequential burst. The command field will be cleared after a command has been executed. When changing the value of the CAS delay, a LOAD-MODE-REGISTER command should be generated at the same time. NOTE: when issuing SDRAM commands, the SDRAM refresh must be disabled.

31.8.7 Read cycles

A read cycle is started by performing an ACTIVATE command to the desired bank and row, followed by a READ command after the programmed CAS delay. A read burst is performed if a burst access has been requested on the AHB bus. The read cycle is terminated with a PRE-CHARGE command, no banks are left open between two accesses.

GRIP
Apr 2024, Version 2024.1

347

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

31.8.8 Write cycles

Write cycles are performed similarly to read cycles, with the difference that WRITE commands are issued after activation. A write burst on the AHB bus will generate a burst of write commands without idle cycles in-between.

After the WRITE command has completed, if there is an immediately following read or write access (not RMW) to the same 1KiB page on the AHB bus, this access is performed during the same access cycle without closing and re-opening the row.

31.8.9 Read-modify-write cycles

If EDAC is enabled and a byte or half-word write is performed, the controller will perform a read-modify-write cycle to update the checkbits correctly. This is done by performing an ACTIVATE command, followed by READ, WRITE and PRE-CHARGE. The write command interrupts the read burst and the data mask signals will be raised two cycles before this happens as required by the SDRAM standard.

31.8.10 Address bus

The memory controller can be configured to either share the address and data buses with the SRAM, or to use separate address and data buses. When the buses are shared, the address bus of the SDRAMs should be connected to A[14:2], the bank address to A[16:15]. The MSB part of A[14:2] can be left unconnected if not used. When separate buses are used, the SDRAM address bus should be connected to SA[12:0] and the bank address to SA[14:13].

31.8.11 Data bus

SDRAM can be connected to the memory controller through the common or separate data bus. If the separate bus is used the width is configurable to 32 or 64 bits. 64-bit data bus allows the 64-bit SDRAM devices to be connected using the full data capacity of the devices. 64-bit SDRAM devices can be connected to 32-bit data bus if 64-bit data bus is not available but in this case only half the full data capacity will be used. There is a drive signal vector and separate data vector available for SDRAM. The drive vector has one drive signal for each data bit. These signals can be used to remove timing problems with the output delay when a separate SDRAM bus is used.

31.8.12 Clocking

The SDRAM controller is designed for an external SDRAM clock that is in phase or slightly earlier than the internal AHB clock. This provides the maximum margin for setup and hold on the external signals, and allows highest possible frequency. For Xilinx and Altera device, the GRLIB Clock Generator (CLKGEN) can be configured to produce a properly synchronized SDRAM clock. For other FPGA targets, the custom clock synchronization must be designed. For ASIC targets, the SDRAM clock can be derived from the AHB clock with proper delay adjustments during place&route.

31.8.13 Initialisation

Each time the SDRAM is enabled (bit 14 in MCFG2), an SDRAM initialisation sequence will be sent to both SDRAM banks. The sequence consists of one PRECHARGE, eight AUTO-REFRESH and one LOAD-COMMAND-REGISTER command.

31.9   Memory EDAC

31.9.1 BCH EDAC

The FTMCTRL is provided with an BCH EDAC that can correct one error and detect two errors in a 32-bit word. For each word, a 7-bit checksum is generated according to the equations below. A cor-

rectable error will be handled transparently by the memory controller, but adding one waitstate to the access. If an un-correctable error (double-error) is detected, the current AHB cycle will end with an error response. The EDAC can be used during access to PROM, SRAM and SDRAM areas by setting the corresponding EDAC enable bits in the MCFG3 register. The equations below show how the EDAC checkbits are generated:

```
CB0 = D0 ^ D4 ^ D6 ^ D7 ^ D8 ^ D9 ^ D11 ^ D14 ^ D17 ^ D18 ^ D19 ^ D21 ^ D26 ^ D28 ^ D29 ^ D31
CB1 = D0 ^ D1 ^ D2 ^ D4 ^ D6 ^ D8 ^ D10 ^ D12 ^ D16 ^ D17 ^ D18 ^ D20 ^ D22 ^ D24 ^ D26 ^ D28
CB2 = D0 ^ D3 ^ D4 ^ D7 ^ D9 ^ D10 ^ D13 ^ D15 ^ D16 ^ D19 ^ D20 ^ D23 ^ D25 ^ D26 ^ D29 ^ D31
CB3 = D0 ^ D1 ^ D5 ^ D6 ^ D7 ^ D11 ^ D12 ^ D13 ^ D16 ^ D17 ^ D21 ^ D22 ^ D23 ^ D27 ^ D28 ^ D29
CB4 = D2 ^ D3 ^ D4 ^ D5 ^ D6 ^ D7 ^ D14 ^ D15 ^ D18 ^ D19 ^ D20 ^ D21 ^ D22 ^ D23 ^ D30 ^ D31
CB5 = D8 ^ D9 ^ D10 ^ D11 ^ D12 ^ D13 ^ D14 ^ D15 ^ D24 ^ D25 ^ D26 ^ D27 ^ D28 ^ D29 ^ D30 ^ D31
CB6 = D0 ^ D1 ^ D2 ^ D3 ^ D4 ^ D5 ^ D6 ^ D7 ^ D24 ^ D25 ^ D26 ^ D27 ^ D28 ^ D29 ^ D30 ^ D31
```

If the SRAM is configured in 8-bit mode, the EDAC checkbit bus (CB[7:0]) is not used but it is still possible to use EDAC protection. Data is always accessed as words (4 bytes at a time) and the corresponding checkbits are located at the address acquired by inverting the word address (bits 2 to 27) and using it as a byte address. The same chip-select is kept active. A word written as four bytes to addresses 0, 1, 2, 3 will have its checkbits at address 0xFFFFFFF, addresses 4, 5, 6, 7 at 0xFFFFFFE and so on. All the bits up to the maximum bank size will be inverted while the same chip-select is always asserted. This way all the bank sizes can be supported and no memory will be unused (except for a maximum of 4 byte in the gap between the data and checkbit area). A read access will automatically read the four data bytes individually from the nominal addresses and the EDAC checkbit byte from the top part of the bank. A write cycle is performed the same way. Byte or half-word write accesses will result in an automatic read-modify-write access where 4 data bytes and the checkbit byte are firstly read, and then 4 data bytes and the newly calculated checkbit byte are writen back to the memory. This 8-bit mode applies to SRAM while SDRAM always uses 32-bit accesses. The size of the memory bank is determined from the settings in MCFG2. The EDAC cannot be used on memory areas configured in 16-bit mode.

If the ROM is configured in 8-bit mode, EDAC protection is provided in a similar way as for the SRAM memory described above. The difference is that write accesses are not being handled automatically. Instead, write accesses must only be performed as individual byte accesses by the software, writing one byte at a time, and the corresponding checkbit byte must be calculated and be written to the correct location by the software.

NOTE: when the EDAC is enabled in 8-bit bus mode, only the first bank select (RAMSN[0], PROMSN[0]) can be used.

The operation of the EDAC can be tested trough the MCFG3 register. If the WB (write bypass) bit is set, the value in the TCB field will replace the normal checkbits during memory write cycles. If the RB (read bypass) is set, the memory checkbits of the loaded data will be stored in the TCB field during memory read cycles. NOTE: when the EDAC is enabled, the RMW bit in memory configuration register 2 must be set.

Data access timing with EDAC enabled is identical to access without EDAC, if the *edac* VHDL generic is set to 1. To improve timing of the HREADY output, a pipeline stage can be inserted in the EDAC error detection by setting the *edac* VHDL generic to 2. One clock extra latency will then occur on single word reads, or on the first data word in a burst.

EDAC is not supported for 64-bit wide SDRAM data buses.

31.9.2 Reed-Solomon EDAC

The Reed-Solomon EDAC provides block error correction, and is capable of correcting up to two 4-bit nibble errors in a 32-bit data word or 16-bit checksum. The Reed-Solomon EDAC can be enabled for the SDRAM area only, and uses a 16-bit checksum. Operation and timing is identical to the BCH EDAC with the pipeline option enabled. The Reed-Solomon EDAC is enabled by setting the RSE and

GRIP

RE bits in MCFG3, and the RMW bit in MCFG2. The Reed-Solomon EDAC is not supported for 64-bit wide SDRAM buses.

The Reed-Solomon data symbols are 4-bit wide, represented as GF(2^4). The basic Reed-Solomon code is a shortened RS(15, 13, 2) code, represented as RS(6, 4, 2). It has the capability to detect and correct a single symbol error anywhere in the codeword. The EDAC implements an interleaved RS(6, 4, 2) code where the overall data is represented as 32 bits and the overall checksum is represented as 16 bits. The codewords are interleaved nibble-wise. The interleaved code can correct two 4-bit errors when each error is located in a nibble and not in the same original RS(6, 4, 2) codeword.

The Reed-Solomon RS(15, 13, 2) code has the following definition:

- there are 4 bits per symbol;

- there are 15 symbols per codeword;

- the code is systematic;

- the code can correct one symbol error per codeword;

- the field polynomial is

$$f(x) = x^4 + x + 1$$

- the code generator polynomial is

$$g(x) = \prod_{i=7}^{8} (x + \alpha^i) = \sum_{j=0}^{2} g_j \cdot x^j$$

for which the highest power of x is stored first;

- a codeword is defined as 15 symbols:

$c_0, c_1, c_2, c_3, c_4, c_5, c_6, c_7, c_8, c_9, c_{10}, c_{11}, c_{12}, c_{13}, c_{14}$

where c_0 to c_{12} represent information symbols and c_{13} to c_{14} represent check symbols.

The shortened and interleaved RS(6, 4, 2) code has the following definition:

- the codeword length is shortened to 4 information symbols and 2 check symbols and as follows:

$c_0 = c_1 = c_2 = c_3 = c_4 = c_5 = c_6 = c_7 = c_8 = 0$

where the above information symbols are suppressed or virtually filled with zeros;

- two codewords are interleaved (i.e. interleaved depth I=2) with the following mapping to the 32-bit data and 16-bit checksum, were $c_{i,j}$ is a symbol with codeword index i and symbol index j:

$c_{0,9}\ = sd[31:28]$

$c_{1,9}\ = sd[27:24]$

$c_{0,10} = sd[23:20]$

$c_{1,10} = sd[19:16]$

$c_{0,11} = sd[15:12]$

$c_{1,11} = sd[11:8]$

$c_{0,12} = sd[7:4]$

$c_{1,12} = sd[3:0]$

$c_{0,13} = scb[15:12]$

$c_{1,13} = scb[11:8]$

+46 31 7758650 | frontgrade.com/gaisler

$c_{0,14} = \text{scb}[7{:}4]$

$c_{1,14} = \text{scb}[3{:}0]$

where SD[ ] is interchanable with DATA[] and SCB[ ] is interchangable with CB[ ]

Note that the FTMCTRL must have the *edac* VHDL generic set to 3 to enable the RS EDAC functionality. The Reed-Solomon EDAC is not supported for 64-bit wide SDRAM buses.

31.9.3 EDAC Error reporting

As mentioned above an un-correctable error results in an AHB error response which can be monitored on the bus. Correctable errors however are handled transparently and are not visible on the AHB bus. A sideband signal is provided which is asserted during one clock cycle for each access for which a correctable error is detected. This can be used for providing an external scrubbing mechanism and/or statistics. The correctable error signal is most commonly connected to the AHB status register which monitors both this signal and error responses on the bus. Please see the AHB status register section for more information.

31.10 Bus Ready signalling

The BRDYN signal can be used to stretch all types of access cycles to the PROM, I/O area and the SRAM area decoded by RAMSN[4]. This covers read and write accesses in general, and additionally read-modify-write accesses to the SRAM area. The accesses will always have at least the pre-programmed number of waitstates as defined in memory configuration registers 1 & 2, but will be further stretched until BRDYN is asserted. BRDYN should be asserted in the cycle preceding the last one. If bit 29 in MCFG1 is set, BRDYN can be asserted asynchronously with the system clock. In this case, the read data must be kept stable until the de-assertion of OEN/RAMOEN and BRDYN must be asserted for at least 1.5 clock cycle. The use of BRDYN can be enabled separately for the PROM, I/O and RAMSN[4] areas. It is recommended that BRDYN is asserted until the corresponding chip select signal is de-asserted, to ensure that the access has been properly completed and avoiding the system to stall.
Figure 80. READ cycle with one extra data2 cycle added with BRDYN (synchronous sampling). Lead-out cycle is only applicable for I/O accesses.

Figure 81 shows the use of BRDYN with asynchronous sampling. BRDYN is kept asserted for more than 1.5 clock-cycle. Two synchronization registers are used so it will take at least one additional cycle from when BRDYN is first asserted until it is visible internally. In figure 81 one cycle is added to the data2 phase.

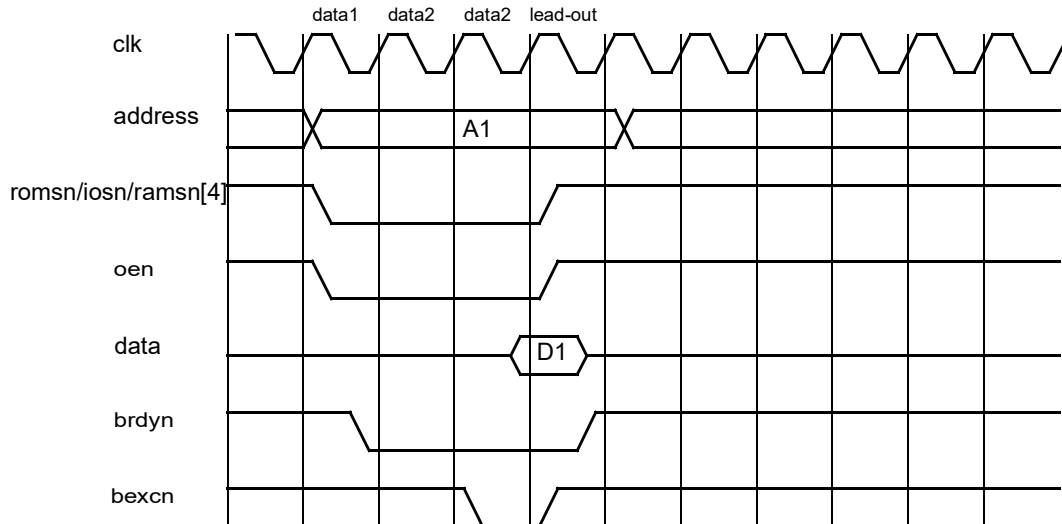

Figure 81. BRDYN (asynchronous) sampling and BEXCN timing. Lead-out cycle is only applicable for I/O-accesses.
Figure 82. Read cycle with one waitstate (configured) and one BRDYN generated waitstate (synchronous sampling).

If burst accesses and BRDYN signaling are to be used together, special care needs to be taken to make sure BRDYN is raised between the separate accesses of the burst. The controller does not raise the select and OEN signal (in the read case) between accesses during the burst so if BRDYN is kept asserted until the select signal is raised, all remaining accesses in the burst will finish with the configured fixed number of wait states.

The core can optionally be implemented with a bus ready timeout counter. The counter value and counter reload value are then available in MCFG7. The counter will be reloaded whenever the bus ready signal is low (asserted). If the reload value is nonzero, then the counter will decrement with one each clock cycle the core is waiting for bus ready to be asserted. If the counter reaches zero, the action taken depends on the state of Bus Error Enable (BEXCN) in MCFG1. If BEXCN is '1', then an AMBA ERROR response will be generated and the counter will be reloaded. If BEXCN is '0', then the bus ready enable for the accessed memory area will be disabled and the core will ignore bus ready for the accessed area.

Bus ready timeout functionality is disabled when the bus ready counter reload value is zero (MCFG7.BRDYCNTRLD = 0).

+46 31 7758650 | frontgrade.com/gaisler

31.11 Access errors

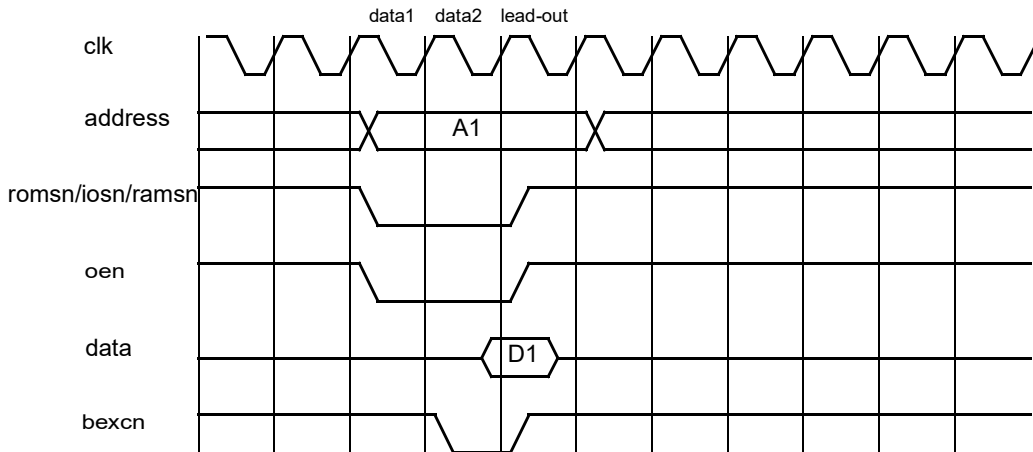
An access error can be signalled by asserting the BEXCN signal for read and write accesses. For reads it is sampled together with the read data. For writes it is sampled on the last rising edge before chip select is de-asserted, which is controlled by means of waitstates or bus ready signalling. If the usage of BEXCN is enabled in memory configuration register 1, an error response will be generated on the internal AHB bus. BEXCN can be enabled or disabled through memory configuration register 1, and is active for all areas (PROM, IO and RAM). BEXCN is only sampled in the last access for 8- and 16-bit mode for RAM and PROM. That is, when four bytes are written for a word access to 8-bit wide memory BEXCN is only sampled in the last access with the same timing as a single access in 32-bit mode.


Figure 83. Read cycle with BEXCN.
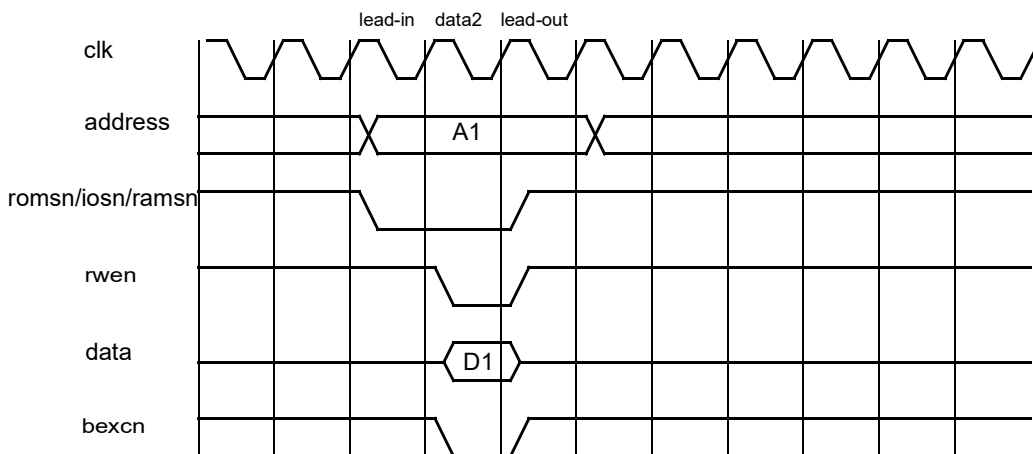

Figure 84. Write cycle with BEXCN. Chip-select (iosn) is not asserted in lead-in cycle for io-accesses.

31.12 Attaching an external DRAM controller

To attach an external DRAM controller, RAMSN[4] should be used since it allows the cycle time to vary through the use of BRDYN. In this way, delays can be inserted as required for opening of banks and refresh.

31.13 Output enable timing

A drive signal vector for the data I/O-pads is provided which has one drive signal for each data bit. It can be used if the synthesis tool does not generate separate registers automatically for the current technology. This can remove timing problems with output delay. An additional vector is used for the separate SDRAM bus.

31.14 Read strobe

The READ signal indicates the direction of the current PROM,SRAM,IO or SDRAM transfer, and it can be used to drive external bi-directional buffers on the data bus. It always is valid at least one cycle before and after the bus is driven, at other times it is held either constant high or low.

31.15 Endianness

The core is designed for big-endian systems.

31.16 Registers

The core is programmed through registers mapped into APB address space.

*Table 377.*FTMCTRL memory controller registers

23 : 20	I/O waitstates (IO WAITSTATES) - Sets the number of waitstates during I/O accesses ("0000"=0, "0001"=1, "0010"=2,..., "1111"=15). The values above describe the default configuration The core can be configred at implementation to extend the number of waitstates. The number of wait states inserted will be (IO WAITSTATES)*2^{wsshift}, where *wsshift* can be read from the first user-defined register in the core's plug&play area (default is wsshift = 0).
19	I/O enable (IOEN) - Enables accesses to the memory bus I/O area.
18	RESERVED
17: 14	PROM bank size (ROMBANKSZ) - Returns current PROM bank size when read. "0000" is a special case and corresponds to a bank size of 256MiB. All other values give the bank size in binary steps: "0001"=16KiB, "0010"=32KiB, "0011"=64KiB,... , "1111"=256MiB (i.e. 8KiB * 2**ROM-BANKSZ). For value "0000" or "1111" only two chip selects are available. For other values, two chip select signals are available for fixed bank sizes. For other values, four chip select signals are available for programmable bank sizes. Programmable bank sizes can be changed by writing to this register field. The written values correspond to the bank sizes and number of chip-selects as above. Reset to "0000" when programmable. Programmable ROMBANKSZ is only available when romasel VHDL generic is 0. For other values this is a read-only register field containing the fixed bank size value.
13:12	RESERVED
11	PROM write enable (PWEN) - Enables write cycles to the PROM area.
10	RESERVED
9 : 8	PROM width (PROM WIDTH) - Sets the data width of the PROM area ("00"=8, "01"=16, "10"=32).
7 : 4	PROM write waitstates (PROM WRITE WS) - Sets the number of wait states for PROM write cycles ("0000"=0, "0001"=2, "0010"=4,..., "1111"=30). The values above describe the default configuration The core can be configred at implementation to extend the number of waitstates. The number of wait states inserted will be (PROM WRITE WS)*2*2^{wsshift}, where *wsshift* can be read from the first user-defined register in the core's plug&play area (default is wsshift = 0).
3 : 0	PROM read waitstates (PROM READ WS) - Sets the number of wait states for PROM read cycles ("0000"=0, "0001"=2, "0010"=4,...,"1111"=30). Reset to "1111". The values above describe the default configuration The core can be configred at implementation to extend the number of waitstates. The number of wait states inserted will be (PROM READ WS)*2*2^{wsshift}, where *wsshift* can be read from the first user-defined register in the core's plug&play area (default is wsshift = 0).

During reset, the prom width (bits [9:8]) are set with value on BWIDTH inputs. The prom waitstates fields are set to 15 (maximum). External bus error and bus ready are disabled. All other fields are undefined.

31.16.2 Memory configuration register 2 (MCFG2)

Memory configuration register 2 is used to control the timing of the SRAM and SDRAM.

Table 379.0x04 - MCFG2 - Memory configuration register 2

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 379.*0x04 - MCFG2 - Memory configuration register 2

30	SDRAM TRP parameter (TRP) - t_{RP} will be equal to 2 or 3 system clocks (0/1).
29 : 27	SDRAM TRFC parameter (SDRAM TRFC) - t_{RFC} will be equal to 3+field-value system clocks.
26	SDRAM TCAS parameter (TCAS) - Selects 2 or 3 cycle CAS delay (0/1). When changed, a LOAD-COMMAND-REGISTER command must be issued at the same time. Also sets RAS/CAS delay (t_{RCD}).
25 : 23	SDRAM bank size (SDRAM BANKSZ) - Sets the bank size for SDRAM chip selects (“000”=4MiB, “001”=8MiB, “010”=16MiB,...,. “111”=512MiB). When configured for 64-bit wide SDRAM data bus (sdbits=64), the meaning of this field doubles so that “000”=8 MiB, .., “111”=1024 MiB
22 : 21	SDRAM column size (SDRAM COLSZ) - “00”=256, “01”=512, “10”=1024, “11”=2048 except when bit[25:23]=˘111˘ then ˘11˘=4096
20 : 19	SDRAM command (SDRAM CMD) - Writing a non-zero value will generate a SDRAM command. “01”=PRECHARGE, “10”=AUTO-REFRESH, “11”=LOAD-COMMAND-REGISTER. The field is reset after the command has been executed.
18	64-bit SDRAM data bus (D64) - Reads ‘1’ if the memory controller is configured for 64-bit SDRAM data bus width, ‘0’ otherwise. Read-only.
17	SDRAM Page Burst (SDPB) - SDRAM programmed for page bursts on read when set, else programmed for line burst lengths of 8 on read. Programmable when pageburst VHDL generic is 2, else read-only.
16 : 15	RESERVED
14	SDRAM enable (SE) - Enables the SDRAM controller and disables fifth SRAM bank (RAMSN[4]).
13	SRAM disable (SI) - Disables accesses to SRAM bank if bit 14 (SE) is set to ‘1’.
12 : 9	RAM bank size (RAM BANK SIZE) - Sets the size of each RAM bank (“0000”=8KiB, “0001”=16KiB, “0010”=32KiB, “0011”= 64KiB,.., “1111”=256MiB)(i.e. 8KiB * 2**RAM BANK SIZE).
8	RESERVED
7	RAM bus ready enable (RBRDY) - Enables bus ready signaling for the RAM area. Bus read signaling for the RAM area is only available for the fifth chip-select and this field is only available if the memory controller has been implemented with the VHDL generic srbanks set to 5.
6	Read-modify-write enable (RMW) - Enables read-modify-write cycles for sub-word writes to 16- bit 32-bit areas with common write strobe (no byte write strobe).
5 : 4	RAM width (RAM WIDTH) - Sets the data width of the RAM area (“00”=8, “01”=16, “1X”=32).
3 : 2	RAM write waitstates (RAM WRITE WS) - Sets the number of wait states for RAM write cycles (“00”=0, “01”=1, “10”=2, “11”=3). The values above describe the default configuration The core can be configred at implementation to extend the number of waitstates. The number of wait states inserted will be (RAM WRITE WS)*$2^{ws\text{-}shift}$, where *wsshift* can be read from the first user-defined register in the core’s plug&play area (default is wsshift = 0).
1 : 0	RAM read waitstates (RAM READ WS) - Sets the number of wait states for RAM read cycles (“00”=0, “01”=1, “10”=2, “11”=3). The values above describe the default configuration The core can be configred at implementation to extend the number of waitstates. The number of wait states inserted will be (RAM READ WS)*$2^{ws\text{-}shift}$, where *wsshift* can be read from the first user-defined register in the core’s plug&play area (default is wsshift = 0).

31.16.3 Memory configuration register 3 (MCFG3)

MCFG3 contains the reload value for the SDRAM refresh counter and to control and monitor the memory EDAC.

*Table 380.*0x08 - MCFG3 - Memory configuration register 3

31	29	28	27	26

31 : 29	RESERVED
28	Reed-Solomon EDAC enable (RSE) - if set, will enable Reed-Solomon protection of SDRAM area when implemented
27	Memory EDAC (ME) - Indicates if memory EDAC is present. (read-only)
26 : 12	SDRAM refresh counter reload value (SDRAM REFRESH COUNTER)
11	EDAC diagnostic write bypass (WB) - Enables EDAC write bypass.
10	EDAC diagnostic read bypass (RB) - Enables EDAC read bypass.
9	RAM EDAC enable (RE) - Enable EDAC checking of the RAM area (including SDRAM).
8	PROM EDAC enable (PE) - Enable EDAC checking of the PROM area. Ar reset, this bit is initialized with the value of MEMI.EDAC.
7 : 0	Test checkbits (TCB) - This field replaces the normal checkbits during write cycles when WB is set. It is also loaded with the memory checkbits during read cycles when RB is set.

The period between each AUTO-REFRESH command is calculated as follows:

$$t_{REFRESH} = ((\text{reload value}) + 1) / SYSCLK$$

31.16.4 Memory configuration register 4 (MCFG4)

MCFG4 is only present if the Reed-Solomon EDAC has been enabled with the *edac* VHDL generic.

MCFG4 provides means to insert Reed-Solomon EDAC errors into memory for diagnostic purposes.

Table 381.0x0C - MCFG4 - Memory configuration register 4

31.18 Implementation

31.18.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers. See the documentation for the *syncrst* VHDL generic for information on asynchronous reset affecting external signals.

31.18.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

31.19 Configuration options

Table 385 shows the configuration options of the core (VHDL generics).

*Table 385.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	1 - NAHBSLV-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
romaddr	ADDR field of the AHB BAR0 defining PROM address space. Default PROM area is 0x0 - 0x1FFFFFFF. Also see documentation of romasel VHDL generic below.	0 - 16#FFF#	16#000#
rommask	MASK field of the AHB BAR0 defining PROM address space.. Also see documentation of romasel VHDL generic below.	0 - 16#FFF#	16#E00#
ioaddr	ADDR field of the AHB BAR1 defining I/O address space. Default I/O area is 0x20000000 - 0x2FFFFFFF.	0 - 16#FFF#	16#200#
iomask	MASK field of the AHB BAR1 defining I/O address space.	0 - 16#FFF#	16#E00#
ramaddr	ADDR field of the AHB BAR2 defining RAM address space. Default RAM area is 0x40000000-0x7FFFFFFF.	0 - 16#FFF#	16#400#
rammask	MASK field of the AHB BAR2 defining RAM address space.	0 -16#FFF#	16#C00#
paddr	ADDR field of the APB BAR configuration registers address space.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR configuration registers address space.	0 - 16#FFF#	16#FFF#
wprot	RAM write protection.	0 - 1	0
invclk	unused	N/A	0
fast	Enable fast SDRAM address decoding.	0 - 1	0

+46 31 7758650 | frontgrade.com/gaisler

*Table 385.*Configuration options

Generic	Function	Allowed range	Default
romasel	Sets the PROM bank size. *romasel 0*: selects a programmable mode where the ROM-BANKSZ field in the MCFG1 register sets the bank size. When romasel is 0 and the bank size is configured (MCFG1 register, ROMBANKSZ field, via the core's register interface) to 0b000 or 0b1111 then address bit 28 is used to decode the banks. This means that the core must be mapped at a 512 MiB address boundary (0x0, 0x20000000, 0x40000000, .. see romaddr and rommask VHDL generics) for address decoding to work correctly. *romasel 1 - 14:* Values 1 - 14 sets the size in binary steps (1 = 16KiB, 2 = 32KiB, 3=64KiB, ..., 14=128MiB). Four chip-selects are available for these values. 15 sets the bank size to 256MiB with two chip-selects. *romasel 16 - 28:* Values 16 - 28 sets the bank size in binary steps (16 = 64 KiB, 17 = 128KiB, ... 28 = 256MiB). Two chip-selects are available for this range. The selected bank size is readable from the rombanksz field in the MCFG1 register for the non-programmable modes. The PROM area will wrap back to the first bank after the end of the last decoded bank. As an example, if romasel is set to 14 the following banks will be decoded: bank 0: 0x00000000 - 0x07FFFFFF bank 1: 0x08000000 - 0x0FFFFFFF bank 2: 0x10000000 - 0x17FFFFFF bank 3: 0x18000000 - 0x1FFFFFFF ...bank 0 starting again at 0x20000000 (the same pattern applies for other values less than 14, addresses will wrap after the last decoded bank). If romasel is 15 then the address decoding will result in the following: bank 0: 0x00000000 - 0x0FFFFFFF bank 1: 0x10000000 - 0x1FFFFFFF .. bank 0 starting again at offset 0x20000000 When instantiating the core care must be taken to see how many chip-selects that will be used as a result of the setting of romasel. This affects the base address at which the core can be placed (setting of romaddr and rommask VHDL generics). As an example, placing the PROM area at a 256 MiB address boundary, like the base address 0x10000000 and using romasel = 0, 14, 15 or 28 will NOT result in ROM chip-select 0 getting asserted for an access to the PROM base address as the address decoding requires that the core has been placed on a 512 MiB address boundary.	0 - 28	28
sdrasel	log2(RAM address space size) - 1. E.g if size of the RAM address space is 0x40000000 sdrasel is log2(2^30)-1= 29.	14 - 31	29
srbanks	Number of SRAM banks.	0 - 5	4
ram8	Enable 8-bit PROM, SRAM and I/O access.	0 - 1	0
ram16	Enable 16-bit PROM, SRAM and I/O access.	0 - 1	0
sden	Enable SDRAM controller.	0 - 1	0
sepbus	SDRAM is located on separate bus.	0 - 1	1
sdbits	32 or 64 -bit SDRAM data bus.	32, 64	32
oepol	Select polarity of drive signals for data pads. 0 = active low, 1 = active high.	0 - 1	0

GRIP
Apr 2024, Version 2024.1

*Table 385.*Configuration options

Generic	Function	Allowed range	Default
edac	Enable EDAC. 0 = No EDAC; 1 = BCH EDAC; 2 = BCH EDAC with pipelining; 3 = BCH + RS EDAC	0 - 3	0
sdlsb	Select least significant bit of the address bus that is connected to SDRAM.	-	2
syncrst	Choose between synchronous and asynchronous reset for chip-select, oen and drive signals.	0 - 1	0
pageburst	Line burst read of length 8 when 0, page burst read when 1, programmable read burst type when 2.	0-2	0
scantest	Enable scan test support	0 - 1	0
netlist	Use technology specific netlist instead of RTL code	0 - 1	0
tech	Technology to use for netlists	0 - NTECH	0
rahold	Unused	0 - 16	0
wsshift	Wait state counter shift. This value defines the number of steps to shift the wait state counter. The number of waitstates that the core can generate is limited by $2^{wsshift}$. See the wait state fields in the core's APB register descriptions to see the effect of this generic. The value of this generic can be read out in the first user-defined register of the core's plug&play area. This means that if wsshift is non-zero then the AHB controller must have full plug&play decoding enabled.	-	0
brdynto	Bus ready timeout conunter enable. If this generic is non-zero then the core will be implemented with a bus ready timeout counter (see MCFG7).	0 - 1	0

31.20   Scan support

Scan support is enabled by setting the SCANTEST generic to 1. When enabled, the asynchronous reset of any flip-flop will be connected to AHBI.testrst during when AHBI.testen = '1'.

31.21   Signal descriptions

Table 386 shows the interface signals of the core (VHDL ports).

*Table 386.*Signal descriptions

Signal name	Field	Type	Function	Active

31.25 Instantiation

This example shows how the core can be instantiated.

The example design contains an AMBA bus with a number of AHB components connected to it including the memory controller. The external memory bus is defined on the example designs port map and connected to the memory controller. System clock and reset are generated by GR Clock Generator and Reset Generator.

Memory controller decodes default memory areas: PROM area is 0x0 - 0x1FFFFFFF, I/O-area is 0x20000000-0x3FFFFFFF and RAM area is 0x40000000 - 0x7FFFFFFF. SDRAM controller is enabled. SDRAM clock is synchronized with system clock by clock generator.

32   FTSDCTRL - 32/64-bit PC133 SDRAM Controller with EDAC

32.1   Overview

The fault tolerant SDRAM memory interface handles PC133 SDRAM compatible memory devices attached to a 32- or 64-bit wide data bus. The interface acts as a slave on the AHB bus where it occupies configurable amount of address space for SDRAM access. An optional Error Detection And Correction Unit (EDAC) logic (only for the 32 - bit bus) corrects one bit error and detects two bit errors.

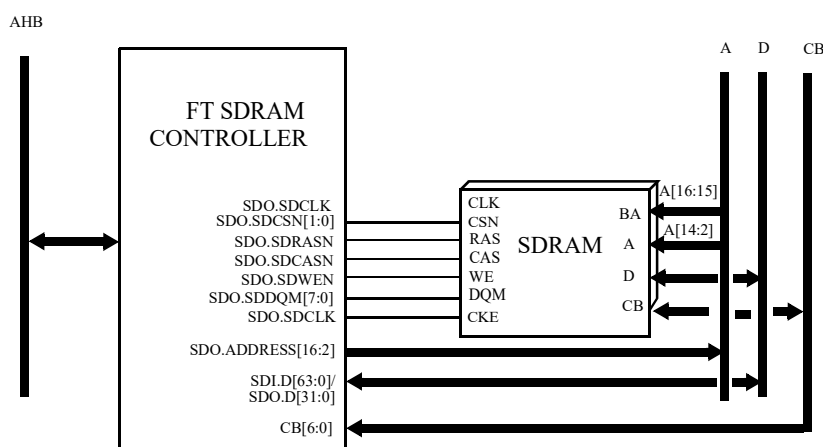
The SDRAM controller function is programmed by means of register(s) mapped into AHB I/O address space. Chip-select decoding is done for two SDRAM banks.


Figure 88. FT SDRAM memory controller connected to AMBA bus and SDRAM

32.2   Operation

32.2.1   General

Synchronous Dynamic RAM (SDRAM) access is supported to two banks of PC100/PC133 compatible devices. The controller supports 64, 256 and 512 Mbyte devices with 8 - 12 column-address bits, up to 13 row-address bits, and 4 banks. The size of each of the two banks can be programmed in binary steps between 4 Mbyte and 512 Mbyte. The operation of the SDRAM controller is controlled through the configuration register SDCFG. A second register, ECFG, is available for configuring the EDAC functions. SDRAM banks data bus width is configurable between 32 and 64 bits.

32.2.2   Initialization

When the SDRAM controller is enabled, it automatically performs the SDRAM initialization sequence of PRECHARGE, 8x AUTO-REFRESH and LOAD-MODE-REG on both banks simultaneously. When mobile SDRAM functionality is enabled, the initialization sequence is appended with a LOAD-EXTMODE-REG command. The controller programs the SDRAM to use page burst on read accesses and single location access on write accesses. If the *pwron* VHDL generic is 1, the initialization sequence is also sent automatically when reset is released. Note that some SDRAM devices require a stable clock of 100 us before any commands might be sent. When using on-chip PLL, this might not always be the case and the *pwron* VHDL generic should be set to 0 in such cases.

32.2.3 Configurable SDRAM timing parameters

To provide optimum access cycles for different SDRAM devices (and at different frequencies), three SDRAM parameters can be programmed through memory configuration register 2 (MCFG2): TCAS, TRP and TRFCD. The value of these fields affect the SDRAM timing as described in table 391.

Table 391. SDRAM programmable minimum timing parameters

SDRAM timing parameter	Minimum timing (clocks)
CAS latency, RAS/CAS delay (t_{CAS}, t_{RCD})	TCAS + 2
Precharge to activate (t_{RP})	TRP + 2
Auto-refresh command period (t_{RFC})	TRFC + 3
Activate to precharge (t_{RAS})	TRFC + 1
Activate to Activate (t_{RC})	TRP + TRFC + 4

If the TCAS, TRP and TRFC are programmed such that the PC100/133 specifications are fulfilled, the remaining SDRAM timing parameters will also be met. The table below shows typical settings for 100 and 133 MHz operation and the resulting SDRAM timing (in ns):

Table 392. SDRAM example programming

SDRAM settings	t_{CAS}	t_{RC}	t_{RP}	t_{RFC}	t_{RAS}
100 MHz, CL=2; TRP=0, TCAS=0, TRFC=4	20	80	20	70	50
100 MHz, CL=3; TRP=0, TCAS=1, TRFC=4	30	80	20	70	50
133 MHz, CL=2; TRP=1, TCAS=0, TRFC=6	15	82	22	67	52
133 MHz, CL=3; TRP=1, TCAS=1, TRFC=6	22	82	22	67	52

When mobile SDRAM support is enabled, one additional timing parameter (TXSR) can be programmed though the Power-Saving configuration register.

Table 393. Mobile SDRAM programmable minimum timing parameters

SDRAM timing parameter	Minimum timing (clocks)
Exit Self Refresh mode to first valid command (t_{XSR})	tXSR

32.2.4 Refresh

The SDRAM controller contains a refresh function that periodically issues an AUTO-REFRESH command to both SDRAM banks. The period between the commands (in clock periods) is programmed in the refresh counter reload field in the SDCFG register. Depending on SDRAM type, the required period is typically 7.8 or 15.6 μs (corresponding to 780 or 1560 clocks at 100 MHz). The generated refresh period is calculated as (reload value+1)/sysclk. The refresh function is enabled by setting bit 31 in SDCFG register.

32.2.5 Self Refresh

The self refresh mode can be used to retain data in the SDRAM even when the rest of the system is powered down. When in the self refresh mode, the SDRAM retains data without external clocking and refresh are handled internally. The memory array that is refreshed during the self refresh operation is defined in the extended mode register. These settings can be changed by setting the PASR bits in the Power-Saving configuration register. The extended mode register is automatically updated when the PASR bits are changed. The supported "Partial Array Self Refresh" modes are: Full, Half, Quarter, Eighth, and Sixteenth array. "Partial Array Self Refresh" is only supported when mobile SDRAM functionality is enabled. To enable the self refresh mode, set the PMODE bits in the Power-Saving configuration register to "010" (Self Refresh). The controller will enter self refresh mode after

GRIP
Apr 2024, Version 2024.1

371

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

every memory access (when the controller has been idle for 16 clock cycles), until the PMODE bits are cleared. When exiting this mode the controller introduce a delay defined by tXSR in the Power-Saving configuration register and a AUTO REFRESH command before any other memory access is allowed. The minimum duration of this mode is defined by tRAS. This mode is only available when the VHDL generic *mobile* is >= 1.

32.2.6 Power-Down

When entering the power-down mode all input and output buffers, excluding SDCKE, are deactivated. All data in the SDRAM is retained during this operation. To enable the power-down mode, set the PMODE bits in the Power-Saving configuration register to "001" (Power-Down). The controller will enter power-down mode after every memory access (when the controller has been idle for 16 clock cycles), until the PMODE bits is cleared. The REFRESH command will still be issued by the controller in this mode. When exiting this mode a delay of one clock cycles are added before issue any command to the memory. This mode is only available when the VHDL generic *mobile* is >= 1.

32.2.7 Deep Power-Down

The deep power-down operating mode is used to achieve maximum power reduction by eliminating the power of the memory array. Data will not be retained after the device enters deep power-down mode. To enable the deep power-down mode, set the PMODE bits in the Power-Saving configuration register to "101" (Deep Power-Down). To exit the deep power-down mode the PMODE bits in the Power-Saving configuration register must be cleared. The controller will respond with an AMBA ERROR response to an AMBA access, that will result in a memory access, during Deep Power-Down mode. This mode is only available when the VHDL generic *mobile* is >= 1 and mobile SDRAM functionality is enabled.

32.2.8 Temperature-Compensated Self Refresh

The settings for the temperature-compensation of the Self Refresh rate can be controlled by setting the TCSR bits in the Power-Saving configuration register. The extended mode register is automatically updated when the TCSR bits are changed. Note that some vendors implements a Internal Temperature-Compensated Self Refresh feature, which makes the memory ignore the TCSR bits. This functionality is only available when the VHDL generic *mobile* is >= 1 and mobile SDRAM functionality is enabled.

32.2.9 Drive Strength

The drive strength of the output buffers can be controlled by setting the DS bits in the Power-Saving configuration register. The extended mode register is automatically updated when the DS bits are changed. The available options are: full, three-quarter, one-half, and one-quarter drive strengths. This functionality is only available when the VHDL generic *mobile* is >= 1 and mobile SDRAM functionality is enabled.

32.2.10 SDRAM commands

The controller can issue four SDRAM commands by writing to the SDRAM command field in the SDRAM Configuration register: PRE-CHARGE, AUTO-REFRESH, LOAD-MODE-REG (LMR) and LOAD-EXTMODE-REG (EMR). If the LMR command is issued, the CAS delay as programmed in SDCFG will be used. Line burst of length 8 will be set for read when pageburst VHDL generic is 0. Page burst will be set for read when pageburst VHDL generic is 1. Page burst or line burst of length 8, selectable via the SDCFG register will be set, when pageburst VHDL generic is 2. Remaining fields are fixed: page read burst, single location write, sequential burst. If the EMR command is issued, the DS, TCSR and PASR as programmed in Power-Saving configuration register will be used. The command field will be cleared after a command has been executed. Note that when changing the value of the CAS delay, a LOAD-MODE-REGISTER command should be generated at the same time.

GRIP

Apr 2024, Version 2024.1

372

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

32.2.11 Read cycles

A read cycle is started by performing an ACTIVATE command to the desired bank and row, followed by a READ command after the programmed CAS delay. A read burst is performed if a burst access has been requested on the AHB bus. The read cycle is terminated with a PRE-CHARGE command, no banks are left open between two accesses. Note that only word bursts are supported by the SDRAM controller. The AHB bus supports bursts of different sizes such as bytes and halfwords but they cannot be used.

32.2.12 Write cycles

Write cycles are performed similarly to read cycles, with the difference that WRITE commands are issued after activation. A write burst on the AHB bus will generate a burst of write commands without idle cycles in-between. As in the read case, only word bursts are supported.

32.2.13 Address bus connection

The SDRAM address bus should be connected to SA[12:0], the bank address to SA[14:13], and the data bus to SD[31:0] or SD[63:0] if 64-bit data bus is used.

32.2.14 Data bus

Data bus width is configurable to 32 or 64 bits. 64-bit data bus allows the 64-bit SDRAM devices to be connected using the full data capacity of the devices. 64-bit SDRAM devices can be connected to 32-bit data bus if 64-bit data bus is not available but in this case only half the full data capacity will be used.

32.2.15 EDAC

The controller optionally contains Error Detection And Correction (EDAC) logic, using a BCH(32, 7) code. It is capable of correcting one bit error and detecting two bit errors. The EDAC logic does not add any additional waitstates during normal operation. Detected errors will cause additional waitstates for correction (single errors) or error reporting (multiple errors). Single errors are automatically corrected and generally not visible externally unless explicitly checked.

This checking is done by monitoring the ce signal and single error counter. This counter holds the number of detected single errors. The ce signal is asserted one clock cycle when a single error is detected and should be connected to the AHB status register. This module stores the AHB status of the instruction causing the single error and generates interrupts (see the AHB status register documentation for more information).

The EDAC functionality can be enabled/disabled during run-time from the ECFG register (and the logic can also be completely removed during synthesis with VHDL generics. The ECFG register also contains control bits and checkbit fields for diagnostic reads. These diagnostic functions are used for testing the EDAC functions on-chip and allows one to store arbitrary checkbits with each written word. Checkbits read from memory can also be controlled.

64-bit bus support is not provided when EDAC is enabled. Thus, the and edacen VHDL generic should never be set to one when the sdbits VHDL generic is set to 64.

The equations below show how the EDAC checkbits are generated:

```
CB0 = D0 ^ D4 ^ D6 ^ D7 ^ D8 ^ D9 ^ D11 ^ D14 ^ D17 ^ D18 ^ D19 ^ D21 ^ D26 ^ D28 ^ D29 ^ D31

32.2.16 Clocking

The SDRAM controller is designed for an external SDRAM clock that is in phase or slightly earlier than the internal AHB clock. This provides the maximum margin for setup and hold on the external signals, and allows highest possible frequency. For Xilinx and Altera devices, the GRLIB Clock Generator (CLKGEN) can be configured to produce a properly synchronized SDRAM clock. For other FPGA targets, the custom clock synchronization must be designed, or the inverted clock option can be used (see below). For ASIC targets, the SDRAM clock can be derived from the AHB clock with proper delay adjustments during place&route.

If the VHDL generic INVCLK is set, then all outputs from the SDRAM controller are delayed for 1/2 clock. This is done by clocking all output registers on the falling clock edge. This option can be used on FPGA targets where proper SDRAM clock synchronization cannot be achieved. The SDRAM clock can be the internal AHB clock without further phase adjustments. Since the SDRAM signals will only have 1/2 clock period to propagate, this option typically limits the maximum SDRAM frequency to 40 - 50 MHz.

32.2.17 Endianness

The core is designed for big-endian systems.

32.3 Registers

The memory controller is programmed through register(s) mapped into the AHB I/O space defined by the controllers AHB BAR1.

If EDAC is enabled through the use of the edacen VHDL generic, an EDAC configuration register will be available.

Only 32-bit single-accesses to the registers are supported.

*Table 394.*FT SDRAM controller registers

AHB address offset	Register
0x0	SDRAM Configuration register
0x4	EDAC Configuration register
0x8	SDRAM Power-Saving configuration register

32.3.1 SDRAM configuration register (SDCFG)

The SDRAM configuration register is used to control the timing of the SDRAM.

Table 395. 0x00 - SDCFG - SDRAM configuration register

31	30	29 27	26	25 23	22 21	20 18	17	16	15	14 0
Refresh	tRP	tRFC	tCD	SDRAM bank size	SDRAM col. size	SDRAM command	Page-Burst	MS	D64	SDRAM refresh load value
0	1	0b111	1	0	0b10	0	*	*	*	NR
rw	rw	rw	rw	rw	rw	rw	rw*	r	r	rw

31	SDRAM refresh. If set, the SDRAM refresh will be enabled.
30	SDRAM t_{RP} timing. t_{RP} will be equal to 2 or 3 system clocks (0/1).
29: 27	SDRAM t_{RFC} timing. t_{RFC} will be equal to 3 + field-value system clocks.
26	SDRAM CAS delay. Selects 2 or 3 cycle CAS delay (0/1). When changed, a LOAD-MODE-REGISTER command must be issued at the same time. Also sets RAS/CAS delay (tRCD).

Table 395. 0x00 - SDCFG - SDRAM configuration register

25: 23	SDRAM banks size. Defines the decoded memory size for each SDRAM chip select: "000"= 4 Mbyte, "001"= 8 Mbyte, "010"= 16 Mbyte .... "111"= 512 Mbyte.
	When configured for 64-bit wide SDRAM data bus (sdbits=64), the meaning of this field doubles so that "000"=8 Mbyte, .., "111"=1024 Mbyte
22: 21	SDRAM column size. "00"=256, "01"=512, "10"=1024, "11"=2048 except when bit[25:23]=˘111˘ then ˘11˘=4096
20: 18	SDRAM command. Writing a non-zero value will generate an SDRAM command: "010"=PRE-CHARGE, "100"=AUTO-REFRESH, "110"=LOAD-MODE-REGISTER, "111"=LOAD-EXT-MODE-REGISTER. The field is reset after command has been executed.
17	1 = pageburst is used for read operations, 0 = line burst of length 8 is used for read operations. (Only available when VHDL generic pageburst i set to 2)
16	Mobile SDR support enabled. '1' = Enabled, '0' = Disabled (read-only).
15	64-bit data bus (D64) - Reads '1' if memory controller is configured for 64-bit data bus, otherwise '0'. Read-only.
14: 0	The period between each AUTO-REFRESH command - Calculated as follows: tREFRESH = ((reload value) + 1) / SYSCLK

32.3.2 EDAC configuration register (ECFG)

The EDAC configuration register controls the EDAC functions of the SDRAM controller during run time.

Table 396. 0x04 - ECFG - EDAC configuration register

31	30 cntbits + 10	cnbits + 9 10	9	8	7	6 0
EAV	RESERVED	SEC	WB	RB	EN	TCB
*	0	NR	NR	NR	0	NR
r	r	wc	rw	rw	rw	rw

6: 0	TCB : Test checkbits. These bits are written as checkbits into memory during a write operation when the WB bit in the ECFG register is set. Checkbits read from memory during a read operation are written to this field when the RB bit is set.
7:	EN : EDAC enable. Run time enable/disable of the EDAC functions. If EDAC is disabled no error detection will be done during reads and subword writes. Checkbits will still be written to memory during write operations.
8:	RB : Read bypass. Store the checkbits read from memory during a read operation into the TCB field.
9:	WB : Write bypass. Write the TCB field as checkbits into memory for all write operations.
cntbits + 9: 10	SEC : Single error counter. This field is available when the errcnt VHDL generic is set to one during synthesis. It increments each time a single error is detected. It saturates when the maximum value is reached. The maximum value is the largest number representable in the number of bits used, which in turn is determined by the cntbits VHDL generic. Each bit in the counter can be reset by writing a one to it.
30:cntbits + 10	Reserved.
31:	EAV : EDAC available. This bit is always one if the SDRAM controller contains EDAC.

32.3.3 SDRAM Power-Saving configuration register (SDCFG2)

The SDRAM Power-Saving register is used to control the power settings of the SDRAM.

Table 397. 0x08 - SDCFG2 - SDRAM Power-Saving configuration register

31	30	29 24	23 20	19	18 16	15 7	6 5	4 3	2 0
ME	CE	RESERVED	tXSR	R	PMODE	RESERVED	DS	TCSR	PASR

*Table 397.*0x08 - SDCFG2 - SDRAM Power-Saving configuration register

rw*	rw*	r	rw*	r	rw	r	rw	rw	rw

31	Mobile SDRAM functionality enabled. '1' = Enabled (support for Mobile SDRAM), '0' = disabled (support for standard SDRAM)
30	Clock enable (CE). This value is driven on the CKE inputs of the SDRAM. Should be set to '1' for correct operation. This register bit is read only when Power-Saving mode is other then none.
29: 24	Reserved
23: 20	SDRAM tXSR timing. tXSR will be equal to field-value system clocks. (Read only when Mobile SDR support is disabled).
19	Reserved
18: 16	Power-Saving mode (Read only when Mobile SDR support is disabled). "000": none "001": Power-Down (PD) "010": Self-Refresh (SR) "101": Deep Power-Down (DPD)
15: 7	Reserved
6: 5	Selectable output drive strength (Read only when Mobile SDR support is disabled). "00": Full "01": One-half "10": One-quarter "11": Three-quarter
4: 3	Reserved for Temperature-Compensated Self Refresh (Read only when Mobile SDR support is disabled). "00": 70ªC "01": 45ªC "10": 15ªC "11": 85ªC
2: 0	Partial Array Self Refresh (Read only when Mobile SDR support is disabled). "000": Full array (Banks 0, 1, 2 and 3) "001": Half array (Banks 0 and 1) "010": Quarter array (Bank 0) "101": One-eighth array (Bank 0 with row MSB = 0) "110": One-sixteenth array (Bank 0 with row MSB = 00)

32.4   Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x055. For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

32.5   Implementation

32.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). By default, the core makes use of synchronous reset and resets a subset of its internal registers.

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

The registers driving SDRAM chip select and output enables for the SDRAM data bus have asynchronous reset.

32.5.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

32.6 Configuration options

Table 398 shows the configuration options of the core (VHDL generics).

*Table 398.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	1 - NAHBSLV-1	0
haddr	ADDR field of the AHB BAR0 defining SDRAM area. Default is 0xF0000000 - 0xFFFFFFFF.	0 - 16#FFF#	16#000#
hmask	MASK field of the AHB BAR0 defining SDRAM area.	0 - 16#FFF#	16#F00#
ioaddr	ADDR field of the AHB BAR1 defining I/O address space where SDCFG register is mapped.	0 - 16#FFF#	16#000#
iomask	MASK field of the AHB BAR1 defining I/O address space.	0 - 16#FFF#	16#FFF#
wprot	Write protection.	0 - 1	0
invclk	Inverted clock is used for the SDRAM.	0 - 1	0
fast	Enable fast SDRAM address decoding.	0 - 1	0
pwron	Enable SDRAM at power-on.	0 - 1	0
sdbits	32 or 64 -bit data bus width.	32, 64	32
edacen	EDAC enable. If set to one, EDAC logic will be included in the synthesized design. An EDAC configuration register will also be available.	0 - 1	0
errcnt	Include an single error counter which is accessible from the EDAC configuration register.	0 - 1	0
cntbits	Number of bits used in the single error counter	1 - 8	1
pageburst	Enable SDRAM page burst operation. 0: Controller uses line burst of length 8 for read operations. 1: Controller uses pageburst for read operations. 2: Controller uses pageburst/line burst depending on PageBurst bit in SDRAM configuration register.	0 - 2	0
mobile	Enable Mobile SDRAM support 0: Mobile SDRAM support disabled 1: Mobile SDRAM support enabled but not default 2: Mobile SDRAM support enabled by default 3: Mobile SDRAM support only (no regular SDR support)	0 - 3	0

32.10 Library dependencies

Table 5 shows libraries used when instantiating the core (VHDL libraries).

Table 402. Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AHB signal definitions
GAISLER	MEMCTRL	Signals, component	Memory bus signals definitions, component declaration

32.11 Instantiation

This example shows how the core can be instantiated.

The example design contains an AMBA bus with a number of AHB components connected to it including the FT SDRAM controller. The external SDRAM bus is defined in the example designs port map and connected to the SDRAM controller. System clock and reset are generated by GR Clock Generator and Reset Generator. It is also shown how the correctable error (CE) signal is connected to the ahb status register. It is not mandatory to connect this signal. In this example, 3 units can be connected to the status register.

The SDRAM controller decodes SDRAM area: 0x60000000 - 0x6FFFFFFF. SDRAM Configuration and EDAC configuration registers are mapped into AHB I/O space on address (AHB I/O base address + 0x100).

33 FTSRCTRL - Fault Tolerant 32-bit PROM/SRAM/IO Controller

33.1 Overview

The fault tolerant 32-bit PROM/SRAM memory interface uses a common 32-bit memory bus to interface PROM, SRAM and I/O devices. Support for 8-bit PROM banks can also be separately enabled. In addition it also provides an Error Detection And Correction Unit (EDAC), correcting one and detecting two errors. Configuration of the memory controller functions is performed through the APB bus interface.
Figure 90. 32-bit FT PROM/SRAM/IO controller

33.2 Operation

The controller is configured through VHDL generics to decode three address ranges: PROM, SRAM and I/O area. By default the PROM area is mapped into address range 0x0 - 0x00FFFFFF, the SRAM area is mapped into address range 0x40000000 - 0x40FFFFFF, and the I/O area is mapped to 0x20000000 - 0x20FFFFFF.

One chip select is decoded for the I/O area, while SRAM and PROM can have up to 8 chip select signals. The controller generates both a common write-enable signal (WRITEN) as well as four byte-write enable signals (WREN). If the SRAM uses a common write enable signal the controller can be configured to perform read-modify-write cycles for byte and half-word write accesses. Number of waitstates is separately configurable for the three address ranges.

The EDAC function is optional, and can be enabled with the *edacen* VHDL generic. The configuration of the EDAC is done through a configuration register accessed from the APB bus. During nominal operation, the EDAC checksum is generated and checked automatically. Single errors are corrected without generating any indication of this condition in the bus response. If a multiple error is detected, a two cycle error response is given on the AHB bus.

GRIP

Apr 2024, Version 2024.1

383

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Single errors can be monitored in two ways:

- by monitoring the CE signal which is asserted for one cycle each time a single error is detected.

- by checking the single error counter which is accessed from the MCFG3 configuration register.

The CE signal can be connected to the AHB status register which stores information of the AHB instruction causing the error and also generates interrupts. See the AHB status register documentation for more information. When EDAC is enabled, one extra latency cycle is generated during reads and subword writes.

The EDAC function can be enabled for SRAM and PROM area accesses, but not for I/O area accesses. For the SRAM area, the EDAC functionality is only supported for accessing 32-bit wide SRAM banks. For the PROM area, the EDAC functionality is supported for accessing 32-bit wide PROM banks, as well as for read accesses to 8-bit wide PROM banks.

The equations below show how the EDAC checkbits are generated:

```
CB0 = D0 ^ D4 ^ D6 ^ D7 ^ D8 ^ D9 ^ D11 ^ D14 ^ D17 ^ D18 ^ D19 ^ D21 ^ D26 ^ D28 ^ D29 ^ D31
CB1 = D0 ^ D1 ^ D2 ^ D4 ^ D6 ^ D8 ^ D10 ^ D12 ^ D16 ^ D17 ^ D18 ^ D20 ^ D22 ^ D24 ^ D26 ^ D28
CB2 = D0 ^ D3 ^ D4 ^ D7 ^ D9 ^ D10 ^ D13 ^ D15 ^ D16 ^ D19 ^ D20 ^ D23 ^ D25 ^ D26 ^ D29 ^ D31
CB3 = D0 ^ D1 ^ D5 ^ D6 ^ D7 ^ D11 ^ D12 ^ D13 ^ D16 ^ D17 ^ D21 ^ D22 ^ D23 ^ D27 ^ D28 ^ D29
CB4 = D2 ^ D3 ^ D4 ^ D5 ^ D6 ^ D7 ^ D14 ^ D15 ^ D18 ^ D19 ^ D20 ^ D21 ^ D22 ^ D23 ^ D30 ^ D31
CB5 = D8 ^ D9 ^ D10 ^ D11 ^ D12 ^ D13 ^ D14 ^ D15 ^ D24 ^ D25 ^ D26 ^ D27 ^ D28 ^ D29 ^ D30 ^ D31
CB6 = D0 ^ D1 ^ D2 ^ D3 ^ D4 ^ D5 ^ D6 ^ D7 ^ D24 ^ D25 ^ D26 ^ D27 ^ D28 ^ D29 ^ D30 ^ D31
```

33.2.1 8-bit PROM access

The FTSRCTRL controller can be configured to access an 8-bit wide PROM. The data bus of the external PROM should be connected to the upper byte of the 32-bit data bus, i.e. D[31:24]. The 8-bit mode is enabled with the prom8en VHDL generic. When enabled, read accesses to the PROM area will be done in four-byte bursts for all 32-, 16- and 8-bit AMBA AHB accesses. The whole 32-bit word is then output on the AHB data bus, allowing the master to chose the bytes needed (big-endian).

Writes should be done one byte at a time. For correct word aligned 32-bit word write accesses, the byte should always be driven on bits 31 to 24 on the AHB data bus. For non-aligned 32-bit word write accesses, the byte should be driven on the bits of the AHB data bus that correspond to the byte address (big-endian). For correct half-word aligned 16-bit half-word write accesses, the byte should always be driven on bits 31 to 24, or 15 to 8, on the AHB data bus. For non-aligned 16-bit half-word write accesses, the byte should be driven on the bits of the AHB data bus that correspond to the byte address (big-endian). For 8-bit word write accesses the byte should always be driven on the AHB data bus bits that corresponds to the byte address (big-endian). To summarize, all legal AMBA AHB write accesses are supported according to the AMBA standard, additional illegal accesses are supported as described above, and it is always the addressed byte that is output.

It is possible to dynamically switch between 8- and 32-bit PROM mode by writing to the RBW field of the MCFG1 register. The BWIDTH[1:0] input signal determines the reset value of this RBW register field. When RBW is "00" then 8-bit mode is selected. If RBW is "10" then 32-bit mode is selected. Other RBW values are reserved for future use. SRAM access is not affected by the 8-bit PROM mode.

It is also possible to use the EDAC in the 8-bit PROM mode, configured by the edacen VHDL generic, and enabled via the MCFG3 register. Read accesses to the 8-bit PROM area will be done in five-byte bursts for all 32-, 16- and 8-bit AMBA AHB accesses. After a potential correction, the whole 32-bit word is output on the AHB data bus, allowing the master to chose the bytes needed (big-endian). EDAC support is not provided for write accesses, they are instead performed in the same way as without the EDAC enabled. The checksum byte must be written by the user into the correct byte address location.

The fifth byte corresponds to the EDAC checksum and is located in the upper part of the effective memory area, as explained in detail in the definition of the MCFG1 memory configuration register. The EDAC checksums are located in the upper quarter of what is defined as available EDAC area by means of the EBSZ field and the ROMBSZ field or rombanksz VHDL generic. When set to 0, the size

+46 31 7758650 | frontgrade.com/gaisler

of the available EDAC area is defined as the PROM bank size. When set to 1, as twice the PROM bank size. When set to 2, as four times the PROM bank size. And when set to 3, as eight times the PROM bank size. For any other value than 0, the use of multiple PROM banks is required.

Example, if ROMBSZ=10 and EBSZ=1, the EDAC area is 8KiB*2^ROMBSZ*2^EBSZ= 16MiB=0x01000000. The checksum byte for the first word located at address 0x00000000 to 0x00000003 is located at 0x00C00000. The checksum byte for the second word located at address 0x00000004 to 0x00000007 is located at 0x00C00001, and so on. Since EBSZ=1, two PROM banks are required for implementing the EDAC area, each bank with size 8MiB=0x00800000.

33.2.2 Access errors

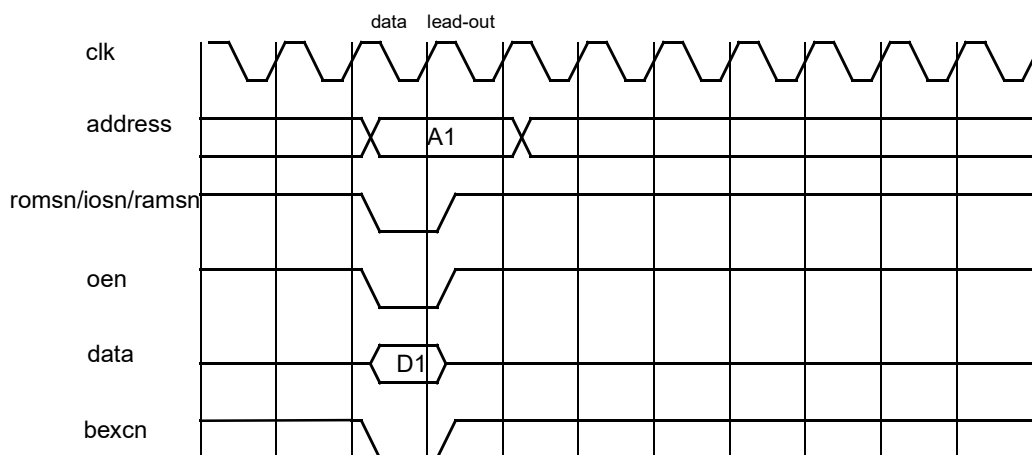
The active low Bus Exception signal (BEXCN) can be used to signal access errors. It is enabled by setting the BEXCEN bit in MCFG1 and is active for all types of accesses to all areas (PROM, SRAM and I/O). The BEXCN signal is sampled on the same cycle as read data is sampled. For writes it is sampled on the last rising edge before writen/rwen is de-asserted (writen and rwen are clocked on the falling edge). When a bus exception is detected an error response will be generated for the access.


Figure 91. Read cycle with BEXCN.
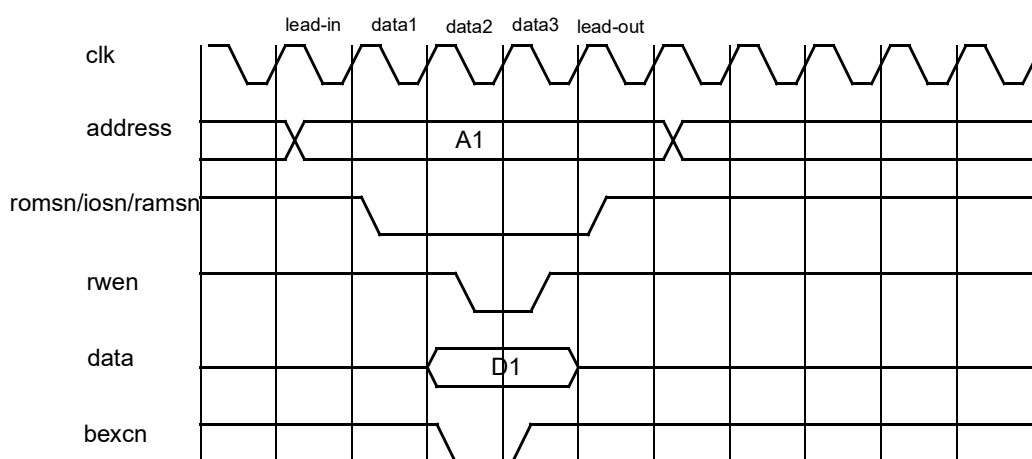

Figure 92. Write cycle with BEXCN.

33.2.3 Using bus ready signalling

The Bus Ready (BRDYN) signal can be used to add waitstates to I/O-area accesses, covering the complete memory area and both read and write accesses. It is enabled by setting the Bus Ready

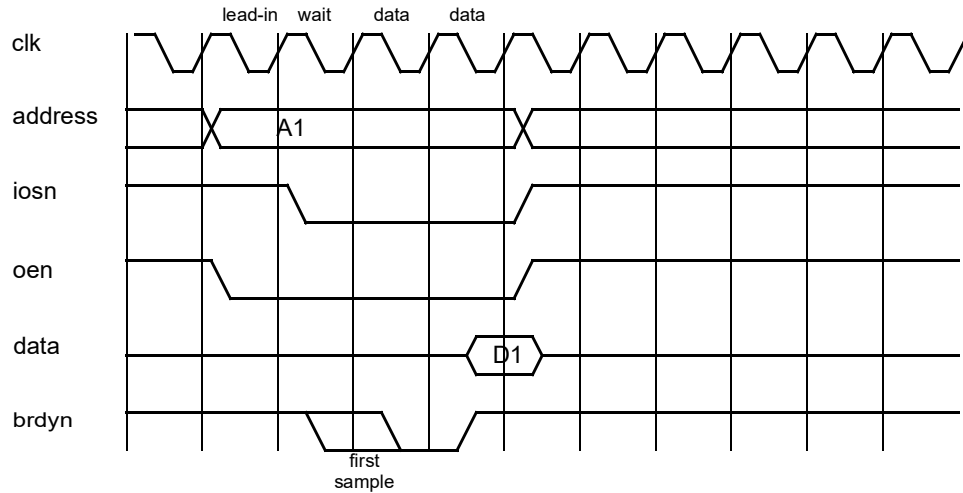
Enable (BRDYEN) bit in the MCFG1 register. An access will have at least the amount of waitstates set with the VHDL generic or through the register, but will be further stretched until BRDYN is asserted. Additional waitstates can thus be inserted after the pre-set number of waitstates by de-asserting the BRDYN signal. BRDYN should be asserted in the cycle preceding the last one. It is recommended that BRDYN remains asserted until the IOSN signal is de-asserted, to ensure that the access has been properly completed and avoiding the system to stall. Read accesses will have the same timing as when EDAC is enabled while write accesses will have the timing as for single accesses even if bursts are performed.


Figure 93. I/O READ cycle, programmed with 1 wait state, and with an extra data cycle added with BRDYN.

33.3 PROM/SRAM/IO waveforms

The internal and external waveforms of the interface are presented in the figures hereafter.

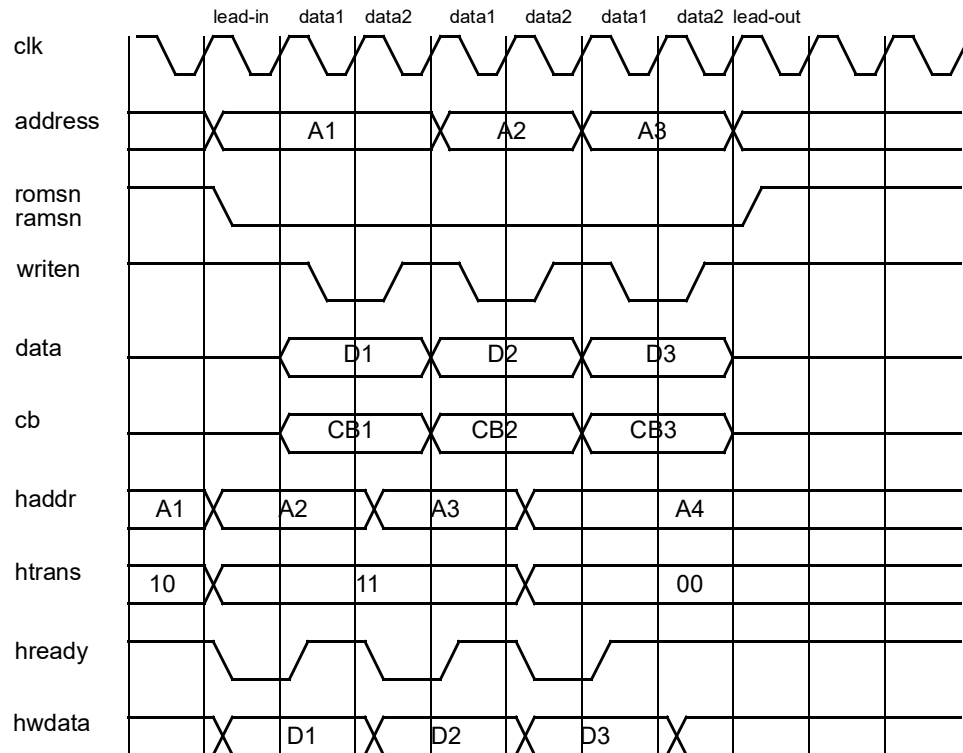

Figure 99. 32-bit PROM/SRAM sequential write access with 0 wait-states and EDAC disabled.

If waitstates are configured through the VHDL generics or registers, one extra data cycle will be inserted for each waitstate in both read and write cycles. The timing for write accesses is not affected when EDAC is enabled while one extra latency cycle is introduced for single access reads and at the beginning of read bursts.

0		0	0	0	0		0		*		*		0	0	*		0		0xF	
r		rw	rw	r	rw		r		rw*		rw*		rw	r	rw		r		rw	

31: 27	RESERVED
26	Bus ready enable (BR) - Enables the bus ready signal (BRDYN) for I/O-area.
25	Bus exception enable (BE) - Enables the bus exception signal (BEXCEN) for PROM, SRAM and I/O areas
24	RESERVED
23: 20	I/O wait states (IOWS) - Sets the number of waitstates for accesses to the I/O-area. Only available if the wsreg VHDL generic is set to one.
19: 18	RESERVED
17: 14	ROM bank size (ROMBSZ) - Sets the PROM bank size. Only available if the rombanksz VHDL generic is set to zero. Otherwise, the rombanksz VHDL generic sets the bank size and the value can be read from this field. 0 = 8KiB, 1 = 16KiB, 2 = 32KiB, 3 = 64KiB, ..., 15=256 MiB (i.e. 8 KiB * 2**ROMBSZ).
13: 12	EDAC bank size (EBSZ) - Sets the EDAC bank size for 8-bit PROM support. Only available if the rombanksz VHDL generic is zero, and edacen and prom8en VHDL generics are one. Otherwise, the value is fixed to 0. The resulting EDAC bank size is $2^{EBSZ} * 2^{ROMBSZ} * 8KiB$. Note that only the three lower quarters of the bank can be used for user data. The EDAC checksums are placed in the upper quarter of the bank.
11	ROM write enable (RW) - Enables writes to the PROM memory area. When disabled, writes to the PROM area will generate an ERROR response on the AHB bus.
10	RESERVED
9: 8	ROM data bus width (RBW) - Sets the PROM data bus width. "00" = 8-bit, "10" = 32-bit, others reserved.
7: 4	RESERVED
3: 0	ROM waitstates (ROMWS) - Sets the number of waitstates for accesses to the PROM area. Reset to all-ones. Only available if the wsreg generic is set to one.

33.5.2 Memory Configuration Register 2

*Table 405.*0x04 - MCFG2 - Memory configuration register 2.

33.5.3 Memory Configuration Register 3

*Table 406.*0x08 - MCFG3 - Memory configuration register 3.

31		20	19		12	11	10	9	8	7		0
RESERVED			SEC			WB	RB	SE	PE	TCB		
0			0			0	0	0	0	NR		
r			wc			rw	rw	rw	rw	rw*		

31: 20	RESERVED
19: 12	Single error counter.(SEC) - This field increments each time a single error is detected until the maximum value that can be stored in the field is reached. Each bit can be reset by writing a one to it.
11	Write bypass (WB) - Enables EDAC write bypass. When enabled the TCB field will be used as checkbits in all write operations.
10	Read bypass (RB) - Enables EDAC read bypass. When enabled checkbits read from memory in all read operations will be stored in the TCB field.
9	SRAM EDAC enable (SE) - Enables EDAC for the SRAM area.
8	PROM EDAC enable (PE) - Enables EDAC for the PROM area. Reset value is taken from the input signal sri.edac.
7: 0	Test checkbits (TCB) - Used as checkbits in write operations when WB is activated and checkbits from read operations are stored here when RB is activated.

All the fields in MCFG3 register are available if the edacen VHDL generic is set to one except SEC field which also requires that the errcnt VHDL generic is set to one. The exact breakpoint between the SEC and RESERVED field depends on the cntbits generic. The breakpoint is 11+cntbits. The values shown in the table is for maximum cntbits value 8.

33.6   Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x051. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

33.7   Implementation

33.7.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers. The registers driving external chip select, output enable and output enables for the data bus have asynchronous reset.

33.7.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

33.8 Configuration options

Table 403 shows the configuration options of the core (VHDL generics).

Table 407. Controller configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index.	1 - NAHBSLV-1	0
romaddr	ADDR field of the AHB BAR0 defining PROM address space. Default PROM area is 0x0 - 0xFFFFFF.	0 - 16#FFF#	16#000#
rommask	MASK field of the AHB BAR0 defining PROM address space.	0 - 16#FFF#	16#FF0#
ramaddr	ADDR field of the AHB BAR1 defining RAM address space. Default RAM area is 0x40000000-0x40FFFFFF.	0 - 16#FFF#	16#400#
rammask	MASK field of the AHB BAR1 defining RAM address space.	0 -16#FFF#	16#FF0#
ioaddr	ADDR field of the AHB BAR2 defining IO address space. Default RAM area is 0x20000000-0x20FFFFFF.	0 - 16#FFF#	16#200#
iomask	MASK field of the AHB BAR2 defining IO address space.	0 - 16#FFF#	16#FF0#
ramws	Number of waitstates during access to SRAM area.	0 - 15	0
romws	Number of waitstates during access to PROM area.	0 - 15	2
iows	Number of waitstates during access to IO area.	0 - 15	2
rmw	Enable read-modify-write cycles.	0 - 1	0
srbanks	Set the number of RAM banks.	1 - 8	1
banksz	Set the size of bank 1 - 4. 1 = 16KiB, 2 = 32KiB, 3 = 64KiB, ... , 15 = 256 MiB (i.e. 8 KiB * 2**banksz). If set to zero, the bank size is set with the rambsz field in the MCFG2 register.	0 - 15	15
rombanks	Sets the number of PROM banks available.	1 - 8	1
rombanksz	Sets the size of one PROM bank. 1 = 16KiB, 2 = 32KiB, 3 = 64KiB, ... , 15 = 256 MiB (i.e. 8 KiB * 2**rombanksz). If set to zero, the bank size is set with the rombsz field in the MCFG1 register.	0 - 15	15
rombankszdef	Sets the reset value of the rombsz register field in MCFG1 if available.	0 - 15	15
pindex	APB slave index.	1 - NAPBSLV-1	0
paddr	APB address.	1 - 16#FFF#	0
pmask	APB address mask.	1 - 16#FFF#	16#FFF#
edacen	EDAC enable. If set to one, EDAC logic is synthesized.	0 - 1	0
errcnt	If one, a single error counter is added.	0 - 1	0
cntbits	Number of bits in the single error counter.	1 - 8	1
wsreg	Enable programmable waitstate generation.	0 - 1	0
prom8en	Enable 8-bit PROM mode.	0 - 1	0
oepol	Select polarity of output enable signals. 0 = active low, 1 = active high.	0 - 1	0

end component;
```

33.14 Instantiation

This example shows how the core can be instantiated.

The example design contains an AMBA bus with a number of AHB components connected to it including the memory controller. The external memory bus is defined in the example design's port map and connected to the memory controller. System clock and reset are generated by GR Clock Generator and Reset Generator. The CE signal of the memory controller is also connected to the AHB status register.

34 FTSRCTRL8 - 8-bit SRAM/16-bit IO Memory Controller with EDAC

34.1 Overview

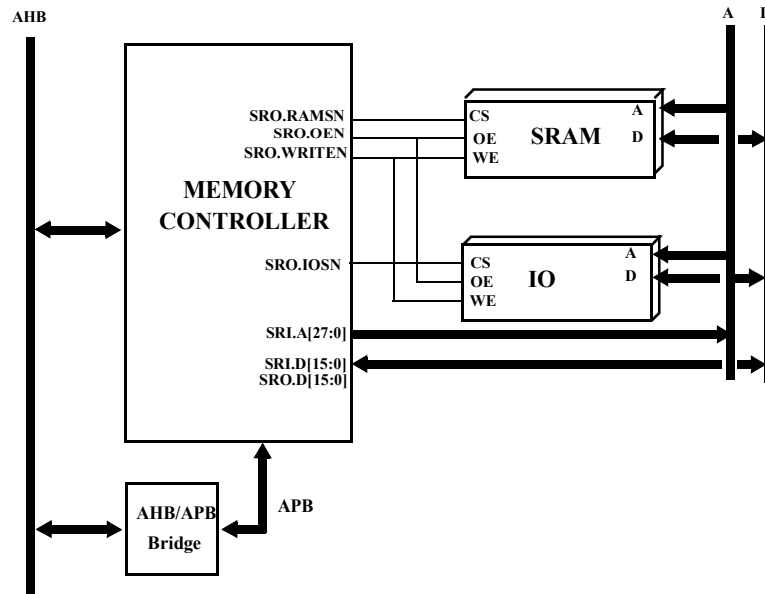
The fault tolerant 8-bit SRAM/16-bit I/O memory interface uses a common 16-bit data bus to interface 8-bit SRAM and 16-bit I/O devices. It provides an Error Detection And Correction unit (EDAC), correcting up to two errors and detecting up to four errors in a data byte. The EDAC eight checkbits are stored in parallel with the 8-bit data in SRAM memory. Configuration of the memory controller functions is performed through the APB bus interface.


Figure 104. Block diagram

34.2 Operation

The controller is configured through VHDL generics to decode two address ranges: SRAM and I/O area. By default the SRAM area is mapped into address range 0x40000000 - 0x40FFFFFF, and the I/O area is mapped to 0x20000000 - 0x20FFFFFF.

One chip select is decoded for the I/O area, while SRAM can have up to 8 chip select signals. The controller generates a common write-enable signal (WRITEN) for both SRAM and I/O. The number of waitstates may be separately configured for the two address ranges.

The EDAC function is optional, and can be enabled with the edacen VHDL generic. The configuration of the EDAC is done through a configuration register accessed from the APB bus. During nominal operation, the EDAC checksum is generated and checked automatically. The 8-bit input to the EDAC function is split into two 4-bit nibbles. A modified hamming(8,4,4) coding featuring a single error correction and double error detection is applied to each 4-bit nibble. This makes the EDAC capable of correcting up to two errors and detecting up to four errors per 8-bit data. Single errors (correctable errors) are corrected without generating any indication of this condition in the bus response. If a multiple error (uncorrectable errors) is detected, a two cycle error response is given on the AHB bus.

Single errors may be monitored in two ways:

- by monitoring the CE signal which is asserted for one cycle each time a correctable error is detected.

- by checking the single error counter which is accessed from the MCFG3 configuration register.

GRIP
Apr 2024, Version 2024.1
402
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The CE signal can be connected to the AHB status register which stores information of the AHB instruction causing the error and also generates interrupts. See the AHB status register documentation for more information.

The EDAC function can only be enabled for SRAM area accesses. If a 16-bit or 32-bit bus access is performed, the memory controller calculates the EDAC checksum for each byte read from the memory but the indication of single error is only signaled when the access is done. (I.e. if more than one byte in a 32-bit access has a single error, only one error is indicated for the hole 32-bit access.)

The equations below show how the EDAC checkbits are generated:

```
CB7 = Data[15] ^ Data[14] ^ Data[13]     // i.e. Data[7]
CB6 = Data[15] ^ Data[14] ^ Data[12]     // i.e. Data[6]
CB5 = Data[15] ^ Data[13] ^ Data[12]     // i.e. Data[5]
CB4 = Data[14] ^ Data[13] ^ Data[12]     // i.e. Data[4]
CB3 = Data[11] ^ Data[10] ^ Data[ 9]     // i.e. Data[3]
CB2 = Data[11] ^ Data[10] ^ Data[ 8]     // i.e. Data[2]
CB1 = Data[11] ^ Data[ 9] ^ Data[ 8]     // i.e. Data[1]
CB0 = Data[10] ^ Data[ 9] ^ Data[ 8]     // i.e. Data[0]
```

34.2.1 Memory access

The memory controller supports 32/16/8-bit single accesses and 32-bit burst accesses to the SRAM. A 32-bit or a 16-bit access is performed as multiple 8-bit accesses on the 16-bit memory bus, where data is transferred on data lines 8 to 15 (Data[15:8]). The eight checkbits generated/used by the EDAC are transferred on the eight first data lines (Data[7:0]). For 32-bit and 16-bit accesses, the bytes read from the memory are arranged according to the big-endian order (i.e. for a 32-bit read access, the bytes read from memory address A, A+1, A+2, and A+3 correspond to the bit[31:24], bit[23:16], bit[15:8], and bit[7:0] in the 32-bit word transferred to the AMBA bus. The table 421 shows the expected latency from the memory controller.

Table 412. FTSCTRL8 access latency

Accesses	Single data	First data (burst)	Middle data (burst)	Last data (burst)
32-bit write	10	8	8	10
32-bit read	6	6	4	4
16-bit write	4 (+1)	-	-	-
16-bit read	4	-	-	-
8-bit write	4	-	-	-
8-bit read	3	-	-	-

One extra cycle is added for 16-bit burst accesses when Bus Exception is enabled.

34.2.2 I/O access

The memory controller accepts 32/16/8-bit single accesses to the I/O area, but the access generated towards the I/O device is always 16-bit. The two least significant bits of the AMBA address (byte address) determine which half word that should be transferred to the I/O device. (i.e. If the byte address is 0 and it is a 32-bit access, bits 16 to 31 on the AHB bus is transferred on the 16-bit memory bus. If the byte address is 2 and it is a 16-bit access, bit 0 to 15 on the AHB bus is transferred on the 16-bit memory bus.) If the access is an 8-bit access, the data is transferred on data lines 8 to 15 (Data[15:8]) on the memory bus. In case of a write, data lines 0 to 7 is also written to the I/O device but these data lines do not transfer any valid data.

34.2.3 Using Bus Exception

The active low Bus Exception signal (BEXCN) can be used to signal access errors. It is enabled by setting the BEXCEN bit in MCFG1 and is only active for the I/O area. The BEXCN signal is sampled on the same cycle as data is written to memory or read data is sampled. When a bus exception is detected an error response will be generated for the access. One additional latency cycle is added to the AMBA access when the Bus Exception is enable.

34.2.4 Using Bus Ready

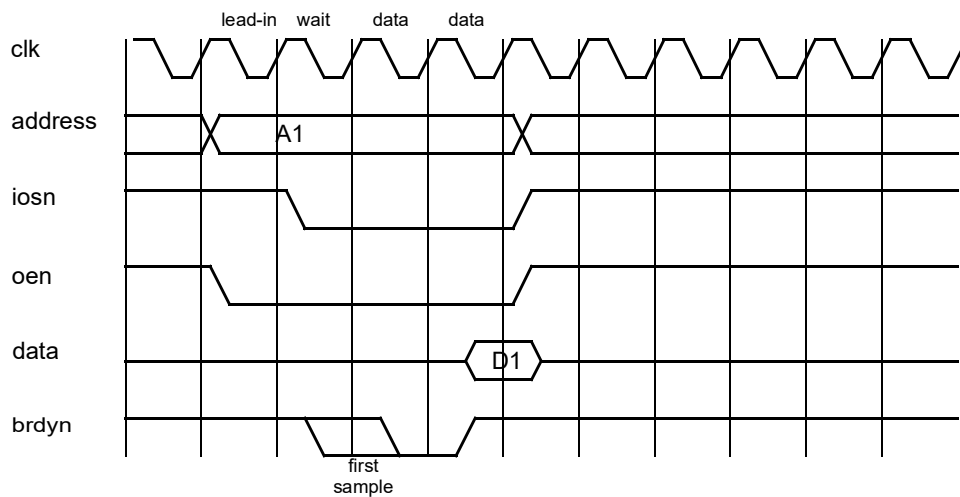
The Bus Ready (BRDYN) signal can be used to add waitstates to I/O-area accesses. It is enabled by setting the Bus Ready Enable (BRDYEN) bit in the MCFG1 register. An access will have at least the amount of waitstates set with the VHDL generic or through the register, but will be further stretched until BRDYN is asserted. Additional waitstates can thus be inserted after the pre-set number of waitstates by deasserting the BRDYN signal. BRDYN should be asserted in the cycle preceding the last one. It is recommended that BRDY remains asserted until the IOSN signal is de-asserted, to ensure that the access has been properly completed and avoiding the system to stall.


Figure 105. I/O READ cycle, programmed with 1 wait state, and with an extra data cycle added with BRDYN.

34.3 SRAM/IO waveforms

The internal and external waveforms of the interface are presented in the figures below.

34.6 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x056. For description of vendor and device identifiers see the GRLIB IP Library User's Manual.

34.7 Implementation

34.7.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers. The registers driving external chip select, output enable and output enables for the data bus have asynchronous reset.

34.7.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

34.8 Configuration options

Table 413 shows the configuration options of the core (VHDL generics).

Table 417. Controller configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index.	1 - NAHBSLV-1	0
ramaddr	ADDR field of the AHB BAR1 defining RAM address space. Default RAM area is 0x40000000-0x40FFFFFF.	0 - 16#FFF#	16#400#
rammask	MASK field of the AHB BAR1 defining RAM address space.	0 -16#FFF#	16#FF0#
ioaddr	ADDR field of the AHB BAR2 defining IO address space. Default RAM area is 0x20000000-0x20FFFFFF.	0 - 16#FFF#	16#200#
iomask	MASK field of the AHB BAR2 defining IO address space.	0 - 16#FFF#	16#FF0#
ramws	Number of waitstates during access to SRAM area.	0 - 15	0
iows	Number of waitstates during access to IO area.	0 - 15	2
srbanks	Set the number of RAM banks.	1 - 8	1
banksz	Set the size of bank 1 - 4. 1 = 16 kB, ... , 15 = 256 MB. If set to zero, the bank size is set with the rambsz field in the MCFG2 register.	0 - 15	15
pindex	APB slave index.	1 - NAPBSLV-1	0
paddr	APB address.	1 - 16#FFF#	0
pmask	APB address mask.	1 - 16#FFF#	16#FFF#
edacen	EDAC enable. If set to one, EDAC logic is synthesized.	0 - 1	0
errcnt	If one, a single error counter is added.	0 - 1	0
cntbits	Number of bits in the single error counter.	1 - 8	1

34.12 Library dependencies

Table 421 shows libraries used when instantiating the core (VHDL libraries).

*Table 421.*Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AHB signal definitions
GAISLER	MEMCTRL	Signals, component	Memory bus signals definitions, component declaration

34.13 Component declaration

The core has the following component declaration.

```
component ftsrctrl8 is
  generic (
    hindex      : integer := 0;
    ramaddr     : integer := 16#400#;
    rammask     : integer := 16#ff0#;
    ioaddr      : integer := 16#200#;
    iomask      : integer := 16#ff0#;
    ramws       : integer := 0;
    iows        : integer := 2;
    srbanks     : integer range 1 to 8  := 1;
    banksz      : integer range 0 to 15 := 15;
    pindex      : integer := 0;
    paddr       : integer := 0;
    pmask       : integer := 16#fff#;
    edacen      : integer range 0 to 1 := 1;
    errcnt      : integer range 0 to 1 := 0;
    cntbits     : integer range 1 to 8 := 1;
    wsreg       : integer := 0;
    oepol       : integer := 0
  );
  port (
    rst         : in  std_ulogic;
    clk         : in  std_ulogic;
    ahbsi       : in  ahb_slv_in_type;
    ahbso       : out ahb_slv_out_type;
    apbi        : in  apb_slv_in_type;
    apbo        : out apb_slv_out_type;
    sri         : in  memory_in_type;
    sro         : out memory_out_type
  );
end component;
```

34.14 Instantiation

This example shows how the core can be instantiated.

The example design contains an AMBA bus with a number of AHB components connected to it including the memory controller. The external memory bus is defined in the example design's port map and connected to the memory controller. The system clock and reset are generated by GR Clock Generator and Reset Generator. The CE signal of the memory controller is also connected to the AHB status register.

The memory controller decodes default memory areas: I/O area is 0x20000000 - 0x20FFFFFF and RAM area is 0x40000000 - 0x40FFFFF.

35   GPTIMER - General Purpose Timer Unit

35.1   Overview

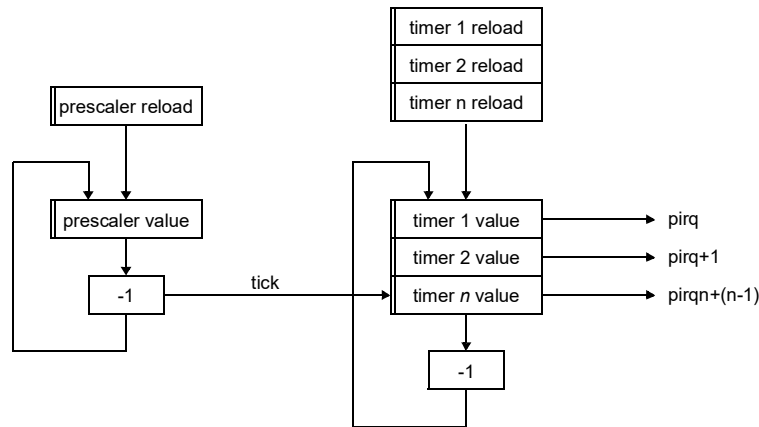
The General Purpose Timer Unit provides a common prescaler and decrementing timer(s). The number of timers is configurable through the *ntimers* VHDL generic in the range 1 to 7. The prescaler width is configured through the *sbits* VHDL generic. Timer width is configured through the *nbits* VHDL generic. The timer unit acts a slave on AMBA APB bus. The unit is capable of asserting interrupts on timer underflow. The interrupt to use is configurable to be common for the whole unit or separate for each timer.


Figure 113. General Purpose Timer Unit block diagram

35.2   Operation

The prescaler is clocked by the system clock and decremented on each clock cycle when at least one timer is enabled. When the prescaler underflows, it is reloaded from the prescaler reload register and a timer tick is generated.

The operation of each timer is controlled through its control register. A timer is enabled by setting the enable bit in the control register. The timer value is then decremented on each prescaler tick. When a timer underflows, it will automatically be reloaded with the value of the corresponding timer reload register if the restart bit in the control register is set, otherwise it will stop at -1 and reset the enable bit.

The timer unit can be configured to a generate shared interrupt line through a VHDL-generic. The shared interrupt will be signaled when any of the timers with interrupt enable bit underflows. The timer unit will signal an interrupt on appropriate line when a timer underflows (if the interrupt enable bit for the current timer is set), when configured to signal interrupt for each timer. The interrupt pending bit in the control register of the underflowed timer will be set and remain set until cleared by writing '1'.

To reduce area, the timers share a single decrementer. A consequence of this is that when a prescaler tick occurs, the individual timers are not decremented on the same clock cycle, but in a staggered manner. If a prescaler tick occurs on system clock cycle x, then timer n will be decremented on clock cycle $x+n$. Another consequence of the shared decrementer is that the minimum allowed prescaler division factor is *ntimers*+1 (reload register = *ntimers*) where *ntimers* is the number of implemented timers.

By setting the chain bit in the control register, timer n can be chained with the preceding timer n-1. Timer n will then be decremented only when timer n-1 underflows. This can be used to form a timer wider than 32 bits. Again, the shared decrementer results in timer n being decremented one clock

cycle after timer *n*-1. Additionally, the APB interface allows only one timer to be read out per access. This can result in a race-condition when reading out the values of chained timers, because it is possible for one of the timers to be decremented in between readouts.

Each timer can be reloaded with the value in its reload register at any time by writing a 'one' to the load bit in the control register. The last timer acts as a watchdog, driving a watchdog output signal when expired, if the *wdog* VHDL generic is set to a time-out value larger than 0. The watchdog timer also implements a window functionality when the *wdogwin* VHDL generic is set to 1. This enables a decrementing counter which reloads each time the timer is reloaded. If the timer is reloaded and the window counter has not reached zero, this will also assert the watchdog output.

Each timer can be configured to latch its value to a dedicated register when an event is detected on the interrupt (functionality enabled via VHDL generic *glatch*). All timers can be forced to reload when an event is detected on the interrupt bus (functionality enabled via VHDL generic *gset*). A dedicated mask register is provided to filter the interrupts.

At reset, all timers are disabled except the watchdog timer (if enabled by the generics). The prescaler value and reload registers are set to all ones, while the watchdog timer is set to the *wdog* VHDL generic. All other registers are uninitialized except for the WDOGDIS and WDOGNMI fields that are reset to '0'.

35.3   Registers

The core is programmed through registers mapped into APB address space. The number of implemented registers depend on the number of implemented timers.

Table 422. General Purpose Timer Unit registers

APB address offset	Register
0x00	Scaler value
0x04	Scaler reload value
0x08	Configuration register
0x0C	Timer latch configuration register
0x10	Timer 1 counter value register
0x14	Timer 1 reload value register
0x18	Timer 1 control register
0x1C	Timer 1 latch register
0x*n*0	Timer *n* counter value register
0x*n*4	Timer *n* reload value register
0x*n*8	Timer *n* control register
0x*n*C	Timer *n* latch register

35.3.1 Scaler Value Register

Table 423.0x00 - SCALER - Scaler value register

31	16	16-1	0
RESERVED		SCALER	
0		all 1	
r		rw	

16-1:   0   Scaler value. This value will also be set by writes to the Scaler reload value register.

Any unused most significant bits are reserved. Always reads as '000...0'.

35.3.2 Scaler Reload Value Register

Table 424.0x04 - SRELOAD - Scaler reload value register

31	16	16-1	0
RESERVED		SCALER RELOAD VALUE	
0		all 1	
r		rw	

16-1:   0   Scaler reload value. Writes to this register also set the scaler value.

Any unused most significant bits are reserved. Always read as '000...0'.

35.3.3 Configuration Register

*Table 425.*0x08 - CONFIG - Configuration register

31　　　　　　　　　23	22　　　　　　　16	15　14	13	12	11	10	9	8	7　　　　　3	2　　　0
"000..0"	TIMEREN	00	EV	ES	EL	EE	DF	SI	IRQ	TIMERS
0	0	0	0	0	0	0	0	*	*	*
r	rw	r	rw	rw	rw	rw	rw	r	r	r

31: 23	Reserved. Always reads as '000...0'.
22: 16	Enable bits for each timer. Writing '1' to one of this bits sets the enable bit in the corresponding timers control register. Writing '0' has no effect to the timers. bit[16] corresponds to timer0, bit[17] to timer 1,...
15: 14	Reserved
13	External Events (EV). If set then the latch events are taken from the secondary input. If this field is zero then the source of the latch events is the interrupt bus.
12	Enable set (ES). If set, on the next matching interrupt, the timers will be loaded with the corresponding timer reload values. The bit is then automatically cleared, not to reload the timer values until set again.
11	Enable latching (EL). If set, on the next matching interrupt, the latches will be loaded with the corresponding timer values. The bit is then automatically cleared, not to load a timer value until set again.
10	Enable external clock source (EE). If set the prescaler is clocked from the external clock source.
9	Disable timer freeze (DF). If set the timer unit can not be frozen, otherwise signal GPTI.DHALT freezes the timer unit.
8	Separate interrupts (SI). Reads '1' if the timer unit generates separate interrupts for each timer, otherwise '0'. Read-only.
7: 3	APB Interrupt: If configured to use common interrupt all timers will drive APB interrupt nr. IRQ, otherwise timer *n* will drive APB Interrupt IRQ+*n* (has to be less the MAXIRQ). Read-only. Note that the maximum value of this register is 31. If the number of interrupts in the system is set higher than 32, this must be taken into account.
2: 0	Number of implemented timers. Read-only.

35.3.4 Timer Latch Configuration Register

*Table 426.*0x0C - CATCHCFG - Timer latch configuration register

31　　　　　　　　　　　　　　　　　　　　　　　　　　　　　　0
LATCHSEL
0
rw

31: 0	Specifies what bits of the interrupt bus, or external latch vector, bus that shall cause the Timer Latch Registers to latch the timer values. If the configuration register EV field is zero then latching is done based on events on the interrupt bus. If the EV field is '1' then the external latch vecor is used.

35.3.5 Timer N Counter Value Register

*Table 427.*0xn0, when n selects the times - TCNTVALn - Timer n counter value register

32-1　　　　　　　　　　　　　　　　　　　　　　　　　　　　　0
TCVAL
0
rw

32-1: 0	Timer Counter value. Decremented by 1 for each prescaler tick. Any unused most significant bits are reserved. Always reads as '000...0'.

35.3.6 Timer N Reload Value Register

Table 428. 0xn4, when n selects the times - TRLDVALn - Timer n reload value register

32-1	0
TRCDUAL	
*	
rw	

32-1:	0	Timer Reload value. This value is loaded into the timer counter value register when '1' is written to the LD bit in the timer's control register or when the RS bit is set in the control register and the timer underflows.
		Any unused most significant bits are reserved. Always reads as '000...0'.

35.3.7 Timer N Control Register

Table 429. 0xn8, when n selects the times - TCTRLn - Timer n control register

31 16	15 9	8	7	6	5	4	3	2	1	0
WDOGWINC	RESERVED	WS	WN	DH	CH	IP	IE	LD	RS	EN
0	0	0	0	0	0	0	*	0	*	*
rw	r	rw	rw	r	rw	wc	rw	rw	rw	rw

31: 16	Reload value for the watchdog window counter. The window counter is reloaded with this value each time the watchdog counter is reloaded. This functionality is only available when the core has been implemented with VHDL generic *wdog* /= 0, *wdogwin* /= 0 and only for the last timer
15: 9	Reserved. Always reads as '000...0'.
8	Disable Watchdog Output (WS/WDOGDIS): If this field is set to '1' then the GPTO.WDOG and GPTO.WDOGN outputs are disabled (fixed to '0' and '1' respectively). This functionality is only available when the core has been implemented with VHDL generic wdog /= 0 and only for the last timer. If wdog = 0 then this register is read-only and always '0'.
7	Enable Watchdog NMI (WN/WDOGNMI): If this field is set to '1' then the watchdog timer will also generate a non-maskable interrupt (interrupt 15) when an interrupt is signalled. This functionality is only available when the core has been implemented with VHDL generic wdog /= 0 and only for the last timer. If wdog = 0 then this register is read-only and always '0'.
6	Debug Halt (DH): Value of GPTI.DHALT signal which is used to freeze counters (e.g. when a system is in debug mode). Read-only.
5	Chain (CH): Chain with preceding timer. If set for timer *n*, timer *n* will be decremented each time when timer (*n*-1) underflows.
4	Interrupt Pending (IP): The core sets this bit to '1' when an interrupt is signalled. This bit remains '1' until cleared by writing '1' to this bit, writes of '0' have no effect.
3	Interrupt Enable (IE): If set the timer signals interrupt when it underflows. The reset value for this bit is '0' unless watchdog functionality has been enabled. If watchdog functionality has been enabled then this bit for the last timer will have reset value '1'.
2	Load (LD): Load value from the timer reload register to the timer counter value register. This bit is automatically cleared when the value has been loaded.
1	Restart (RS): If set, the timer counter value register is reloaded with the value of the reload register when the timer underflows
0	Enable (EN): Enable the timer.

35.3.8 Timer N Latch Register

Table 430. 0xnC, when n selects the times - TLATCHn - Timer n latch register

31	0
LTCV	
0	
r	

31: 0	Latched timer counter value (LTCV): Valued latched from corresponding timer. Read-only.

35.4 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x011. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

35.5 Implementation

35.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

35.6 Configuration options

Table 431 shows the configuration options of the core (VHDL generics).

Table 431. Configuration options

Generic	Function	Allowed range	Default
pindex	Selects which APB select signal (PSEL) will be used to access the timer unit	0 to NAPBSLV-1	0
paddr	The 12-bit MSB APB address	0 to 4095	0
pmask	The APB address mask	0 to 4095	4095
nbits	Defines the number of bits in the timers	1 to 32	32
ntimers	Defines the number of timers in the unit	1 to 7	1
pirq	Defines which APB interrupt the timers will generate	0 to NAHBIRQ-1	0
sepirq	If set to 1, each timer will drive an individual interrupt line, starting with interrupt *pirq*. If set to 0, all timers will drive the same interrupt line (*pirq*).	0 to 1 (note: *ntimers* + p*irq* must be less than or equal to NAHBIRQ if *sepirq* is set to 1)	0
sbits	Defines the number of bits in the scaler	1 to 32	16
wdog	Watchdog reset value. When set to a non-zero value, the last timer will be enabled and pre-loaded with this value at reset. When the timer value reaches 0, the WDOG output is driven active.	0 to 2^{nbits} - 1	0
ewdogen	External watchdog enable. When set to a non-zero value, the enable bit of the watchdog timer will be set during core reset via the signal gpti.wdogen. Otherwise the enable bit will be set to '1' during core reset.	0 - 1	0
glatch	Enable external timer latch (via interrupt or external vector)	0 - 1	0
gextclk	Enable external timer clock input	0 - 1	0
gset	Enable external timer reload (via interrupt or external vector)	0 - 1	0
gelatch	Enable support for external latch events 0: Timer latch/set is only support for interrupt bus (if enabled via glatch and gset generics) 1: Timer latch/set is disabled after an, unmasked, event on GPTI.LATCHV 2: Timer latch/set is performed on an, unmasked, event on GPTI.LATCHV and timer latch/set is disabled on GPTI.LATCHD events.	0 - 2	0
wdogwin	Enables the watchdog window counter.	0 - 1	0

35.7 Signal descriptions

Table 432 shows the interface signals of the core (VHDL ports).

Table 432. Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
GPTI	DHALT	Input	Freeze timers	High
	EXTCLK	Input	Use as alternative clock	-
	WDOGEN	Input	Sets enable bit of the watchdog timer if VHDL generics wdog and ewdogen are set to non-zero values.	-
	LATCHV[31:0]	Input	External latch/set vector, used if VHDLgeneric gelatch /=0	High
	LATCHD[31:0]	Input	External latch/set disable vector, used if VHDL generic gelatch = 2.	High
GPTO	TICK[0:7]	Output	Timer ticks. TICK[0] is high for one clock each time the scaler underflows. TICK[1-n] are high for one clock each time the corresponding timer underflows.	High
	WDOG	Output	Watchdog output. Equivalent to interrupt pending bit of last timer.	High
	WDOGN	Output	Watchdog output. Equivalent to interrupt pending bit of last timer.	Low

* see GRLIB IP Library User's Manual

35.8 Signal definitions and reset values

One common use of the *wdogn* output is to connect it to an output pad with active low assertion and tri-stated when negated. This allows multiple on-board devices, including the timer watchdog, to generate a system reset if the signal has an external pull-up. To accomplish this the wdogn output of the core can be used as an output enable of the external pad.

When the watchdog times out, the *wdogn* output is driven active low, else it is in tri-state and therefore requires an external pull-up.

The signals and their reset values are described in table 433.

Table 433. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
wdogn	Tri-state output	Watchdog output. Equivalent to interrupt pending bit of last timer.	Low	Tri-state

36 GR1553B - MIL-STD-1553B / AS15531 Interface

36.1 Overview

This interface core connects the AMBA AHB/APB bus to a single- or dual redundant MIL-STD-1553B bus, and can act as either Bus Controller, Remote Terminal or Bus Monitor.

MIL-STD-1553B (and derived standard SAE AS15531) is a bus standard for transferring data between up to 32 devices over a shared (typically dual-redundant) differential wire. The bus is designed for predictable real-time behavior and fault-tolerance. The raw bus data rate is fixed at 1 Mbit/s, giving a maximum of around 770 kbit/s payload data rate.

One of the terminals on the bus is the Bus Controller (BC), which controls all traffic on the bus. The other terminals are Remote Terminals (RTs), which act on commands issued by the bus controller. Each RT is assigned a unique address between 0-30. In addition, the bus may have passive Bus Monitors (BM:s) connected.

There are 5 possible data transfer types on the MIL-STD-1553 bus:

- BC-to-RT transfer ("receive")
- RT-to-BC transfer ("transmit")
- RT-to-RT transfer
- Broadcast BC-to-RTs
- Broadcast RT-to-RTs

Each transfer can contain 1-32 data words of 16 bits each.

The bus controller can also send "mode codes" to the RTs to perform administrative tasks such as time synchronization, and reading out terminal status.

36.2 Electrical interface

The core is connected to the MIL-STD-1553B bus wire through single or dual transceivers, isolation transformers and transformer or stub couplers as shown in figure 115. If single-redundancy is used, the unused bus receive P/N signals should be tied both-high or both-low. The transmitter enables are typically inverted and therefore called transmitter inibit (txinh). See the standard and the respective component's data sheets for more information on the electrical connection.
Figure 115. Interface between core and MIL-STD-1553B bus (dual-redundant, transformer coupled)

36.3   Operation

36.3.1   Operating modes

The core contains three separate control units for the Bus Controller, Remote Terminal and Bus Monitor handling, with a shared 1553 codec. All parts may not be present in the hardware, which parts are available can be checked from software by looking at the BCSUP/RTSUP/BMSUP register bits.

The operating mode of the core is controlled by starting and stopping of the BC/RT/BM units via register writes. At start-up, none of the parts are enabled, and the core is completely passive on both the 1553 and AMBA bus.

The BC and RT parts of the core can not be active on the 1553 bus at the same time. While the BC is running or suspended, only the BC (and possibly BM) has access to the 1553 bus, and the RT can only receive and respond to commands when both the BC schedules are completely stopped (not running or even suspended).

The Bus Monitor, however, is only listening on the codec receivers and can therefore operate regardless of the enabled/disabled state of the other two parts.

36.3.2   Register interface

The core is configured and controlled through control registers accessed over the APB bus. Each of the BC,RT,BM parts has a separate set of registers, plus there is a small set of shared registers.

Some of the control register fields for the BC and RT are protected using a 'key', a field in the same register that has to be written with a certain value for the write to take effect. The purpose of the keys are to give RT/BM designers a way to ensure that the software can not interfere with the bus traffic by enabling the BC or changing the RT address. If the software is built without knowledge of the key to a certain register, it is very unlikely that it will accidentally perform a write with the correct key to that control register.

36.3.3   Interrupting

The core has one interrupt output, which can be generated from several different source events. Which events should cause an interrupt can be controlled through the IRQ Enable Mask register.

36.3.4   MIL-STD-1553 Codec

The core's internal codec receives and transmits data words on the 1553 bus, and generates and checks sync patterns and parity.

Loop-back checking logic checks that each transmitted word is also seen on the receive inputs. If the transmitted word is not echoed back, the transmitter stops and signals an error condition, which is then reported back to the user.

Two versions of the codec are available and can be selected at build time through the codecver generic. The new version (codecver=1) provides better noise rejection performance, otherwise there is no functional difference. The new version of the codec is recommended for new designs, and the old version will eventually be deprecated.

36.4 Bus Controller Operation

36.4.1 Overview

When operating as Bus Controller, the core acts as master on the MIL-STD-1553 bus, initiates and performs transfers.

This mode works based on a scheduled transfer list concept. The software sets up in memory a sequence of transfer descriptors and branches, data buffers for sent and received data, and an IRQ pointer ring buffer. When the schedule is started (through a BC action register write), the core processes the list, performs the transfers one after another and writes resulting status into the transfer list and incoming data into the corresponding buffers.

36.4.2 Timing control

In each transfer descriptor in the schedule is a "slot time" field. If the scheduled transfer finishes sooner than its slot time, the core will pause the remaining time before scheduling the next command. This allows the user to accurately control the message timing during a communication frame.

If the transfer uses more than its slot time, the overshooting time will be subtracted from the following command's time slot. The following command may in turn borrow time from the following command and so on. The core can keep track of up to one second of borrowed time, and will not insert pauses again until the balance is positive, except for intermessage gaps and pauses that the standard requires.

If you wish to execute the schedule as fast as possible you can set all slot times in the schedule to zero. If you want to group a number of transfers you can move all the slot time to the last transfer.

The schedule can be stopped or suspended by writing into the BC action register. When suspended, the schedule's time will still be accounted, so that the schedule timing will still be correct when the schedule is resumed. When stopped, on the other hand, the schedule's timers will be reset.

When the extsync bit is set in the schedule's next transfer descriptor, the core will wait for a positive edge on the external sync input before starting the command. The schedule timer and the time slot balance will then be reset and the command is started. If the sync pulse arrives before the transfer is reached, it is stored so the command will begin immediately. The trigger memory is cleared when stopping (but not when suspending) the schedule. Also, the trigger can be set/cleared by software through the BC action register.

36.4.3 Bus selection

Each transfer descriptor has a bus selection bit that allows you to control on which one of the two redundant buses ('0' for bus A, '1' for bus B) the transfer will occur.

Another way to control the bus usage is through the per-RT bus swap register, which has one register bit for each RT address. The bus swap register is an optional feature, software can check the BCFEAT read-only register field to see if it is available.

Writing a '1' to a bit in the per-RT Bus Swap register inverts the meaning of the bus selection bit for all transfers to the corresponding RT, so '0' now means bus 'B' and '1' means bus 'A'. This allows you to switch all transfers to one or a set of RT:s over to the other bus with a single register write and without having to modify any descriptors.

The hardware determines which bus to use by taking the exclusive-or of the bus swap register bit and the bus selection bit. Normally it only makes sense to use one of these two methods for each RT, either the bus selection bit is always zero and the swap register is used, or the swap register bit is always zero and the bus selection bit is used.

If the bus swap register is used for bus selection, the store-bus descriptor bit can be enabled to automatically update the register depending on transfer outcome. If the transfer succeeded on bus A, the bus swap register bit is set to '0', if it succeeds on bus B, the swap register bit is set to '1'. If the transfer fails, the bus swap register is set to the opposite value.

36.4.4 Secondary transfer list

The core can be set up with a secondary "asynchronous" transfer list with the same format as the ordinary schedule. This transfer list can be commanded to start at any time during the ordinary schedule. While the core is waiting for a scheduled command's slot time to finish, it will check if the next asynchronous transfer's slot time is lower than the remaining sleep time. In that case, the asynchronous command will be scheduled.

If the asynchronous command doesn't finish in time, time will be borrowed from the next command in the ordinary schedule. In order to not disturb the ordinary schedule, the slot time for the asynchronous messages must therefore be set to pessimistic values.

The exclusive bit in the transfer descriptor can be set if one does not want an asynchronous command scheduled during the sleep time following the transfer.

Asynchronous messages will not be scheduled while the schedule is waiting for a sync pulse or the schedule is suspended and the current slot time has expired, since it is then not known when the next scheduled command will start.

36.4.5 Interrupt generation

Each command in the transfer schedule can be set to generate an interrupt after certain transfers have completed, with or without error. Invalid command descriptors always generate interrupts and stop the schedule. Before a transfer-triggered interrupt is generated, the address to the corresponding descriptor is written into the BC transfer-triggered IRQ ring buffer and the BC Transfer-triggered IRQ Ring Position Register is incremented.

A separate error interrupt signals DMA errors. If a DMA error occurs when reading/writing descriptors, the executing schedule will be suspended. DMA errors in data buffers will cause the corresponding transfer to fail with an error code (see table 439).

Whether any of these interrupt events actually cause an interrupt request on the AMBA bus is controlled by the IRQ Mask Register setting.

36.4.6 Transfer list format

The BC:s transfer list is an array of transfer descriptors mixed with branches as shown in table 436. Each entry has to be aligned to start on a 128-bit (16-byte) boundary. The two unused words in the branch case are free to be used by software to store arbitrary data.

Table 436. GR1553B transfer descriptor format

Offset	Value for transfer descriptor	DMA R/W	Value for branch	DMA R/W
0x00	Transfer descriptor word 0 (see table 437)	R	Condition word (see table 441)	R
0x04	Transfer descriptor word 1 (see table 438)	R	Jump address, 128-bit aligned	R
0x08	Data buffer pointer, 16-bit aligned. For write buffers, if bit 0 is set the received data is discarded and the pointer is ignored. This can be used for RT-to-RT transfers where the BC is not interested in the data transferred.	R	Unused	-
0x0C	Result word, written by core (see table 439)	W	Unused	-

The transfer descriptor words are structured as shown in tables 437-439 below.

Table 437. GR1553B BC transfer descriptor word 0 (offset 0x00)

31	30	29	28	27	26	25	24 23	22 20	19	18	17 16	15 0
0	WTRIG	EXCL	IRQE	IRQN	SUSE	SUSN	RETMD	NRET	STBUS	GAP	RESERVED	STIME

31	Must be 0 to identify as descriptor
30	Wait for external trigger (WTRIG)
29	Exclusive time slot (EXCL) - Do not schedule asynchronous messages
28	IRQ after transfer on Error (IRQE)
27	IRQ normally (IRQN) - Always interrupts after transfer
26	Suspend on Error (SUSE) - Suspends the schedule (or stops the async transfer list) on error
25	Suspend normally (SUSN) - Always suspends after transfer
24 : 23	Retry mode (RETMD). 00 - Retry on same bus only. 01 - Retry alternating on both buses 10: Retry first on same bus, then on alternating bus. 11 - Reserved, do not use
22 : 20	Number of retries (NRET) - Number of automatic retries per bus The total number of tries (including the first attempt) is NRET+1 for RETMD=00, 2 x (NRET+1) for RETMD=01/10
19	Store bus (STBUS) - If the transfer succeeds and this bit is set, store the bus on which the transfer succeeded (0 for bus A, 1 for bus B) into the per-RT bus swap register. If the transfer fails and this bit is set, store the opposite bus instead. (only if the per-RT bus mask is supported in the core) See section 36.4.3 for more information.
18	Extended intermessage gap (GAP) - If set, adds an additional amount of gap time, corresponding to the RTTO field, after the transfer
17 : 16	Reserved - Set to 0 for forward compatibility
15 : 0	Slot time (STIME) - Allocated time in 4 microsecond units, remaining time after transfer will insert delay

Table 438. GR1553B BC transfer descriptor word 1 (offset 0x04)

31	30	29 26	25 21	20 16	15 11	10	9 5	4 0
DUM	BUS	RTTO	RTAD2	RTSA2	RTAD1	TR	RTSA1	WCMC

31	Dummy transfer (DUM) - If set to '1' no bus traffic is generated and transfer "succeeds" immediately For dummy transfers, the EXCL,IRQN,SUSN,STBUS,GAP,STIME settings are still in effect, other bits and the data buffer pointer are ignored.	
30	Bus selection (BUS) - Bus to use for transfer, 0 - Bus A, 1 - Bus B	
29:26	RT Timeout (RTTO) - Extra RT status word timeout above nominal in units of 4 us (0000 -14 us, 1111 -74 us). Note: This extra time is also used as extra intermessage gap time if the GAP bit is set.	
25:21	Second RT Address for RT-to-RT transfer (RTAD2)	See table 440 for details on how to setup RTAD1,RTSA1,RTAD2,RTSA2,WCMC,TR for different transfer types.
20:16	Second RT Subaddress for RT-to-RT transfer (RTSA2)	
15:11	RT Address (RTAD1)	
10	Transmit/receive (TR)	Note that bits 15:0 correspond to the (first) command word on the 1553 bus
9:5	RT Subaddress (RTSA1)	
4:0	Word count/Mode code (WCMC)

36.5 Remote Terminal Operation

36.5.1 Overview

When operating as Remote Terminal, the core acts as a slave on the MIL-STD-1553B bus. It listens for requests to its own RT address (or broadcast transfers), checks whether they are configured as legal and, if legal, performs the corresponding transfer or, if illegal, sets the message error flag in the status word. Legality is controlled by the subaddress control word for data transfers and by the mode code control register for mode codes.

To start the RT, set up the subaddress table and log ring buffer, and then write the address and RT enable bit is into the RT Config Register.

36.5.2 Data transfer handling

The Remote Terminal mode uses a three-level structure to handle data transfer DMA. The top level is a subaddress table, where each subaddress has a subaddress control word, and pointers to a transmit descriptor and a receive descriptor. Each descriptor in turn contains a descriptor control/status word, pointer to a data buffer, and a pointer to a next descriptor, forming a linked list or ring of descriptors. Data buffers can reside anywhere in memory with 16-bit alignment.

When the RT receives a data transfer request, it checks in the subaddress table that the request is legal. If it is legal, the transfer is then performed with DMA to or from the corresponding data buffer. After a data transfer, the descriptor's control/status word is updated with success or failure status and the subaddress table pointer is changed to point to the next descriptor.

If logging is enabled, a log entry will be written into a log ring buffer area. A transfer-triggered IRQ may also be enabled. To identify which transfer caused the interrupt, the RT Event Log IRQ Position points to the corresponding log entry. For that reason, logging must be enabled in order to enable interrupts.

If a request is legal but can not be fulfilled, either because there is no valid descriptor ready or because the data can not be accessed within the required response time, the core will signal a RT table access error interrupt and not respond to the request. Optionally, the terminal flag status bit can be automatically set on these error conditions.

36.5.3 Mode Codes

Which of the MIL-STD-1553B mode codes that are legal and should be logged and interrupted are controlled by the RT Mode Code Control register. As for data transfers, to enable interrupts you must also enable logging. Inhibit mode codes are controlled by the same fields as their non-inhibit counterpart and mode codes that can be broadcast have two separate fields to control the broadcast and non-broadcast variants.

The different mode codes and the corresponding action taken by the RT are tabulated below. Some mode codes do not have a built-in action, so they will need to be implemented in software if desired. The relation between each mode code to the fields in the RT Mode Code control register is also shown.

*Table 442.*RT Mode Codes

Mode code		Description	Built-in action, if mode code is enabled	Can log/ IRQ	Enabled after reset	Ctrl. reg bits
0	00000	Dynamic bus control	If the DBCA bit is set in the RT Bus Status register, a Dynamic Bus Control Acceptance response is sent.	Yes	No	17:16
1	00001	Synchronize	The time field in the RT sync register is updated. The output rtsync is pulsed high one AMBA cycle.	Yes	Yes	3:0
2	00010	Transmit status word	Transmits the RT:s status word Enabled always, can not be logged or disabled.	No	Yes	-
3	00011	Initiate self test	No built-in action	Yes	No	21:18
4	00100	Transmitter shutdown	The RT will stop responding to commands on the other bus (not the bus on which this command was given).	Yes	Yes	11:8
5	00101	Override transmitter shutdown	Removes the effect of an earlier transmitter shutdown mode code received on the same bus	Yes	Yes	11:8
6	00110	Inhibit terminal flag	Masks the terminal flag of the sent RT status words	Yes	No	25:22
7	00111	Override inhibit terminal flag	Removes the effect of an earlier inhibit terminal flag mode code.	Yes	No	25:22
8	01000	Reset remote terminal	The fail-safe timers, transmitter shutdown and inhibit terminal flag inhibit status are reset. The Terminal Flag and Service Request bits in the RT Bus Status register are cleared. The extreset output is pulsed high one AMBA cycle.	Yes	No	29:26
16	10000	Transmit vector word	Responds with vector word from RT Status Words Register	Yes	No	13:12
17	10001	Synchronize with data word	The time and data fields in the RT sync register are updated. The rtsync output is pulsed high one AMBA cycle	Yes	Yes	7:4
18	10010	Transmit last command	Transmits the last command sent to the RT. Enabled always, can not be logged or disabled.	No	Yes	-
19	10011	Transmit BIT word	Responds with BIT word from RT Status Words Register	Yes	No	15:14
20	10100	Selected transmitter shutdown	No built-in action	No	No	-
21	10101	Override selected transmitter shutdown	No built-in action	No	No	-

36.5.4 Event Log

The event log is a ring of 32-bit entries, each entry having the format given in table 443. Note that for data transfers, bits 23-0 in the event log are identical to bits 23-0 in the descriptor status word.

*Table 443.*GR1553B RT Event Log entry format

31	30	29	28	24	23	10	9	8	3	2	0
IRQSR	TYPE		SAMC		TIMEL		BC	SZ		TRES	

31	IRQ Source (IRQSRC) - Set to '1' if this transfer caused an interrupt
30 : 29	Transfer type (TYPE) - 00 - Transmit data, 01 - Receive data, 10 - Mode code
28 : 24	Subaddress / Mode code (SAMC) - If TYPE=00/01 this is the transfer subaddress, If TYPE=10, this is the mode code
23 : 10	TIMEL - Low 14 bits of time tag counter.
9	Broadcast (BC) - Set to 1 if request was to the broadcast address
8 : 3	Transfer size (SZ) - Count in 16-bit words (0-32)
2 : 0	Transfer result (TRES)
	000 = Success
	001 = Superseded (canceled because a new command was given on the other bus)
	010 = DMA error or memory timeout occurred
	011 = Protocol error (improperly timed data words or decoder error)
	100 = The busy bit or message error bit was set in the transmitted status word and no data was sent
	101 = Transfer aborted due to loop back checker error

36.5.5 Subaddress table format

*Table 444.*GR1553B RT Subaddress table entry for subaddress number N, 0<N<31

Offset	Value	DMA R/W
0x10*N + 0x00	Subaddress N control word (table 445)	R
0x10*N + 0x04	Transmit descriptor pointer, 16-byte aligned (0x3 to indicate invalid pointer)	R/W
0x10*N + 0x08	Receive descriptor pointer, 16-byte aligned (0x3 to indicate invalid pointer)	R/W
0x10*N + 0x0C	Unused	-

Note: The table entries for mode code subaddresses 0 and 31 are never accessed by the core.

*Table 445.*GR1553B RT Subaddress table control word (offset 0x00)

31	19	18	17	16	15	14	13	12	8	7	6	5	4	0
0 (reserved)		WRAP	IGNDV	BCRXE	RXEN	RXLOG	RXIRQ	RXSZ		TXEN	TXLOG	TXIRQ	TXSZ	

31 : 19	Reserved - set to 0 for forward compatibility
18	Auto-wraparound enable (WRAP) - Enables a test mode for this subaddress, where transmit transfers send back the last received data. This is done by copying the finished transfer's descriptor pointer to the transmit descriptor pointer address after each successful transfer.
	Note: If WRAP=1, you should not set TXSZ > RXSZ as this might cause reading beyond buffer end
17	Ignore data valid bit (IGNDV) - If this is '1' then receive transfers will proceed (and overwrite the buffer) if the receive descriptor has the data valid bit set, instead of not responding to the request.
	This can be used for descriptor rings where you don't care if the oldest data is overwritten.
16	Broadcast receive enable (BCRXEN) - Allow broadcast receive transfers to this subaddress
15	Receive enable (RXEN) - Allow receive transfers to this subaddress
14	Log receive transfers (RXLOG) - Log all receive transfers in event log ring (only used if RXEN=1)
13	Interrupt on receive transfers (RXIRQ) - Each receive transfer will cause an interrupt (only if also RXEN,RXLOG=1)
12 : 8	Maximum legal receive size (RXSZ) to this subaddress - in16-bit words, 0 means 32
7	Transmit enable (TXEN) - Allow transmit transfers from this subaddress
6	Log transmit transfers (TXLOG) - Log all transmit transfers in event log ring (only if also TXEN=1)
5	Interrupt on transmit transfers (TXIRQ) - Each transmit transfer will cause an interrupt (only if TXEN,TXLOG=1)
4 : 0	Maximum legal transmit size (TXSZ) from this subaddress - in 16-bit words, 0 means 32

*Table 446.*GR1553B RT Descriptor format

Offset	Value	DMA R/W
0x00	Control and status word, see table 447	R/W
0x04	Data buffer pointer, 16-bit aligned	R
0x08	Pointer to next descriptor, 16-byte aligned or 0x0000003 to indicate end of list	R

*Table 447.*GR1553B RT Descriptor control/status word (offset 0x00)

31	30	29 26	25 10	9	8 3	2 0
DV	IRQEN	Reserved (0)	TIME	BC	SZ	TRES

31	Data valid (DV) - Should be set to 0 by software before and set to 1 by hardware after transfer. If DV=1 in the current receive descriptor before the receive transfer begins then a descriptor table error will be triggered. You can override this by setting the IGNDV bit in the subaddress table.
30	IRQ Enable override (IRQEN) - Log and IRQ after transfer regardless of SA control word settings Can be used for getting an interrupt when nearing the end of a descriptor list.
29 : 26	Reserved - Write 0 and mask out on read for forward compatibility
25 : 10	Transmission time tag (TTIME) - Set by the core to the value of the RT timer when the transfer finished.
9	Broadcast (BC) - Set by the core if the transfer was a broadcast transfer
8 : 3	Transfer size (SZ) - Count in 16-bit words (0-32)
2 : 0	Transfer result (TRES) 000 = Success 001 = Superseded (canceled because a new command was given on the other bus) 010 = DMA error or memory timeout occurred 011 = Protocol error (improperly timed data words or decoder error) 100 = The busy bit or message error bit was set in the transmitted status word and no data was sent 101 = Transfer aborted due to loop back checker error

36.6 Bus Monitor Operation

36.6.1 Overview

The Bus Monitor (BM) can be enabled by itself, or in parallel to the BC or RT. The BM acts as a passive logging device, writing received data with time stamps to a ring buffer.

36.6.2 Filtering

The Bus Monitor can also support filtering. This is an optional feature, software can check for this by testing whether the BM filter registers are writable.

Transfers can be filtered per RT address and per subaddress or mode code, and the filter conditions are logically AND:ed. If all bits of the three filter registers and bits 2-3 of the control register are set to '1', the BM core will log all words that are received on the bus.

In order to filter on subaddress/mode code, the BM has logic to track 1553 words belonging to the same message. All 10 message types are supported. If an unexpected word appears, the filter logic will restart. Data words not appearing to belong to any message can be logged by setting a bit in the control register.

The filter logic can be manually restarted by setting the BM enable bit low and then back to high. This feature is mainly to improve testability of the BM itself.

The filtering capability can be configured out of the BM to save area. If this is done, all words seen are logged and the filter control registers become read-only and always read out as all-ones. You can, however, still control whether Manchester/parity errors are logged.

36.6.3 No-response handling

In the MIL-STD-1553B protocol, a command word for a mode code using indicator 0 or a regular transfer to subaddress 8 has the same structure as a legal status word. Therefore ambiguity can arise when the subaddress or mode code filters are used, an RT is not responding on a subaddress, and the BC then commands the same RT again on subaddress 8 or mode code indicator 0 on the same bus. This can lead to the second command word being interpreted as a status word and filtered out.

The BM can use the instrumentation bit and reserved bits to disambiguate, which means that this case will never occur when subaddresses 1-7, 9-30 and mode code indicator 31 are used. Also, this case does not occur when the subaddress/mode code filters are unused and only the RT address filter is used.

36.6.4 Log entry format

Each log entry is two 32-bit words.

*Table 448.*GR1553B BM Log entry word 0 (offset 0x00)

31	30	24	23		0
1	Reserved		TIME		

	31	Always written as 1
	30 : 24	Reserved - Mask out on read for forward compatibility
	23 : 0	Time tag (TIME)

*Table 449.*GR1553B BM Log entry word 1 (offset 0x04)

31	30	20	19	18	17	16	15	0
0	Reserved		BUS	WST		WTP	WD	

31	Always written as 0
30 : 20	Reserved - Mask out on read for forward compatibility
19	Receive data bus (BUS) - 0:A, 1:B
18 : 17	Word status (WST) - 00=word OK, 01=Manchester error, 10=Parity error
16	Word type (WTP) - 0:Data, 1:Command/status
15 : 0	Word data (WD)

36.7 Clocking

The core needs a separate clock for the 1553 codec.

The core operates in two clock domains, the AMBA clock domain and the 1553 codec clock domain, with synchronization and handshaking between the domains. The AMBA clock can be at any frequency but must be at a minimum of 10 MHz. A propagation delay of up to one codec clock cycle (50 ns) can be tolerated in each clock-domain crossing signal.

The core has two separate reset inputs for the two clock domains. They should be reset simultaneously, for instance by using two Reset generator cores connected to the same reset input but clocked by the respective clocks.

36.8 AXI support

The core is designed for an AMBA system but can be adapted for AXI using the AHBM2AXI adapter.

36.9 Registers

The core is programmed through registers mapped into APB address space. If the RT, BC or BM parts of the core have been configured out, the corresponding registers will become unimplemented and return zero when read. Reserved register fields should be written as zeroes and masked out on read.

*Table 450.*MIL-STD-1553B interface registers

APB address offset	Register	R/W	Reset value
0x00	IRQ Register	RW (write '1' to clear)	0x00000000

w	rw	rw	rw	r	r	rw	rw

31 : 16	Safety code (RTKEY) - Must be written as 0x1553 when changing the RT address, otherwise the address field is unaffected by the write. When reading the register, this field reads 0x0000.
	If extra safety keys are enabled (see Hardware Config Register), the lower half of the key is used to also protect the other fields in this register.
15	Sync signal enable (SYS) - Set to '1' to pulse the rtsync output when a synchronize mode code (without data) has been received
14	Sync with data signal enable (SYDS) - Set to '1' to pulse the rtsync output when a synchronize with data word mode code has been received
13	Bus reset signal enable (BRS) - Set to '1' to pulse the busreset output when a reset remote terminal mode code has been received.
6	Reads '1' if current address was set through external inputs.
	After setting the address from software this field is set to '0'
5 : 1	RT Address (RTADDR) - This RT:s address (0-30)
0	RT Enable (RTEN) - Set to '1' to enable listening for requests

36.9.16 RT Bus Status Register

*Table 469.*0x88 - RTBS - GR1553B RT Bus status register

31 9	8	7 5	4	3	2	1	0
RESERVED	TFDE	RESERVED	SREQ	BUSY	SSF	DBCA	TFLG
0	0	0	0	0	0	0	0
r	rw	rw	rw	rw	rw	rw	rw

8	Set Terminal flag automatically on DMA and descriptor table errors (TFDE)
4 : 0	These bits will be sent in the RT:s status responses over the 1553 bus.
4	Service request (SREQ)
3	Busy bit (BUSY)
	Note: If the busy bit is set, the RT will respond with only the status word and the transfer "fails"
2	Subsystem Flag (SSF)
1	Dynamic Bus Control Acceptance (DBCA)
	Note: This bit is only sent in response to the Dynamic Bus Control mode code
0	Terminal Flag (TFLG)
	The BC can mask this flag using the "inhibit terminal flag" mode command, if legal

36.9.17 RT Status Words Register

*Table 470.*0x8C - RTSW - GR1553B RT Status words register

31 16	15 0
BIT WORD (BITW)	VECTOR WORD (VECW)
0	0
rw	rw

31 : 16	BIT Word - Transmitted in response to the "Transmit BIT Word" mode command, if legal
15 : 0	Vector word - Transmitted in response to the "Transmit vector word" mode command, if legal.

31 : 0   Pointer to the next position that will be written to in the BM log buffer

Only bits 21:3 are settable, i.e. the buffer can not cross a 4 MB boundary Bits 31:22 read the same as the buffer start address.Due to alignment, bits 2:0 are always equal to 0

36.9.33 BM Time Tag Control Register

*Table 486.*0xE0 - BMTTC - GR1553B BM Time tag control register

31	24	23	0
TIME TAG RESOLUTION		TIME TAG VALUE	
0		0	
rw		rw	

31 : 24   Time tag resolution (TRES) - Time unit of BM:s time tag counter in microseconds, minus 1

23 : 0   Time tag value (TVAL) - Current value of running time tag counter

36.10 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x04D. For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

36.11 Implementation

36.11.1 Reset

The core does not changs reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core has two separate reset inputs for the two clock domains. They should be reset simultaneously, for instance by using two Reset generator cores connected to the same reset input but clocked by the respective clocks See the documentation of the *syncrst* VHDL generic for possible reset implementations.

36.11.2 External control

An external control synthesis option is available that changes the core so that some of the configuration register fields inside the core driven directly from external signals (auxin.extctrl) instead from the internal logic of the IP core. The fields that are externally controlled can no longer be overwritten through the register interface, however the registers can still be read out through the APB interface and will return the values that were externally assigned. Note also that the external control of rtaddr/rten fields will also override the ordinary auxin.rtaddr/auxin.rtpar functionality.

36.11.3 Endianness

The core support both big-endian and little-endian systems. The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The endianness can be configured through the *ahbendian* generic.

36.12 Configuration options

Table 487 shows the configuration options of the core (VHDL generics).

*Table 487.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB master index	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#
pirq	Index of the interrupt line.	0 - NAHBIRQ-1	0
bc_enable	Selects whether BC support is built into the core	0 - 1	1
rt_enable	Selects whether RT support is built into the core	0 - 1	1
bm_enable	Selects whether BM support is built into the core	0 - 1	1
bc_timer	Selects whether the BC timer and wake-up interrupt features are built into the core. 0=None, 1=Timer, 2=Timer and wake-up	0-2	1
bc_rtbusmask	Selects whether the BC per-RT bus swap register is built into the core.	0-1	1
extra_regkeys	Enables extra safety keys for the BM control register and for all fields in the RT control registers	0-1	0
syncrst	Selects reset configuration: 0: Asynchronous reset, all registers in core are reset 1: Synchronous, minimal set of registers are reset 2: Synchronous, most registers reset (increases area slightly to simplify netlist simulation)	0-2	1
ahbendian	Selects AHB bus endianness (for use in non-GRLIB systems), 0=Big endian, 1=Little endian	0 - 1	0
bm_filters	Enable BM filtering capability	0 - 1	1
codecfreq	Codec clock domain frequency in MHz	20 or 24	20
sameclk	AMBA clock and reset is same as codec (removes internal synchronization)	0 - 1	0
codecver	Version selection for internal 1553 codec. 0: Old version, 1: New version, 2: Soft programmable	0 - 2	1
extctrlen	Enables external signal control of register fields from auxin.extctrl record	0 - 1	0

36.13 Signal descriptions

Tables 488-489 shows the interface signals of the core (VHDL ports).

Table 488. Signal descriptions on AMBA side

Signal name	Field	Type	Function	Active
CLK	N/A	Input	Clock, AMBA clock domain	-
RST	N/A	Input	Reset for registers in CLK clock domain	Low
AHBMI	*	Input	AHB master input signals	-
AHBMO	*	Output	AHB master output signals	-
APBSI	*	Input	APB slave input signals	-
APBSO	*	Output	APB slave output signals	-
AUXIN	EXTSYNC	Input	External sync input for Bus Controller Re-synchronized to AMBA clk internally. Edge-detection checks for the sampled pattern "01", i.e. pulses should be at least one CLK cycle to always get detected.	Pos. edge
	RTADDR	Input	Reset value for RT address, if parity matches.	-
	RTPAR	Input	RT address odd parity	-
	EXTCTRL	Input	External control register input record, used only when extctrlen=1. RTEN, RTADDR,BRS,SYS,SYDS:: Controls fields with the same name in the RT Configuration register BUSY: Controls the BUSY field in the RT Bus Status register SATB: Controls the RT Subaddress table base register. MCCR: Controls the RT mode code control register	-
AUXOUT	RTSYNC	Output	Pulsed for one CLK cycle after receiving a synchronize mode command in RT mode	High
	BUSRESET	Output	Pulsed for one CLK cycle after receiving a reset remote terminal mode command in RT mode	High
	VALIDCMDA	Output	Pulsed for one CLK cycle after receiving a valid command word on bus A/B in RT mode	High
	VALIDCMDB	Output		High
	TIMEDOUTA	Output	Asserted when the terminal fail-safe timer has triggered on bus A/B.	High
	TIMEDOUTB	Output		High
	BADREG	Output	Pulsed for one CLK cycle when an invalid register access is performed, either: - an access to an undefined register, - read/write from a write-only/read-only register, - a read/write to a non-implemented part of the core - an incorrect BCKEY/BMKEY	High
	IRQVEC	Output	Auxiliary IRQ vector. Pulsed at the same time as the ordinary PIRQ line, but with a separate line for each interrupt: 7: BM Timer overflow, 6: BM DMA Error, 5: RT Table error, 4: RT DMA Error, 3: RT Event 2: BC Wake-up, 1: BC DMA Error, 0: BC Event	High

* see GRLIB IP Library User's Manual

Table 489. Signal descriptions on 1553 side

Signal name	Field	Type	Function	Active
CODEC_CLK	N/A	Input	Codec clock	-
CODEC_RST	N/A	Input	Reset for registers in CODEC_CLK domain	Low
TXOUT	BUSA_TXP	Output	Bus A transmitter, positive output	High **
	BUSA_TXN	Output	Bus A transmitter, negative output	High **
	BUSA_TXEN	Output	Bus A transmitter enable	High
	BUSA_RXEN	Output	Bus A receiver enable	High
	BUSB_TXP	Output	Bus B transmitter, positive output	High **
	BUSB_TXN	Output	Bus B transmitter, negative output	High **
	BUSB_TXEN	Output	Bus B transmitter enable	High
	BUSB_RXEN	Output	Bus B receiver enable	High
	BUSA_TXIN	Output	Inverted version of BUSA_TXEN (for VHDL coding convenience)	High
	BUSB_TXIN	Output	Inverted version of BUSB_TXEN	High
TXOUT_FB	See TXOUT	Input	Feedback input to the terminal fail-safe timers. Should be tied directly to TXOUT, but are exposed to allow testing the fail-safe timer function. This input is re synchronized to CODEC_CLK so it can be asynchronous.	See TXOUT
RXIN	BUSA_RXP	Input	Bus A receiver, positive input	High **
	BUSA_RXN	Input	Bus A receiver, negative input	High **
	BUSB_RXP	Input	Bus B receiver, positive input	High **
	BUSB_RXN	Input	Bus B receiver, negative input	High **

** The core will put both P/N outputs low when not transmitting. For input, it accepts either both-low or both-high idle.

36.14 Signal definitions and reset values

The signals and their reset values are described in table 490.

Table 490. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
busa_rxen	Output	Enable for the A receiver	High	Logical 0
busa_rxp	Input	Positive data input from the A receiver	High*	-
busa_rxn	Input	Negative data input from the A receiver	High*	-
busa_txinh	Output	Enable for the A transmitter	Low**	Logical 1
busa_txp	Output	Positive data to the A transmitter	High	Logical 0
busa_txn	Output	Negative data to the A transmitter	High	Logical 0
busb_rxen	Output	Enable for the B receiver	High	Logical 0
busb_rxp	Input	Positive data input from the B receiver	High*	-
busb_rxn	Input	Negative data input from the B receiver	High*	-
busb_txinh	Output	Enable for the B transmitter	Low**	Logical 1
busb_txp	Output	Positive data to the B transmitter	High	Logical 0
busb_txn	Output	Negative data to the B transmitter	High	Logical 0

* rx inputs can be either both-high or both-low when bus is idle

** txinh inhibits (disables) transmission when high, enables transmission when low

36.19   Note: AHB Interface Compatibility

36.19.1 Introduction

When using the GR1553B core in a non-GRLIB environment, the AHB system designer must make sure that the slaves to be accessed by the core are compatible with the accesses the master makes.

36.19.2 Generic access patterns

The GR1553B core performs the following accesses on the AHB bus:

- 32-bit sequential read burst, unspecified length, Length 2-3, 128-bit aligned start address. (BC,RT)
- 32-bit sequential write burst, length 2 (BM)
- Single 32-bit read/write (BC,RT)
- Single 16-bit write (BC,RT)
- Idle transfers

The master supports wait states (hready low) as well as split and retry responses. In either case, it will retry accesses indefinitely until getting an OKAY or ERROR response.

Busy cycles and locked transfers are not used by the core.

36.19.3 Endianness

The GR1553B core, in its standard configuration, only works on big-endian systems. Byte-swapping in software is not enough because of the 16-bit writes.

Little-endian bus support can be configured by setting the ahbendian generic to 1. The endian-ness setting only changes the handling of data buffers, data structures are still read using 32-bit reads/ writes and bit fields extracted from the same bit positions.

For data buffers, the core is designed to make 16-bit addressing correct, so that each 16-bit data word in memory is transferred msb to lsb in increasing address order. Note that with little-endian addressing this means that the data will not be sent in byte order. This means that care must be taken to ensure correct ordering when transferring data from 1553 buffers to/from byte streams (files, network packets, etc.).

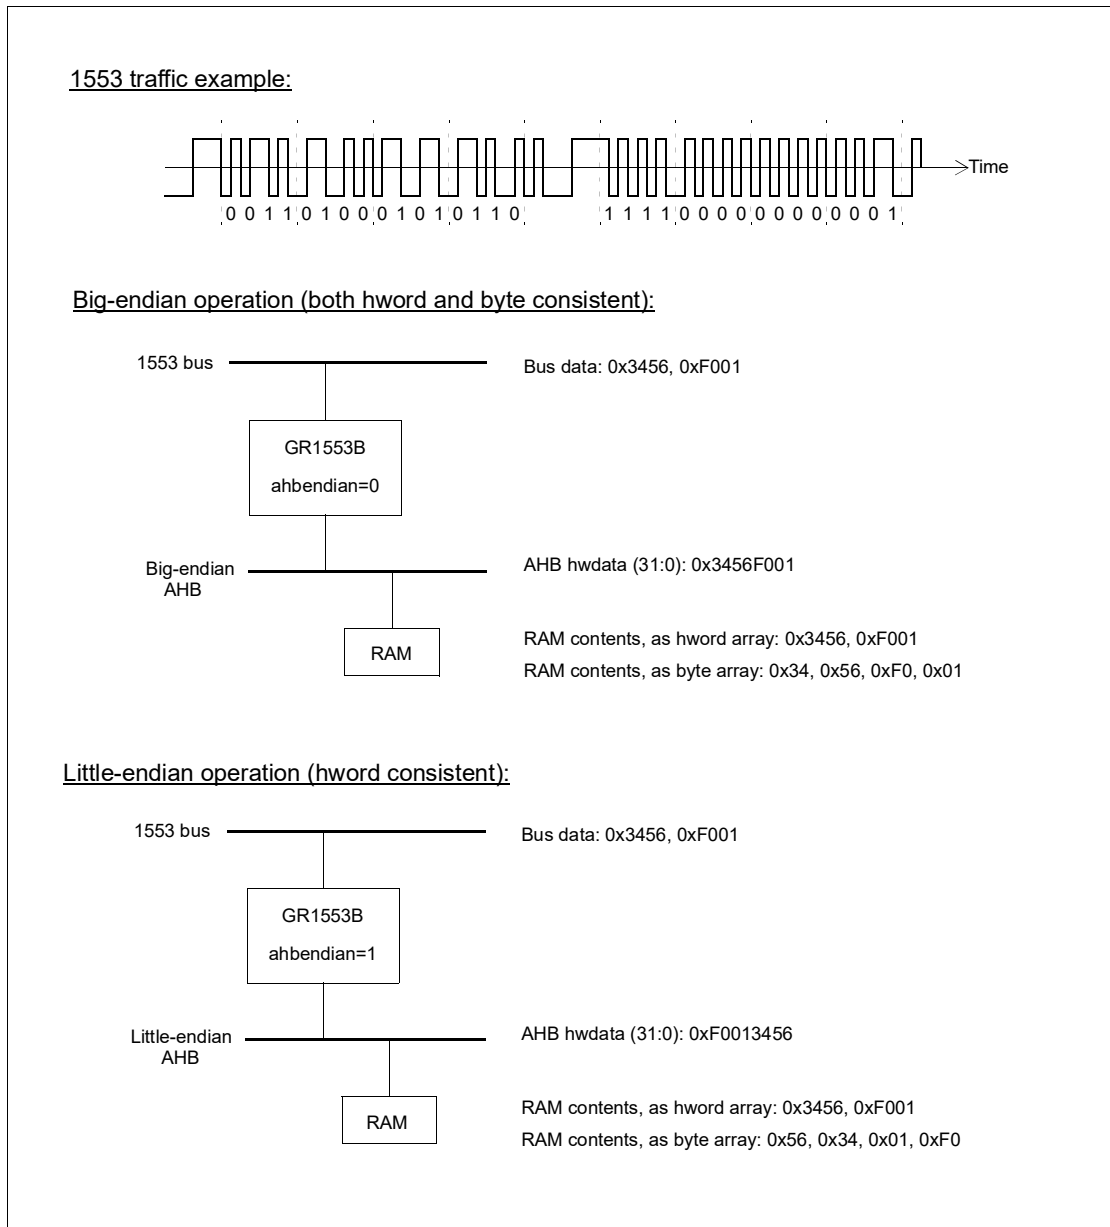

Figure 118. Relation between transferred 1553 data order and RAM contents for little/big-

36.20 Note: AHB Latency and throughput requirements

36.20.1 Introduction

Since the AMBA AHB bus standard does not in itself guarantee any maximum latency or throughput, the AHB bus system must be carefully designed so that the core can satisfy the 1553 requirements reliably.

Throughput is not normally a problem, since even at the lowest supported AMBA frequency of 10 MHz, the core can only use a few percent of the bus bandwidth.

Latency is a larger concern, especially when there are other bus masters with high bandwidth utilization or large burst access patterns.

Some general recommendations:

- Make GR1553B the highest priority master on the bus
- Limit the maximum length of other master's bursts to the order of 5 us.
- Use local RAM for descriptors and preferably also data.

36.20.2 BC Descriptor processing

Between transfers, the BC core first writes the descriptor status word using a 32-bit write, then fetches the following descriptor using a 3 x 32-bit read burst.

If the next location in the schedule is a branch, then the burst fetches only the first two 32-bit words, then processes the condition for one cycle, and then continues.

The core keeps the bus request signal high continuously until the next descriptor has been read. Between the status write and the descriptor read, there is one idle AHB transaction, i.e. the descriptor read is started the cycle after the status write finishes. Between a branch read and the next descriptor read, there are two idle AHB transactions, i.e. one completely idle cycle between the end of branch read and the start of descriptor read.

36.20.3 BC Asynchronous scheduling

If the asynchronous list is started and there is slack in the regular schedule, the BC needs to read the next asynchronous descriptor in order to make the scheduling decision. In case there is less slack than was specified in the asynchronous descriptor, the BC will then read the regular descriptor and proceed with the regular schedule. In this case, the BC remembers the asynchronous time requirement and will not need to re-read the asynchronous descriptor until the asynchronous transfer is actually scheduled.

If there is less than 24 us of slack in the regular schedule, then the BC will assume there is no time for the asynchronous transfer, not read the asynchronous descriptor and just proceed with the regular schedule. This means that as long as two BC descriptors can be read within 24 us, the asynchronous descriptor processing can not affect the ordinary schedule.

36.20.4 BC Data Buffer processing

When transferring data from BC-to-RT, the core reads the first one or two (depending on alignment) 16-bit data words from memory using a 32-bit read, while the command word is being transferred. The core then reads an additional 32-bit word every time the last previously read data word is sent and there is more to send.

For transfers from RT-to-BC, the core either writes the first data word using a 16-bit write, or writes the first two data words using a 32-bit write, depending on data buffer alignment. It will then perform a 32-bit write after every two data words received. While performing the write, the core does not buffer another data word so the write has to complete within 20 us.

If there is one received data word left after the transfer, it is written during the 5 us message gap. If it doesn't finish in that time, the descriptor processing will be delayed until after the write finishes.

36.20.5 BC Requirements

The hard requirement on the BC comes from the data buffers, where one read/write should finish in 20 us.

The time needed for descriptor processing will affect the schedule. In order to reduce this time, the time for a 32-bit write followed by a 3x32-bit read burst should be reduced, preferably to the 2-3 us range. This is more of a soft requirement, and for larger schedules it can often be viewed as an average over minor frames or other groups of transfers.

If the asynchronous scheduling feature is used, and you do not want the regular schedule to be affected by this, two 3x32-bit read bursts must be able to finish within 24 us.

36.20.6 RT Transfer Processing

For the RT there are two cases to consider, receive and transmit.

The receive case:

1. The RT gets the receive command

2. While the first data word is transmitted over the bus, the RT looks up the subaddress table and receive descriptor.

3. The data words are stored

4. The RT waits 5-6 us to see that there are no extra (unwanted) data words.

5. The status word is transmitted. In parallel, the results are written to the descriptor and the log and table is updated.

The transmit case:

1. The RT gets the transmit command

2. In parallel there are two processes working:

   Process A:

       A.1 The RT looks up in the subaddress table that the request is legal.

       A.2 The RT looks up the descriptor and reads the first word of data

   Process B:

       B.1 The RT waits 5-6 us to see that there are no extra (unwanted) data words received.

       B.2 Wait for A.1 to finish

       B.3 Send status word

       B.4 Send data

3. The data words are sent

4. The results are written to the descriptor and the log and table is updated.

In the receive case, the subaddress table and descriptor reads (two 3x32-bit read bursts) have to finish within the 20 us period that the data word is transferred.

In the transmit case, the subaddress table read (one 2x32-bit read burst) has to finish in time so that the RT satisfies the response time requirement.

The RT has a status word response time requirement of 12 us mid-bit to mid-sync, which translates into in 10 us maximum bus dead time before responding. These 10 us also include transceiver delays, so the actual time available is typically closer to 9 us.

GRIP

Apr 2024, Version 2024.1

462

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The core has a safety limit of 9 us, after which a table error interrupt is generated and no response is generated. However, this should be seen as a fallback solution and triggering this time-out should be considered a fault at the AMBA bus design level.

36.20.7 RT Requirements

From the cases above, the following requirements can be derived:

One 2x32-bit read burst must finish in 8.5-9 us (from the transmit case above)

Two 3x32-bit read bursts plus one 32-bit read must finish in 20 us.

Each 32-bit data buffer read/write must finish in 20 us.

36.20.8 Bus Monitor

The bus monitor will at full bus traffic, write 2x32-bit data words every 20 us.

If run in parallel with the BC or RT, this will need to be added to the requirements. The core is designed so that, after an RT+BM receives a command word, the RT will access the bus first to do the more urgent accesses.

36.21 Note: BC transfer timing

36.21.1 Introduction

In order to design a transfer schedule for the Bus Controller, the worst-case times for each transfer must be calculated. This note is intended to give some hints on how to do this. Understanding of the 1553B protocol is assumed, see the AS15531 standard (in particular, Figure 9) for details.

36.21.2 Overview

Except for the case of automatic retries, the longest time a transfer takes is the success case, where all permitted time-outs and slack is used.

When reading the standard, there are a few points to note for the calculations:

- The time-outs and gaps in the standard are specified mid-parity to mid-sync. To convert into bus dead time, one must subtract 2 us.

- The timings are specified on the bus side, so transceiver delays must be taken into account.

36.21.3 Transceiver delay

The timings in the 1553 standard are specified on the terminal boundary which is on the bus side of the transceiver. However, the core operates on the other side of the transceiver. Therefore, the transceiver delays must be taken into account.

The BC mode uses the loopback checking mechanism to compensate for transceiver delay. After the command words have been sent, it waits for the words to loop back through the receiver and then starts the RT time-out timer.

36.21.4 BC Transfer Steps: Parts

A BC transfer can be divided into the following steps:

1. Transmission of control words and receive data

This is a continuous transmission which takes 20 us per word sent. Also include 0.2 us starting delay.

2. Transceiver turnaround

The core waits for the transmitted command to loop back into the receiver. By doing this before starting the RT time-out clock, we get an accurate RT timeout regardless of transceiver delay.

The time this takes is the sum of the transmitter and receiver delay, plus internal decoding delays of 0.15-0.40 us.

3. RT Response Time-out

The core allows a maximum of 12.0-12.5 us bus dead time before the beginning of the RT Response. Note that this time can be increased via a descriptor setting.

4. RT Response and transmit data

The BC receives the RT status word and the specified number of data words.

The Bus Controller checks for message continuity and allows a maximum of 1 us of sync drift over the entire message. The maximum time for this part is thus 20 us/word + 1 us.

5. Second RT Response Time-out

For RT-to-RT transfers. See step 3.

6. Second RT Response

For RT-to-RT transfers. See step 4.

7. Word count verification

GRIP

Apr 2024, Version 2024.1

464

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

For non-broadcast and RT-to-RT messages, the BC waits an additional 5 us to ensure that there is no additional word sent out by the last transmitting RT.

8. Store result, fetch next descriptor

The time this takes to perform depends completely on the AMBA system the core is connected to.

9. Broadcast message gap and descriptor processing

For single-RT broadcasts, instead of step 7-8 the core inserts a 3 us message gap, and in parallel starts fetching the next descriptor. This step therefore takes the maximum of 3 us and the time needed for step 8.

36.21.5 BC transfer steps: Composition

The different 1553 message types map to the above steps as:

BC-to-RT, RT-to-BC, Mode: Steps 1-4,7-8

RT-to-RT: Steps 1-8

BC-to-RT broadcast, Mode broadcast: Steps 1,2,9

RT-to-RT broadcast: Steps 1-4,7-8

If broadcast response checking is enabled in the BC status register, the core waits and checks that no RT produces a response on the bus after each broadcast. Thus, the broadcast case changes to 1-4,7-8, and 30-35 us is added to the worst-case transfer time.

36.21.6 Timing calculation

Based on the steps above, and also taking automatic replies into account, we end up with the following calculations:

BC-to-RT, RT-to-BC or Mode, N data words:

$$T = C_{try} \times (20.2 + N \times 20 + T_{loop} + 12.5 + T_{extra} + 21 + 5) + T_{dpr}$$
$$= C_{try} \times (58.7 + N \times 20 + T_{extra} + T_{loop}) + T_{dpr}$$

RT-to-RT, N data words:

$$T = C_{try} \times (40.2 + T_{loop} + 12.5 + T_{extra} + 21 + N \times 20 + 12.5 + T_{extra} + 21 + 5) + T_{dpr}$$
$$= C_{try} \times (112.2 + N \times 20 + 2T_{extra} + T_{loop}) + T_{dpr}$$

BC-to-RT broadcast or Mode broadcast, N data words:

$$T = C_{try} \times (20.2 + N \times 20 + T_{loop} + 3) - 3 + \max(T_{dpr}, 3)$$

RT-to-RT broadcast:

$$T = C_{try} \times (40.2 + T_{loop} + 12.5 + T_{extra} + 21 + N \times 20 + 5) + T_{dpr}$$

Where:

T Worst-case time usage for transfer (i.e. how much the following transfer is delayed when running at maximum rate)

C_{try} The maximum number of attempts, controlled by descriptor, equal to 1 unless automatic retries are used.

T_{loop} Time from the end of a word transmission to receiver decoding the looped-back word. Sum of transceiver transmit and receive delay, plus internal delay of 400 ns.

T_{dpr} Time needed for data processing between this and the next transfer. This includes storing result, processing any branches, and fetching the next descriptor

T_{extra} Extra RT response time, equal to the RTTO field in the transfer descriptor multiplied by 4 us.

GRIP

Apr 2024, Version 2024.1

465

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

36.21.7 Example

Assume for this example that T_{loop} = 1.4 us (transceiver delay of 500 ns + 500 ns) and T_{dpr} = 3 us (90 cycles at 30 MHz).

An RT-to-RT transfer of 5 data words then needs up to 1 x (112.2 + 5x20 + 2x0 + 1.4) + 3 = 216.6 us of time to execute.

36.22 Note: Time synchronization

36.22.1 Introduction

The purpose of time synchronization is to get a common notion of time between the terminals on the bus. This allows the user to relate time stamps from different terminals and coordinate events. If there is an external time base available on one of the terminals it is also interesting to be able to translate the time stamps over into this time base.

This note describes the GR1553B IP core's BC-to-RT time synchronization capabilities and discusses some applications.

36.22.2 Hardware features: BC features

The BC supports sending the 1553 bus standard's two mode commands dedicated to synchronization, synchronize (code 1) and synchronize with data word (code 17). The commands can be sent either to a specific RT, or sent on the broadcast address to all RT:s on one bus.

With the "wait for external trigger" (WTRIG) descriptor bit, any data transfer or mode code in the schedule can be set up to wait for a positive edge on the IP core's auxin.extsync input signal before starting. The external sync can also be triggered from software by writing to the BC Action Register.

It is also possible to use the regular scheduling features of the core to plan synchronization commands within a frame with high precision, just like any other transfer can be planned. This makes it possible to send timed sync pulses at a different interval than the external sync pulses, or to use the internal BC timer as time master with no external time base at all.

36.22.3 Hardware features: RT features

The RT supports receiving the two synchronization mode commands that can be emitted by the BC. In case of synchronization with data word, the attached data word can be read out through the RT sync register.

The RT has an internal timer with configurable scaler, which can be read-out and configured through the RT Time tag control register. When a mode command is received, the timer value is stored into the RT Sync Register which can be read out by software.

There are also a number of core output signals related to synchronization. The validcmdA/B outputs are raised whenever a valid command word is received in the RT, and this happens at the same time as the internal time stamp is taken. There is also an output called rtsync which is set high only after a successfully received sync command. The rtsync output pulse always occurs after the validcmd pulse.

If software handling of synchronization is desired, the core can be configured to generate an IRQ after a sync mode command has been received.

36.22.4 Hardware features: Internal timers

Both the internal timer used for BC scheduling and the timer used for the RT time stamps are based on 1 MHz clock ticks generated in the codec clock domain that are resynchronized to the AMBA clock domain. When the RT timer register is written, the tick generator and the (optional) scaler gets reset, therefore for best timestamp accuracy, the RT timer should be left free-running and used as differential measurements.

In terms of frequency accuracy, the internal timers will have the same characteristics as the codec clock, which is limited by the 1553 standard to 1000 ppm long-term. If the user has a more accurate clock source than this, this will naturally translate into more accurate timing.

36.22.5 Synchronization schemes

36.22.6 Synchronization schemes: Overview

This section describes a few ways to generate and receive synchronization commands on the bus. There are many possible ways to do this, but in this section the basic scheme assumed is by broadcasting sync mode commands from the BC at a regular interval. To handle fault conditions, the sync commands are sent on alternating buses.

Typically the user also wants to send a frame number or a coarse time stamp with the sync command. This can be sent either as the attached data word when using the sync with data mode command, or it can be sent beforehand to a dedicated subaddress on the RT:s. This is not described further in the section.

36.22.7 Synchronization schemes: BC without external time base

If no external real time base is available on the BC, regular sync commands can still be generated by scheduling as shown in the example below.

Table 493. Example BC descriptor structure with synchronization

	Sum of slot times assigned in each frame = sync period/2				
Frame 1	Sync broadcast Bus A	Transfer	Transfer	...	Jump to frame 2
Frame 2	Sync broadcast Bus B	Transfer	Transfer	...	Jump to frame 3
Frame 3	Sync broadcast Bus A	Transfer	Transfer	...	Jump to frame 4
Frame 4	Sync broadcast Bus B	Transfer	Transfer	...	Jump to frame 1

36.22.8 Synchronization schemes: BC with external time base

If there is an external time base connected to the extsync input of the core, this can be used by setting the wait for external trigger descriptor bit at intervals in the schedule corresponding to the sync interval. The schedule can otherwise be kept as is. As the figure shows it is possible to have the sync pulses at a multiple of the sync interval and use the internal time base for the sync commands in between.

Table 494. Example BC descriptor structure with external synchronization

	Sum of slot times assigned in each frame = sync period/2					
Frame 1	Sync broadcast Bus A, wtrig set	Transfer	Transfer	...	Jump to frame 2	Sum of slot times in all four frames gives external sync period
Frame 2	Sync broadcast Bus B	Transfer	Transfer	...	Jump to frame 3	
Frame 3	Sync broadcast Bus A	Transfer	Transfer	...	Jump to frame 4	
Frame 4	Sync broadcast Bus B	Transfer	Transfer	...	Jump to frame 1

36.22.9 Synchronization schemes: RT without external time base

If the resolution of the sync period from the BC is good enough, then the simplest solution is to just take the frame number sent by the BC directly and use it as the time stamp.

If more resolution is needed, the user can read out the current value of the RT Timer, compare with the last sync time stamp in the RT Sync register, and use the difference as a time offset from the last sync time from the BC.

36.22.10 Synchronization schemes: RT with external time base(s)

If an external timer is available, its value can be read out at the same time as the sync time stamp by the hardware using a construct like the one shown below. The first register captures the external timer value whenever a command word is received, and the second register records the time stamp if the command was a sync mode code. With this value, the user will then obtain a common time stamp between the BC time, RT time and external time that can be used in different ways.
Figure 119. Obtaining an RT sync timestamp in hardware with an external time base

36.22.11 Accuracy

36.22.12 Accuracy: Propagation delays

When the sync command is sent, there is first an approximate 500 ns of delay inside the core, followed by analog delays, consisting of BC pad delays, BC transmitter delay, bus propagation delays, RT receiver delays, and RT pad delays.

When using the external BC sync, there is also a 2-3 AHB cycle delay before the sync is detected due to synchronization. This creates a small offset between the external time reference and the internal time.

On the RT digital side, there will first be a delay of 20000 ns to receive the whole command word, followed by internal decoding delays of approximately 500 ns before the command word is recognized and the time stamp is taken.

Most of this delay is constant, in particular the 20 us word length, and can therefore be easily compensated for by offsetting the time stamps. Offsetting the RT timestamps by 24 us should be a reasonable first-order approach, accurate within +/- 4 us or so. If more accuracy is needed, characterization measurements or further analysis of the bus system would need to be done.

36.22.13 Accuracy: Clock drift

Relative drift between the clocks determine how often synchronization is necessary. Since the internal timers of the BC and RT are as accurate as the codec clocks, and both the clocks must have the 1000 ppm worst-case accuracy permitted by the 1553 standard, the BC and RT timers can drift apart up to 2 us for a sync period of 1 ms. Assuming the external time base is much more accurate, the internal and external BC time bases will drift apart of up to 1 us for every ms of external sync period.

37   GRTIMER - General Purpose Timer Unit

37.1   Overview

The GRTIMER IP core's functionality for latching timer values, external clocking and reload on external events has been merged into the GPTIMER core. All new designs should instantiate the GPTIMER IP core.

A GRTIMER entity exists that is a wrapper around the GPTIMER IP core for backward compatibility.

38   GRACECTRL - AMBA System ACE Interface Controller

38.1   Overview

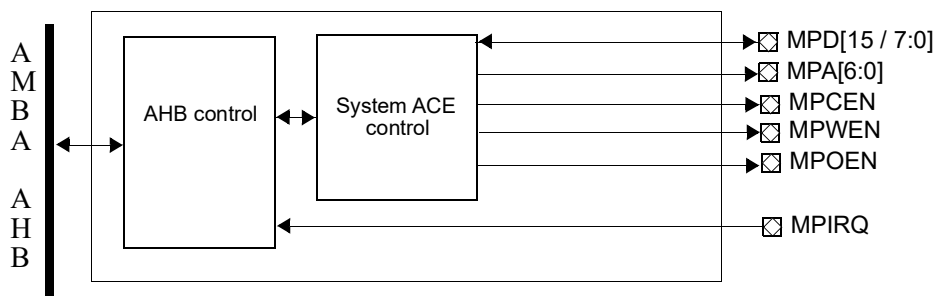
The core provides an AMBA AHB interface to the microprocessor interface of a Xilinx System ACE Compact Flash Solution. Accesses to the core's memory space are directly translated to accesses on the System ACE microprocessor interface (MPU).


Figure 120. Block diagram

38.2   Operation

38.2.1   Operational model

The core has one AHB I/O area, accesses to this area are directly translated to accesses on the Xilinx System ACE's Microprocessor Interface (MPU). When an access is made to the I/O area, the core first checks if there already is an ongoing access on the MPU. If an access is currently active, the core will respond with an AMBA SPLIT response. If the MPU bus is available, the core will start an access on the MPU bus and issue a SPLIT response to the AMBA master. If the core has been configured for a system that does not support SPLIT responses, it will insert wait states instead.

38.2.2   Bus widths

The AMBA access is directly translated to an MPU access where bits 6:0 of the AMBA address bus are connected to the MPU address bus. The core can be configured to connect to a 16-bit MPU interface or a 8-bit MPU interface. When the core is connected to a 8-bit MPU interface it can emulate 16-bit mode by translating 16-bit (half-word) AMBA accesses into two 8-bit MPU accesses. The mode to use is decided at implementation time via the VHDL generic *mode*.

The core does not perform any checks on the size of the AMBA access and software should only make half-word (16-bit), or byte (8-bit) depending on the setting of VHDL generic *mode*, accesses to the core's memory area. Any other access size will be accepted by the core but the operation may not have the desired result. On AMBA writes the core uses address bit 1 (or address bits 1:0 for 8-bit mode) to select if it should propagate the high or the low part of the AMBA data bus to the MPU data bus. On read operations the core will propagate the read MPU data to all parts of the AMBA data bus.

It is recommended to set the *mode* VHDL generic to 2 for 8-bit MPU interfaces, and to 0 for 16-bit MPU interfaces. This way software can always assume that it communicates via a 16-bit MPU interface (accesses to the System ACE BUSMODEREG register are overriden by the core with suitable values when *mode* is set to 2).

38.2.3   Clocking and synchronization

The core has two clock inputs; the AMBA clock and the System ACE clock. The AMBA clock drives the AHB slave interface and the System ACE clock drives the System ACE interface state machine.

All signals crossing between the two clock domains are synchronized to prevent meta-stability. The system clock should have a higher frequency than the System ACE clock.

38.2.4 Endianness

The core is designed for big-endian systems.

38.3 Registers

The core does implement any registers accessible via AMBA.

38.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x067. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

38.5 Implementation

38.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

38.5.2 Technology mapping

The core does not instantiate any technology specific primitives.

38.5.3 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual).

38.5.4 RAM usage

The core does not use any RAM components.

38.6 Configuration options

Table 495 shows the configuration options of the core (VHDL generics).

*Table 495.*Configuration options

Generic name	Function	Allowed range	Default
hindex	AHB slave index	0 - (NAHBSLV-1)	0
hirq	Interrupt line	0 - (NAHBIRQ-1)	0
haddr	ADDR field of the AHB BAR0	0 - 16#FFF#	16#000#
hmask	MASK field of the AHB BAR0	0 - 16#FFF#	16#FFF#
split	If this generic is set to 1 the core will issue AMBA SPLIT responses when it is busy performing an access to the System ACE. Otherwise the core will insert wait states until the operation completes. Note that SPLIT support on the AHBCTRL core MUST be enabled if this generic is set to 1.	0 - 1	0

39   GRADCDAC - ADC / DAC Interface

39.1   Overview

The block diagram shows a possible partitioning of the combined analogue-to-digital converter (ADC) and digital-to-analogue converter (DAC) interface.

The combined analogue-to-digital converter (ADC) and digital-to-analogue converter (DAC) interface is assumed to operate in an AMBA bus system where an APB bus is present. The AMBA APB bus is used for data access, control and status handling.

The ADC/DAC interface provides a combined signal interface to parallel ADC and DAC devices. The two interfaces are merged both at the pin/pad level as well as at the interface towards the AMBA bus. The interface supports simultaneously one ADC device and one DAC device in parallel.

Address and data signals unused by the ADC and the DAC can be used for general purpose input output, providing 0, 8, 16 or 24 channels.

The ADC interface supports 8 and 16 bit data widths. It provides chip select, read/convert and ready signals. The timing is programmable. It also provides an 8-bit address output. The ADC conversion can be initiated either via the AMBA interface or by internal or external triggers. An interrupt is generated when a conversion is completed.

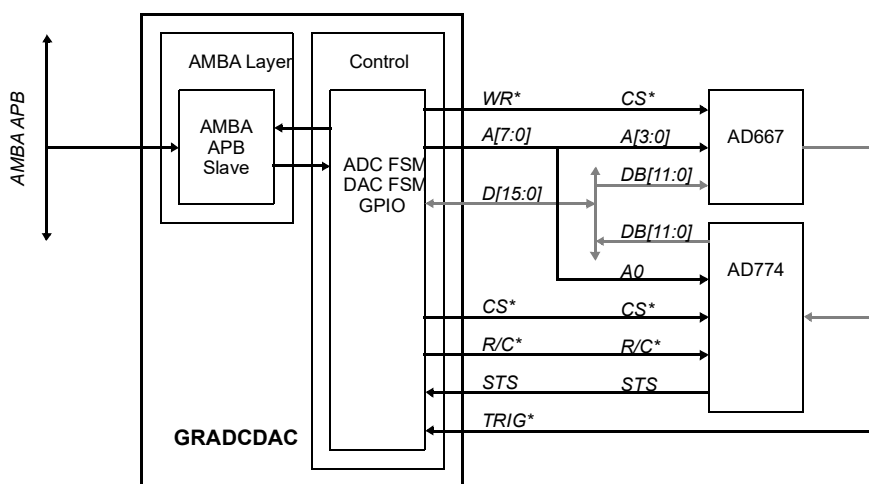
The DAC interface supports 8 and 16 bit data widths. It provides a write strobe signal. The timing is programmable. It also provides an 8-bit address output. The DAC conversion is initiated via the AMBA interface. An interrupt is generated when a conversion is completed.


Figure 121. Block diagram and usage example

39.1.1   Function

The core implements the following functions:

- ADC interface conversion:
-      ready feed-back, or
-      timed open-loop
- DAC interface conversion:
-      timed open-loop
- General purpose input output:
-      unused data bus, and

GRIP

Apr 2024, Version 2024.1

476

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

- unused address bus
- Status and monitoring:
- on-going conversion
- completed conversion
- timed-out conversion

Note that it is not possible to perform ADC and DAC conversions simultaneously. On only one conversion can be performed at a time.

39.1.2 Interfaces

The core provides the following external and internal interfaces:

- Combined ADC/DAC interface
- programmable timing
- programmable signal polarity
- programmable conversion modes
- AMBA APB slave interface

The ADC interface is intended for amongst others the following devices:

Name:Width:Type:

AD574 12-bit   R/C*, CE, CS*, RDY*, tri-state

AD674 12-bit   R/C*, CE, CS*, RDY*, tri-state

AD774 12-bit   R/C*, CE, CS*, RDY*, tri-state

AD670 8-bit   R/W*, CE*, CS*, RDY, tri-state

AD571 10-bit   Blank/Convert*, RDY*, tri-state

AD1671 12-bit Encode, RDY*, non-tri-state

LTC141414-bitConvert*, RDY, non-tri-state

The DAC interface is intended for amongst others the following devices:

Name:Width:Type:

AD56110-bitParallel-Data-in-Analogue-out

AD56512-bitParallel-Data-in-Analogue-out

AD66712-bitParallel-Data-in-Analogue-out, CS*

AD76712-bitParallel-Data-in-Analogue-out, CS*

DAC08 8-bit Parallel-Data-in-Analogue-out

39.2 Operation

39.2.1 Interfaces

The internal interface on the on-chip bus towards the core is a common AMBA APB slave for data access, configuration and status monitoring, used by both the ADC interface and the DAC interface.

The ADC address output and the DAC address output signals are shared on the external interface. The address signals are possible to use as general purpose input output channels. This is only realized when the address signals are not used by either ADC or DAC.

The ADC data input and the DAC data output signals are shared on the external interface. The data input and output signals are possible to use as general purpose input output channels. This is only realized when the data signals are not used by either ADC or DAC.

Each general purpose input output channel shall be individually programmed as input or output. This applies to both the address bus and the data bus. The default reset configuration for each general purpose input output channel is as input. The default reset value each general purpose input output channel is logical zero.

Note that protection toward spurious pulse commands during power up shall be mitigated as far as possible by means of I/O cell selection from the target technology.

39.2.2 Analogue to digital conversion

The ADC interface supports 8 and 16 bit wide input data.

The ADC interface provides an 8-bit address output, shared with the DAC interface. Note that the address timing is independent of the acquisition timing.

The ADC interface shall provide the following control signals:

• Chip Select

• Read/Convert

• Ready

The timing of the control signals is made up of two phases:

• Start Conversion

• Read Result

The Start Conversion phase is initiated by one of the following sources, provided that no other conversion is ongoing:

• Event on one of three separate trigger inputs

• Write access to the AMBA APB slave interface

Note that the trigger inputs can be connected to internal or external sources to the ASIC incorporating the core. Note that any of the trigger inputs can be connected to a timer to facilitate cyclic acquisition. The selection of the trigger source is programmable. The trigger inputs is programmable in terms of: Rising edge or Falling edge. Triggering events are ignored if ADC or DAC conversion is in progress.

The transition between the two phases is controlled by the Ready signal. The Ready input signal is programmable in terms of: Rising edge or Falling edge. The Ready input signaling is protected by means of a programmable time-out period, to assure that every conversion terminates. It is also possible to perform an ADC conversion without the use of the Ready signal, by means of a programmable conversion time duration. This can be seen as an open-loop conversion.

The Chip Select output signal is programmable in terms of:

• Polarity

• Number of assertions during a conversion, either

• Pulsed once during Start Conversion phase only,

• Pulsed once during Start Conversion phase and once during Read Result phase, or

• Asserted at the beginning of the Start Conversion phase and de-asserted at the end of the Read Result phase

GRIP

Apr 2024, Version 2024.1

478

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The duration of the asserted period is programmable, in terms of system clock periods, for the Chip Select signal when pulsed in either of two phases.

The Read/Convert signal is de-asserted during the Start Conversion phase, and asserted during the Read Result phase. The Read/Convert output signal is programmable in terms of: Polarity. The setup timing from Read/Convert signal being asserted till the Chip Select signal is asserted is programmable, in terms of system clock periods. Note that the programming of Chip Select and Read/Convert timing is implemented as a common parameter.

At the end of the Read Result phase, an interrupt is generated, indicating that data is ready for readout via the AMBA APB slave interface. The status of an on-going conversion is possible to read out via the AMBA APB slave interface. The result of a conversion is read out via the AMBA APB slave interface. Note that this is independent of what trigger started the conversion.

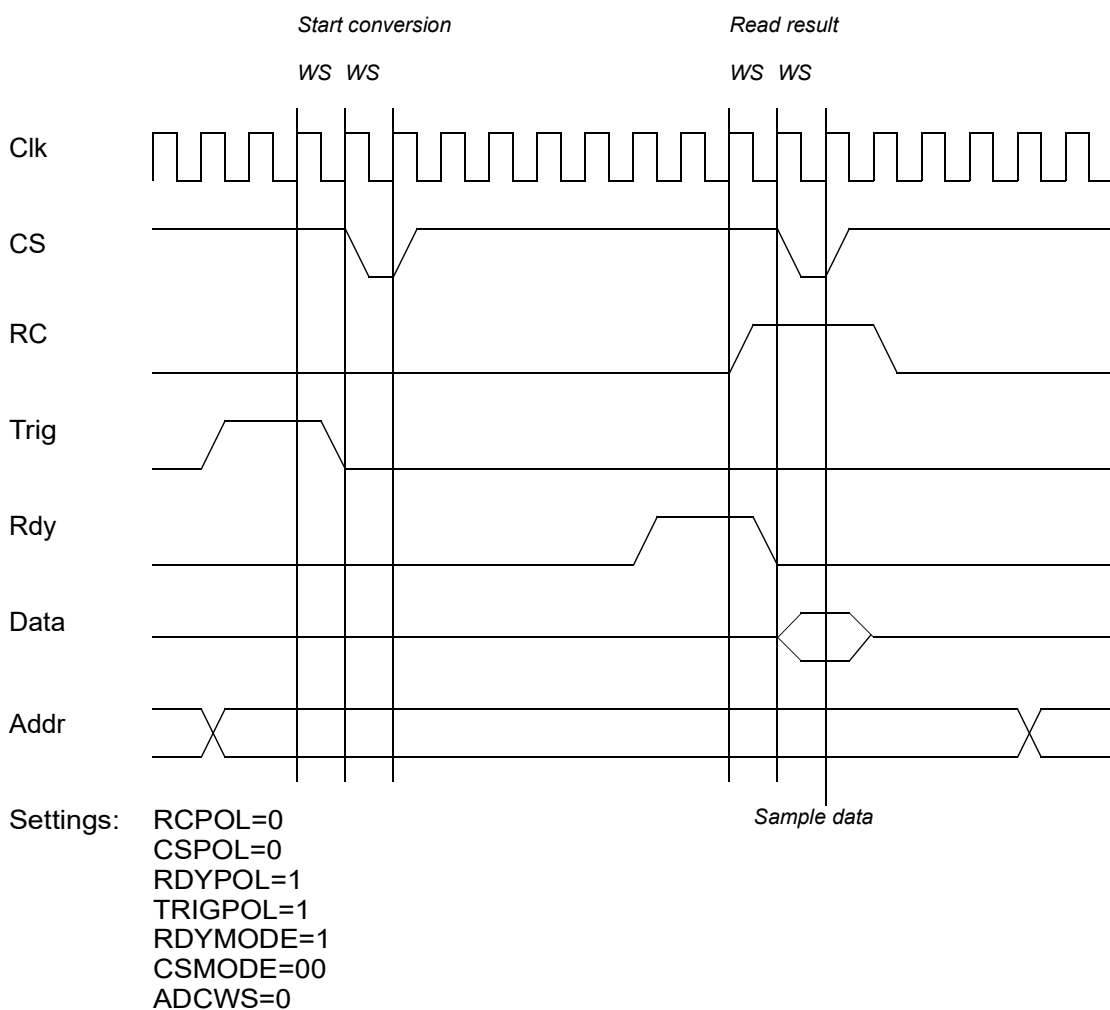
An ADC conversion is non-interruptible. It is possible to perform at least 1000 conversions per second.


Figure 122. Analogue to digital conversion waveform, 0 wait states (WS)

39.2.3 Digital to analogue conversion

The DAC interface supports 8 and 16 bit wide output data. The data output signal is driven during the conversion and is placed in high impedance state after the conversion.

The DAC interface provides an 8-bit address output, shared with the ADC interface. Note that the address timing is independent of the acquisition timing.

GRIP
Apr 2024, Version 2024.1

479

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The DAC interface provides the following control signal: Write Strobe. Note that the Write Strobe signal can also be used as a chip select signal. The Write Strobe output signal is programmable in terms of: Polarity. The Write Strobe signal is asserted during the conversion. The duration of the asserted period of the Write Strobe is programmable in terms of system clock periods.

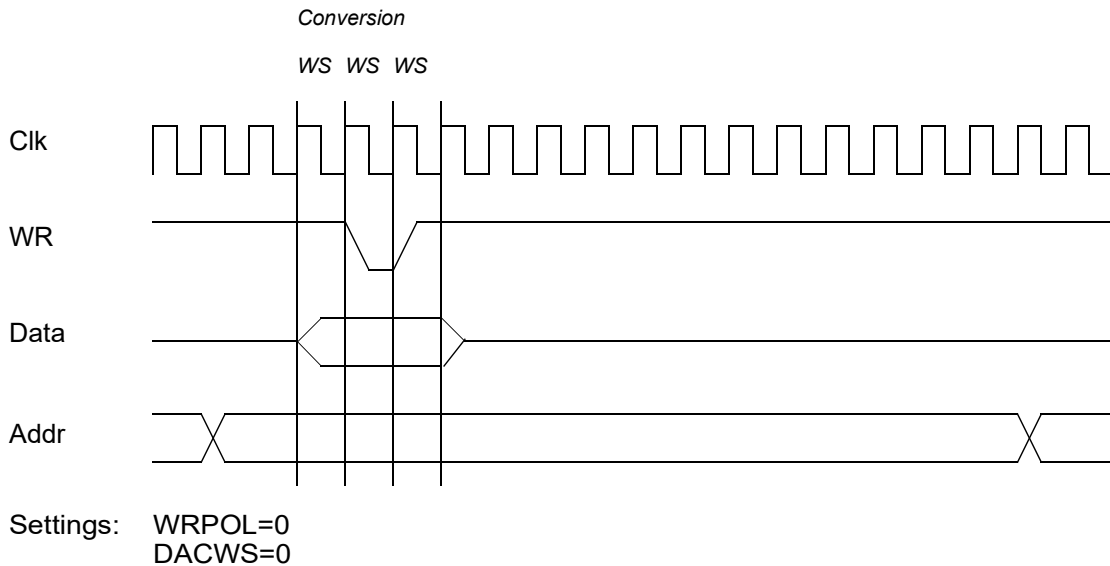
At the end the conversion, an interrupt is generated. The status of an on-going conversion is possible to read out via the AMBA APB slave interface. A DAC conversion is non-interruptible.


Figure 123. Digital to analogue conversion waveform, 0 wait states (WS)

39.3   Operation

39.3.1   Interrupt

Two interrupts are implemented by the ADC/DAC interface:

Index:Name:Description:

0   ADC ADC conversion ready

1   DAC DAC conversion ready

The interrupts are configured by means of the *pirq* VHDL generic.

39.3.2   Reset

After a reset the values of the output signals are as follows:

Signal:Value after reset:

ADO.Aout[7:0]de-asserted

ADO.Aen[7:0]de-asserted

ADO.Dout[15:0]de-asserted

ADO.Den[15:0]de-asserted

ADO.WRde-asserted (logical one)

ADO.CSde-asserted (logical one)

ADO.RCde-asserted (logical one)

39.3.3 Asynchronous interfaces

The following input signals are synchronized to Clk:

- ADI.Ain[7:0]
- ADI.Din[15:0]
- ADI.RDY
- ADI.TRIG[2:0]

39.4 Registers

The core is programmed through registers mapped into APB address space.

*Table 499.*GRADCDAC registers

APB address offset	Register
0x000	Configuration Register
0x004	Status Register
0x010	ADC Data Input Register
0x014	DAC Data Output Register
0x020	Address Input Register
0x024	Address Output Register
0x028	Address Direction Register
0x030	Data Input Register
0x034	Data Output Register
0x038	Data Direction Register

39.4.1 Configuration Register [ADCONF]

*Table 500.*Configuration register

31		24	23		19	18	17	16
			DACWS			WR POL	DACDW	
			0			0	0	
			rw			rw	rw	

15		11	10	9	8	7	6	5	4	3	2	1	0
ADCWS			RCP OL	CSMODE		CSP OL	RD YM OD E	RD YP OL	TRI GP OL	TRIG-MODE		ADCDW	
0			0	0		0	0	0	0	0		0	
rw			rw	rw		rw	rw	rw	rw	rw		rw	

23-19:   DACWS   Number of DAC wait states, 0 to 31 [5 bits]
18:   WRPOL   Polarity of DAC write strobe:
      0b = active low
      1b = active high
17-16:   DACDW   DAC data width
      00b = none
      01b = 8 bit   ADO.Dout[7:0]
      10b = 16 bit   ADO.Dout[15:0]
      11b = none/spare
15-11:   ADCWS   Number of ADC wait states, 0 to 31 [5 bits]

10:	RCPOL	Polarity of ADC read convert: 0b = active low read 1b = active high read
9-8:	CSMODE	Mode of ADC chip select: 00b = asserted during conversion and read phases 01b = asserted during conversion phase 10b = asserted during read phase 11b = asserted continuously during both phases
7:	CSPOL	Polarity of ADC chip select:0b = active low 1b = active high
6:	RDYMODE:	Mode of ADC ready: 0b = unused, i.e. open-loop 1b = used, with time-out
5:	RDYPOL	Polarity of ADC ready: 0b = falling edge 1b = rising edge
4:	TRIGPOL	Polarity of ADC triggers: 0b = falling edge 1b = rising edge
3-2:	TRIGMODE	ADC trigger source: 00b = none 01b = ADI.TRIG[0] 10b = ADI.TRIG[1] 11b = ADI.TRIG[2]
1-0:	ADCDW	ADC data width: 00b = none 01b = 8 bit ADI.Din[7:0] 10b = 16 bit ADI.Din[15:0] 11b = none/spare

The ADCDW field defines what part of ADI.Din[15:0] is read by the ADC.

The DACDW field defines what part of ADO.Dout[15:0] is written by the DAC.

Parts of the data input/output signals used neither by ADC nor by DAC are available for the general purpose input output functionality.

Note that an ADC conversion can be initiated by means of a write access via the AMBA APB slave interface, thus not requiring an explicit ADC trigger source setting.

The ADCONF.ADCWS field defines the number of system clock periods, ranging from 1 to 32, for the following timing relationships between the ADC control signals:

- ADO.RC stable before ADO.CS period
- ADO.CS asserted period, when pulsed
- ADO.TRIG[2:0] event until ADO.CS asserted period
- Time-out period for ADO.RDY: 2048 * (1+ADCONF.ADCWS)
- Open-loop conversion timing: 512 * (1+ADCONF.ADCWS)

The ADCONF.DACWS field defines the number of system clock periods, ranging from 1 to 32, for the following timing relationships between the DAC control signals:

- ADO.Dout[15:0] stable before ADO.WR period
- ADO.WR asserted period
- ADO.Dout[15:0] stable after ADO.WR period

39.6 Implementation

39.6.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

39.7 Configuration options

Table 510 shows the configuration options of the core (VHDL generics).

*Table 510.*Configuration options

Generic	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar.	0 - 16#FFF#	0
pmask	Mask field of the APB bar.	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by the GRADCDAC.	0 - NAHBIRQ-1	1
nchannel	Number of input/outputs	1 - 32	24
npulse	Number of pulses	1 - 32	8
invertpulse	Invert pulse output when set	1 - 32	0
cntrwidth	Pulse counter width	4 to 32	20
oepol	Output enable polarity	0, 1	1

39.8 Signal descriptions

Table 511 shows the interface signals of the core (VHDL ports).

*Table 511.*Signal descriptions

Signal name	Field	Type	Function	Active
RSTN	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
ADI	ADI.Ain[7:0]	Input	Common Address input	-
	ADI.Din[15:0]		ADC Data input	
	ADI.RDY		ADC Ready input	
	ADI.TRIG[2:0]		ADC Trigger inputs	
ADO	ADO.Aout[7:0]	Output	Common Address output	-
	ADO.Aen[7:0]		Common Address output enable	
	ADO.Dout[15:0]		DAC Data output	-
	ADO.Den[15:0]		DAC Data output enable	
	ADO.WRDAC		Write Strobe	
	ADO.CSADC		Chip Select	
	ADO.RCADC		Read/Convert	

* see GRLIB IP Library User's Manual

Note that the VHDL generic oepol is used for configuring the logical level of ADO.Den and ADO.Aen while asserted.

39.9 Signal definitions and reset values

The signals and their reset values are described in table 512.

Table 512. Signal definitions and reset values

Signal name	Type	Function	Active	Reset value
a[]	Input/Output	Address	High	Tri-state
d[]	Input/Output	Data	High	Tri-state
wr	Output	DAC Write Strobe	-	Logical 0
cs	Output	ADC Chip Select	-	Logical 0
rc	Output	ADC Read/Convert	-	Logical 0
rdy	Input	ADC Ready	-	-
trig[]	Input	ADC Trigger	-	-

39.10 Timing

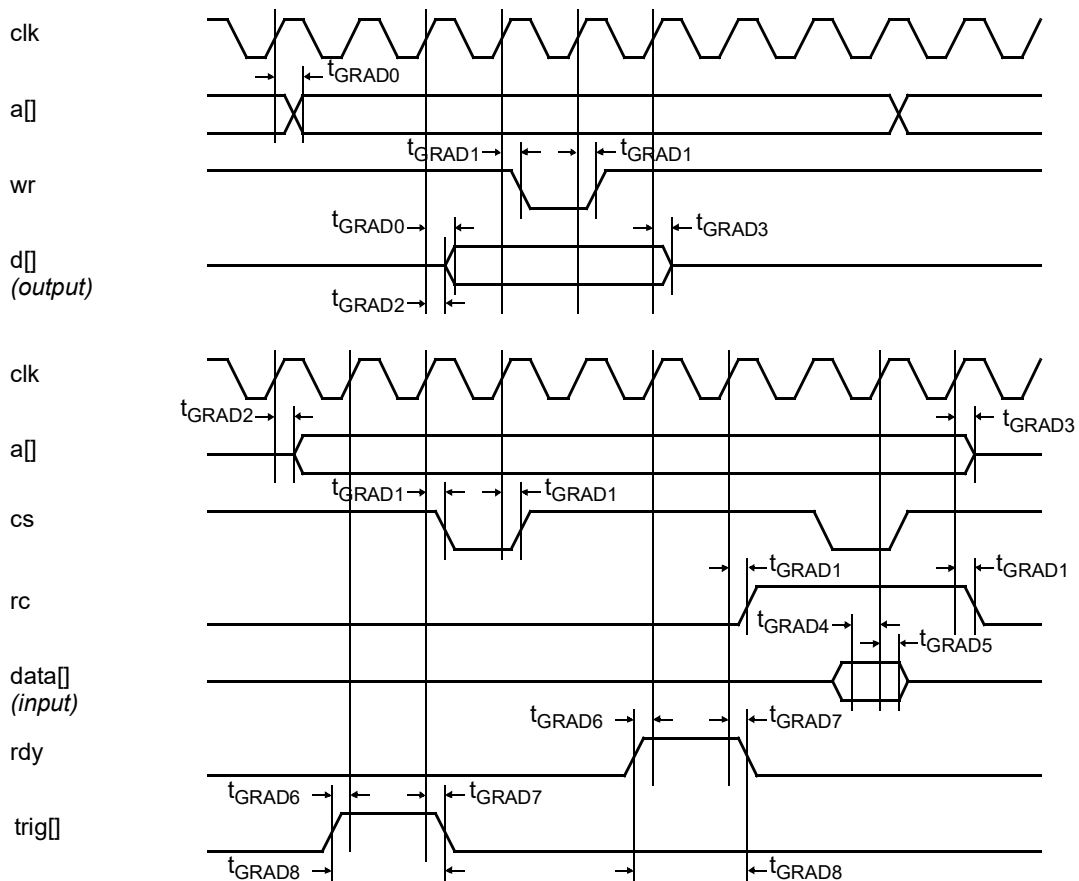
The timing waveforms and timing parameters are shown in figure 124 and are defined in table 513. Note that the input and output polarities of control and response signals are programmable. The figures shows operation where there are zero wait states. Note also that the address timing has no direct correlation with the ADC and DAC accesses, since controlled by a separate set of registers.


Figure 124. Timing waveforms

40 GRAES - Advanced Encryption Standard

40.1 Overview

The Advanced Encryption Standard (AES) is a symmetric encryption algorithm for high throughput application (like audio or video streams). The GRAES core implements the AES-128 algorithm, supporting the Electronic Codebook (ECB) method. The AES-128 algorithm is specified in the "Advanced Encryption Standard (AES)" document, Federal Information Processing Standards (FIPS) Publication 197. The document is established by the National Institute of Standards and Technology (NIST).

The core provides the following internal AMBA AHB slave interface, with sideband signals as per [GRLIB] including:

- interrupt bus
- configuration information
- diagnostic information

The core can be partition in the following hierarchical elements:

- Advanced Encryption Standard (AES) core
- AMBA AHB slave
- GRLIB plug&play wrapper

Note that the core can also be used without the GRLIB plug&play information.

40.2 Operation

The input and output for the AES algorithm each consist of sequences of 128 bits (digits with values of 0 or 1). These sequences will sometimes be referred to as blocks and the number of bits they contain will be referred to as their length. The cipher key for the AES-128 algorithm is a sequence of 128 bits (can also be 192 or 256 bits for other algorithms).

To transfer a 128 bit key or data block four write operations are necessary since the bus interface is 32 bit wide. After supplying a "key will be input" command to the control register, the key is input via four registers. After supplying a "data will be input" command to the control register, the input data is written via four registers. After the last input data register is written, the encryption or decryption is started. The progress can be observed via the debug register. When the operation is completed, an interrupt is generated. The output data is then read out via four registers. Note that the above sequence must be respected. It is not required to write a new key between each data input. There is no command needed for reading out the result.

The implementation requires around 89 clock cycles for a 128 bit data block in encryption direction and around 90 clock cycles for decryption direction. For decryption an initial key calculation is required. This takes around 10 additional clock cycles per every new key. Typically large amounts of data are decrypted (and also encrypted) with the same key. The key initialization for the decryption round does not influence the throughput.

40.3 Background

The Federal Information Processing Standards (FIPS) Publication Series of the National Institute of Standards and Technology (NIST) is the official series of publications relating to standards and guidelines adopted and promulgated under the provisions of the Information Technology Management Reform Act.

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The Advanced Encryption Standard (AES) standard specifies the Rijndael algorithm, a symmetric block cipher that can process data blocks of 128 bits, using cipher keys with lengths of 128, 192, and 256 bits. Rijndael was designed to handle additional block sizes and key lengths, however they are not adopted in this standard.

40.4 AES-128 parameters

The GRAES core implements AES-128. An AES algorithm is defined by the following parameters according to FIPS-197:

- *Nk* number of 32-bit words comprising the cipher key

- *Nr* number of rounds

The AES-128 algorithm is specified as *Nk*=4 and *Nr*=10.

The GRAES core has been verified against the complete set of Known Answer Test vectors included in the AES Algorithm Validation Suite (AESAVS) from National Institute of Standards and Technology (NIST), Information Technology Laboratory, Computer Security Division.

40.5 Throughput

The data throughput for the GRAES core is around 128/90 bits per clock cycle, i.e. approximately 1.4 Mbits per MHz.

The underlaying AES core has been implemented in a dual crypto chip on 250 nm technology as depicted in the figure below. The throughput at 33 MHz operating frequency was 42 Mbit/s, the power consumption was 9,6 mW, and the size was 14,5 kgates.
Figure 125. Dual Crypto Chip

40.6 Characteristics

The GRAES core has been synthesized for a Xilinx Virtex-2 XC2V6000-4 devices with the following results:

- LUTs: 5040 (7%)

- 256x1 ROMs (ROM256X1): 128

40.7 Registers

The core is programmed through registers mapped into AHB I/O address space.. Only 32-bit single-accesses to the registers are supported

Table 515. GRAES registers

AHB I/O address offset	Register
0x00	Control Register
0x10	Data Input 0 Register
0x14	Data Input 1 Register
0x18	Data Input 2 Register
0x1C	Data Input 3 Register
0x20	Data Output 0 Register
0x24	Data Output 1 Register
0x28	Data Output 2 Register
0x2C	Data Output 3 Register
0x3C	Debug Register

40.7.1 Control Register

Table 516. 0x00 - CTRL - Control Register

31		2	1	0
RESERVED			DEC	KEY
-			-	-
w			w	w

31-2:   -   Unused
1:         DEC   0 = "encrypt", 1 = "decrypt" (only relevant when KEY=1)
0:         KEY   0 = "data will be input", 1 = "key will be input"

Note that the Data Input Registers cannot be written before a command is given to the Control Register. Note that the Data Input Registers must then be written in sequence, and all four registers must be written else the core ends up in an undefined state.

The KEY bit determines whether a key will be input (KEY=1), or data will be input (KEY=0). When a "key will be input" command is written, the DEC bit determines whether decryption (DEC=1) or encryption (DEC=0) should be applied to the subsequent data input.

Note that the register cannot be written after a command has been given, until the specific operation completes. A write access will be terminated with an AMBA AHB error response till the Data Input Register 3 has been written, and the with an AMBA AHB retry response till the operation completes. Any read access to this register results in an AMBA AHB error response.

Data/Key(95 downto 64)	
-	
w	

*Table 520.*0x18 - DATAI2 - Data Input 2 Register

31	0
Data/Key(63 downto 32)	
-	
w	

*Table 521.*0x1C - DATAI3 - Data Input 3 Register

31	0
Data/Key(31 downto 0)	
-	
w	

Note that these registers can only be written with a key after a "key will be input" command has been written to the control register. Note that the registers must then be written in sequence, and all four registers must be written else the core ends up in an undefined state.

Note that these registers can only be written with data after a "data will be input" command has been written to the control register, else an AMBA AHB error response is given. Note that the registers must then be written in sequence and all four registers must be written else the core ends up in an undefined state. The encryption or decryption operation is started when the Data Input 3 Register is written to with data.

40.7.4 Data Output Registers (R)

Table 522. 0x20 - DATAO0 - Data Output 0 Register

31	0
Data(127 downto 96)	
-	
r*	

Table 523. 0x24 - DATAO1 - Data Output 1 Register

31	0
Data(95 downto 64)	
-	
r*	

Table 524. 0x28 - DATAO2 - Data Output 2 Register

31	0

-	
r*	

Table 525. 0x2C - DATAO3 - Data Output 3 Register

31	0
Data(31 downto 0)	
-	
r*	

Note that these registers can only be read after encryption or decryption has been completed. An AMBA AHB retry response is given to read accesses that occur while the encryption or decryption is in progress. If a read access is attempted before an encryption or decryption has even been initiated, then an AMBA AHB erro response is given. Write accesses to these registers result in an AMBA AHB error response.

40.8 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x073. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

40.9 Configuration options

Table 526 shows the configuration options of the core (VHDL generics).

Table 526. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB slave index	0 - NAHBSLV-1	0

```

41 GRAES_DMA - Advanced Encryption Standard with DMA

41.1 Overview

The Advanced Encryption Standard (AES) is a symmetric encryption algorithm for high throughput applications (like audio or video streams). The GRAES_DMA core implements the AES algorithm with 256-bit key length using CTR mode of operation. The AES algorithm is specified in the "Advanced Encryption Standard (AES)" document, Federal Information Processing Standards (FIPS) Publication 197. The document is established by the National Institute of Standards and Technology (NIST). DMA is used for efficiently transferring plaintext and ciphertext to the cryptographic core with minimum CPU involvement.

The core provides an AMBA AHB master interface, with sideband signals as per [GRLIB] including:

- interrupt bus
- configuration information
- diagnostic information

The core can be partition in the following hierarchical elements:

- Advanced Encryption Standard (AES) core
- AMBA AHB master

41.2 Operation

The input and output for the AES algorithm each consist of sequences of 128 bits (digits with values of 0 or 1). These sequences will sometimes be referred to as blocks and the number of bits they contain will be referred to as their length. The cipher key for the AES algorithm supported in this core is a sequence of 256 bits.

To encrypt a message a descriptor must be setup. It contains pointers to memory locations where the key, initialization vector and plaintext are located. The memory addresses for the key and initialization vector must be word aligned while the plaintext can start at any address. If the previous key and/or init vector are to be reused there are control bits in the descriptor which can be used to make the core skip the fetching of the respective pointers and also subsequently skip the fetching of the actual key and initvector. Currently the initvector and key always have to be loaded for the core to operate correctly.

The core can also read the key and initialization vector from input signals. This is done by setting the keyvector and initvector address pointers to all ones.

When one or more descriptors have been enabled the core can be enabled and it will automatically start fetching the necessary values from memory, split the data into the required blocks, encrypt/decrypt and finally write back the result to memory. When each descriptor is finished the core will set the enable bit to 0. An interrupt can also optionally be generated. The result of the encryption or decryption can be either written back to the same memory address from where the plain or ciphertext was read or to a different location specified in an additional pointer. The layout of the descriptor is shown in the tables below.

*Table 529.*GRAES_DMA descriptor word 0 (address offset 0x0)

31	21	20		8	7	6	5	4	3	2	1	0
LEN		RESERVED			KE	IV	DO	ED	MD		IE	EN

31: 21	Length (LEN) - Length in bytes of message to process
20: 8	RESERVED
7	Key (KE) - When set a new key will be fetched and used from the memory address set in the key address descriptor word. If not set the currently stored key is used and the key adddress word should not be included in the descriptor.

*Table 529.*GRAES_DMA descriptor word 0 (address offset 0x0)

6	Initialization vector (IV) - When set a new initialization vectir will be fetched and used from the memory address set in the initialization vector address descriptor word. If not set the currently stored initialization vector is used and the initialization vector adddress word should not be included in the descriptor.
5	Dataout (DO) - When set the encrypted/decrypted output will be written to the memory address specified in the dataout descriptor word. Otherwise data is written to the same memory address from where the original plaintext/ciphertext was fetched and the dataout address word should not be included in the descriptor.
4	Encrypt-decrypt (ED) - If set to one encryption will be performed otherwise decryption
3	RESERVED
2	RESERVED
1	Interrupt enable (IE) - When set an interrupt will be generated when the processing of the current enabled descriptor is finished and the interrupt enable bit in the control register is set. It should be noted that, the enable bit in the control register might not be cleared yet when a finish interrupt is generated for the last descriptor because the core will read the next descriptor and stop after encountering a '0' on the descriptor control word enable bit which takes some clock cycles.
0	Enable (EN) - When set to '1' indicates that descriptor is enabled and the GRAES core will process it. After the processing is finished this bit will be cleared and the core will jump to the next register. It should be noted that this bit will not be cleared in case a DMA error is encountered at any point of the processing of the current descriptor. If this bit is clear on the first read from the GRAES_DMA core the core will stop processing.

*Table 530.*GRAES_DMA descriptor word 1 (address offset 0x4)

The descriptor control word should be written last. If one or more words are not included the offsets of the following words should be adjusted accordingly.

41.3 Background

The Federal Information Processing Standards (FIPS) Publication Series of the National Institute of Standards and Technology (NIST) is the official series of publications relating to standards and guidelines adopted and promulgated under the provisions of the Information Technology Management Reform Act.

The Advanced Encryption Standard (AES) standard specifies the Rijndael algorithm, a symmetric block cipher that can process data blocks of 128 bits, using cipher keys with lengths of 128, 192, and 256 bits. Rijndael was designed to handle additional block sizes and key lengths, however they are not adopted in this standard.

41.4 Characteristics

The GRAES_DMA core has been synthesized for a Actel AX2000-std device with the following results:

- Combinational Cells: 9364 of 21504 (44%)
- Sequential Cells: 2374 of 10752 (22%)
- Total Cells: 11738 of 32256 (37%)
- Block Rams : 0 of 64 (0%)
- Frequency:60 MHz

41.5 Endianness

The core is designed for big-endian systems.

41.6.1 Control Register

*Table 536.*0x00 - CTRL - GRAES_DMA control register

31					4	3	2	1	0
RESERVED					AB	IOE	KS	IE	EN
0					0	0	0	0	0
r					rw	rw	rw	rw	rw

31: 5   RESERVED

4   Abort (AB) - If set to '1' the core will stop processing after reaching a new descriptor and it will self-clear the Abort and Enable (bit-0) bits. The software can check the status of Abort or Enable bits after setting the Abort bit to see when the core becomes idle.It should be noted that if the last descriptor that is processed when abort bit is set causes a DMA error the DMA error status bit will be set so the software has to make sure to handle a potential error after abort. This bit can only be written if it is clear. Reset value : '0'

3   Interrupt On Error (IOE)- If set to '1' then the core will generate an interrupt when an DMA error is encountered. This bit is independent from the bit-1 (IE). Read the section related to DMA error handling for further details about error handling. This bit can only be written if enable bit is clear.Reset value : '0'

2   Keysize (KS) - If set to '1' then the core will use 128 bit key length. Otherwise the core makes use of 256 bit key length. This bit can only be written if enable bit is clear.Reset value : '0'

1   Interrupt Enable (IE) - If set, an interrupt is generated each time a message has been decrypted. This bit can only be written if enable bit is clear.Reset value: '0'.

0   Enable (EN) - Write a one to this bit each time new descriptors are activated in the list. Writing a one will cause the core to read a new descriptor and perform the requested operation. This bit is automatically cleared when the core encounters a descriptor which is not enabled or if a DMA error is encountered. This bit can not be set when the error bit in the status register is set. Software has to clear the error bit in the status register to be able to set the Enable bit again. Read the Status Register section for more details. This bit can only be written when it is clear but it can initiate the processing of the last descriptor again in certain conditions to allow dynamic addition of descriptors to the link list. For further details read the descriptor processing section. Reset value: '0'

41.6.2 Status Register

*Table 537.*0x04 - STAT - GRAES_DMA status register

31	0
RESERVED	ER
0	0
r	rw

31: 1   RESERVED

0   Error (ER) - The bit is automatically set to 1 when a DMA error is encountered. When it is set, the enable bit in the ctrl register is locked and can not be set until the error bit is cleared. The error bit is cleared by writing '1' to it.

41.6.3 Descriptor Address

*Table 538.*0x08 - ADDR - GRAES_DMA Descriptor address

31	2	1	0
Descriptor address			R
0			0
rw			r

31: 2   Current descriptor address - Points to current descriptor. Can be initialized with a new pointer when the core is disabled. Is updated by the core while it is progressing through the list of descriptors.

41.7   Descriptor Processing

Software should set up the descriptor or descriptor chain as it described in the operation section. There are two ways to finish the processing of a descriptor or a descriptor chain. First way is to link the next descriptor to itself for the last descriptor in the chain. After processing, the enable bit of the descriptor control word is automatically cleared so if the next descriptor points to itself the enable bit will be cleared and when read again and the core will stop. Another way is to allocate an empty pointer in which the enable bit of the descriptor word is cleared and link it as a last descriptor. It should be noted that when an empty pointer is allocated, size of it should be equal to the maximum possible size (6 words), although the content of the unused words does not matter as soon as the descriptor is not enabled.

If interrupt enable bit is set, an interrupt will be generated after processing an enabled descriptor. But it should be noted that after an interrupt is generated for the last enabled descriptor in the chain, the enable bit in the control word might not be cleared yet due to core being started to process the next descriptor in which it encounters a cleared enable bit and clears the enable bit in the control register. If the software updates the last disabled pointer in the list and enables it while the core is running, and sets the enable bit in the control register while it is already set and it was reading the last pointer, the core will reprocess the last descriptor if the descriptor enable bit was cleared (it did not read the updated descriptor control word), to make sure operation to continue. If the software makes this modification and sets the enable bit in the control register while it was set, then the core will anyway continue operation because it will read the last descriptor as enabled. This feature allows for safe dynamic addition of descriptors to the list while processing is ongoing. It should be noted the control word of a descriptor should always be written last.

The core will immediately stop processing on an DMA error and software has to take certain steps which are explained in the next section (Error Handling).

41.8   Error Handling

If the core encounters a DMA error, the processing will be immediately stopped (enable bit in the core control register will be cleared) and the error bit in the status register will be set. If interrupt on error is enabled an interrupt will also be generated regardless of interrupt enable bit is set on the descriptor control word. When the error bit in the status register is set, the descriptor address that resides in the descriptor address register is the descriptor that caused the DMA error. It should be noted that the enable bit in the descriptor control word will not be cleared during error. In addition, the enable bit in the control word will be locked if the error bit in the status register is set. So after an error the software has to clear the error bit by writing '1' to the position of error bit in the status register. The software should check the status of error bit after the processing of a descriptor chain is finished (en bit is cleared in the control register), to make sure no error has occurred and clear the error bit after an error in order to be able to proceed with the next operations.

After an error is generated the software should either fix the problem related to the error in the descriptor or set the descriptor address to a new descriptor after clearing the error bit and before starting a new operation. Otherwise it can cause an infinite loop because the enable bit of the descriptor word which causes a DMA error is not automatically cleared and the descriptor address points to the failing descriptor when the core stops due to a DMA error.

41.9   Aborting Operation

It is possible to abort the processing of descriptor at a certain point. When the abort bit in the core's control word is set, the processing will stop when the current descriptor has finished processing. After

GRIP

500

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

the abort operation has successfully finished the abort bit and enable bit in the core's control word will be cleared. After finishing, the descriptor address register points to the descriptor which is not processed due to stopping. It should be noted that abort bit will not interrupt the processing of the current descriptor when it is set, hence it can not resolve a problem of unresponsive DMA. The abort bit can be used to make sure the core goes into idle state as soon as possible and does not create any transactions on the DMA bus anymore.

41.10 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x07B. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

41.11 Implementation

41.11.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

41.11.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual).

41.12 Configuration options

Table 539 shows the configuration options of the core (VHDL generics).

Table 539. Configuration options

Generic	Function	Allowed range	Default
hindex	AHB master index	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB BAR	0 - 16#FFF#	0
pmask	Mask field of the APB BAR	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by the GRAES	0 - NAHBIRQ-1	0
extkeyiv	Support key and IV initalization from signals. If this generic is 1 then the keyin and ivin signals can be used to set key and IV values.	0 - 1	0
scantest	Enable SCAN test support	0 - 1	0

42 GRCAN - CAN 2.0 Controller with DMA

42.1 Overview

The CAN controller is assumed to operate in an AMBA bus system where both the AMBA AHB bus and the APB bus are present. The AMBA APB bus is used for configuration, control and status handling. The AMBA AHB bus is used for retrieving and storing CAN messages in memory external to the CAN controller. This memory can be located on-chip, as shown in the block diagram, or external to the chip.

The CAN controller supports transmission and reception of sets of messages by use of circular buffers located in memory external to the core. Separate transmit and receive buffers are assumed. Reception and transmission of sets of messages can be ongoing simultaneously.

After a set of message transfers has been set up via the AMBA APB interface the DMA controller initiates a burst of read accesses on the AMBA AHB bus to fetch messages from memory, which are performed by the AHB master. The messages are then transmitted by the CAN core. When a programmable number of messages have been transmitted, the DMA controller issues an interrupt.

After the reception has been set up via the AMBA APB interface, messages are received by the CAN core. To store messages to memory, the DMA controller initiates a burst of write accesses on the AMBA AHB bus, which are performed by the AHB master. When a programmable number of messages have been received, the DMA controller issues an interrupt.

The CAN controller can detect a SYNC message and generate an interrupt, which is also available as an output signal from the core. The SYNC message identifier is programmable via the AMBA APB interface. Separate synchronisation message interrupts are provided.

The CAN controller can transmit and receive messages on either of two CAN busses, but only on one at a time. The selection is programmable via the AMBA APB interface.

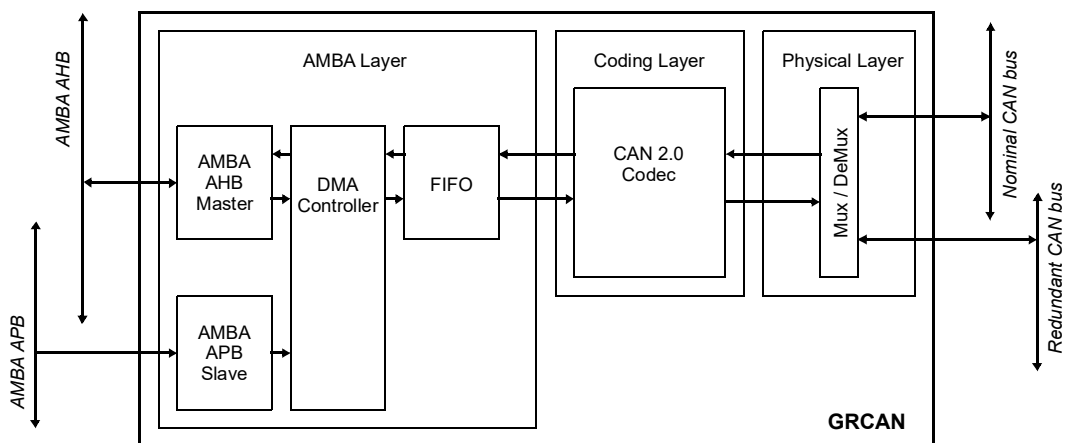
Note that it is not possible to receive a CAN message while transmitting one.


Figure 126. Block diagram

42.1.1 Function

The core implements the following functions:

- CAN protocol
- Message transmission
- Message filtering and reception

GRIP

Apr 2024, Version 2024.1

504

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

- SYNC message reception

- Status and monitoring

- Interrupt generation

- Redundancy selection

42.1.2 Interfaces

The core provides the following external and internal interfaces:

- CAN interface

- AMBA AHB master interface, with sideband signals as per [GRLIB] including:

- cacheability information

- interrupt bus

- configuration information

- diagnostic information

- AMBA APB slave interface, with sideband signals as per [GRLIB] including:

- interrupt bus

- configuration information

- diagnostic information

42.1.3 Hierarchy

The CAN controller core can be partitioned in the following hierarchical elements:

- CAN 2.0 Core

- Redundancy Multiplexer / De-multiplexer

- Direct Memory Access controller

- AMBA APB slave

- AMBA AHB master

42.2 Interface

The external interface towards the CAN bus features two redundant pairs of transmit output and receive input (i.e. 0 and 1).

The active pair (i.e. 0 or 1) is selectable by means of a configuration register bit. Note that all reception and transmission is made over the active pair.

For each pair, there is one enable output (i.e. 0 and 1), each being individually programmable. Note that the enable outputs can be used for enabling an external physical driver. Note that both pairs can be enabled simultaneously. Note that the polarity for the enable/inhibit inputs on physical interface drivers differs, thus the meaning of the enable output is undefined.

Redundancy is implemented by means of Selective Bus Access. Note that the active pair selection above provides means to meet this requirement.

42.3 Protocol

The CAN protocol is based on a CAN 2.0 controller VHDL core. The CAN controller complies with CAN Specification Version 2.0 Part B, except for the overload frame generation.

Note that there are three different CAN types generally defined:

- 2.0A, which considers 29 bit ID messages as an error

GRIP
Apr 2024, Version 2024.1
505
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- 2.0B Passive, which ignores 29 bit ID messages
- 2.0B Active, which handles 11 and 29 bit ID messages

Only 2.0B Active is implemented.

42.4 Status and monitoring

The CAN interface incorporates status and monitoring functionalities. This includes:

- Transmitter active indicator
- Bus-Off condition indicator
- Error-Passive condition indicator
- Over-run indicator
- 8-bit Transmission error counter
- 8-bit Reception error counter

The status is available via a register and is also stored in a circular buffer for each received message.

42.5 Transmission

The transmit channel is defined by the following parameters:

- base address
- buffer size
- write pointer
- read pointer

The transmit channel can be enabled or disabled.

42.5.1 Circular buffer

The transmit channel operates on a circular buffer located in memory external to the CAN controller. The circular buffer can also be used as a straight buffer. The buffer memory is accessed via the AMBA AHB master interface.

Each CAN message occupies 4 consecutive 32-bit words in memory. Each CAN message is aligned to 4 words address boundaries (i.e. the 4 least significant byte address bits are zero for the first word in a CAN message).

The size of the buffer is defined by the CanTxSIZE.SIZE field, specifying the number of CAN messages * 4 that fit in the buffer.

E.g. CanTxSIZE.SIZE =2 means 8 CAN messages fit in the buffer.

Note however that it is not possible to fill the buffer completely, leaving at least one message position in the buffer empty. This is to simplify wrap-around condition checking.

E.g. CanTxSIZE.SIZE =2 means that 7 CAN messages fit in the buffer at any given time.

42.5.2 Write and read pointers

The write pointer (CanTxWR.WRITE) indicates the position+1 of the last CAN message written to the buffer. The write pointer operates on number of CAN messages, not on absolute or relative addresses.

The read pointer (CanTxRD.READ) indicates the position+1 of the last CAN message read from the buffer. The read pointer operates on number of CAN messages, not on absolute or relative addresses.

GRIP
Apr 2024, Version 2024.1
506
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The difference between the write and the read pointers is the number of CAN messages available in the buffer for transmission. The difference is calculated using the buffer size, specified by the CanTxSIZE.SIZE field, taking wrap around effects of the circular buffer into account.

Examples:

- There are 2 CAN messages available for transmit when CanTxSIZE.SIZE=2, CanTxWR.WRITE=2 and CanTxRD.READ=0.

- There are 2 CAN messages available for transmit when CanTxSIZE.SIZE=2, CanTxWR.WRITE =0 and CanTxRD.READ =6.

- There are 2 CAN messages available for transmit when CanTxSIZE.SIZE=2, CanTxWR.WRITE =1 and CanTxRD.READ =7.

- There are 2 CAN messages available for transmit when CanTxSIZE.SIZE=2, CanTxWR.WRITE =5 and CanTxRD.READ =3.

When a CAN message has been successfully transmitted, the read pointer (CanTxRD.READ) is automatically incremented, taking wrap around effects of the circular buffer into account. Whenever the write pointer CanTxWR.WRITE and read pointer CanTxRD.READ are equal, there are no CAN messages available for transmission.

42.5.3   Location

The location of the circular buffer is defined by a base address (CanTxADDR.ADDR), which is an absolute address. The location of a circular buffer is aligned on a 1kbyte address boundary.

42.5.4   Transmission procedure

When the channel is enabled (CanTxCTRL.ENABLE=1), as soon as there is a difference between the write and read pointer, a message transmission will be started. Note that the channel should not be enabled if a potential difference between the write and read pointers could be created, to avoid the message transmission to start prematurely.

A message transmission will begin with a fetch of the complete CAN message from the circular buffer to a local fetch-buffer in the CAN controller. After a successful data fetch, a transmission request will be forwarded to the CAN core. If there is at least an additional CAN message available in the circular buffer, a prefetch of this CAN message from the circular buffer to a local prefetch-buffer in the CAN controller will be performed. The CAN controller can thus hold two CAN messages for transmission: one in the fetch buffer, which is fed to the CAN core, and one in the prefetch buffer.

After a message has been successfully transmitted, the prefetch-buffer contents are moved to the fetch buffer (provided that there is message ready). The read pointer (CanTxRD.READ) is automatically incremented after a successful transmission, i.e. after the fetch-buffer contents have been transmitted, taking wrap around effects of the circular buffer into account. If there is at least an additional CAN message available in the circular buffer, a new prefetch will be performed.

If the write and read pointers are equal, no more prefetches and fetches will be performed, and transmission will stop.

If the single shot mode is enabled for the transmit channel (CanTxCTRL.SINGLE=1), any message for which the arbitration is lost, or failed for some other reason, will lead to the disabling of the channel (CanTxCTRL.ENABLE=0), and the message will not be put up for re-arbitration.

Interrupts are provided to aid the user during transmission, as described in detail later in this section. The main interrupts are the Tx, TxEmpty and TxIrq which are issued on the successful transmission of a message, when all messages have been transmitted successfully and when a predefined number of messages have been transmitted successfully. The TxLoss interrupt is issued whenever transmission arbitration has been lost, could also be caused by a communications error. The TxSync interrupt is issued when a message matching the SYNC Code Filter Register.SYNC and SYNC Mask Filter Reg-

GRIP

Apr 2024, Version 2024.1

507

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

ister.MASK registers is successfully transmitted. Additional interrupts are provided to signal error conditions on the CAN bus and AMBA bus.

42.5.5 Straight buffer

It is possible to use the circular buffer as a straight buffer, with a higher granularity than the 1kbyte address boundary limited by the base address (CanTxADDR.ADDR) field.

While the channel is disabled, the read pointer (CanTxRD.READ) can be changed to an arbitrary value pointing to the first message to be transmitted, and the write pointer (CanTxWR.WRITE) can be changed to an arbitrary value.

When the channel is enabled, the transmission will start from the read pointer and continue to the write pointer.

42.5.6 AMBA AHB error

Definition:

- a message fetch occurs when no other messages is being transmitted
- a message prefetch occurs when a previously fetched message is being transmitted
- the local fetch buffer holds the message being fetched
- the local prefetch buffer holds the message being prefetched
- the local fetch buffer holds the message being transmitted by the CAN core
- a successfully prefetched message is copied from the local prefetch buffer to the local fetch buffer when that buffer is freed after a successful transmission.

An AHB error response occurring on the AMBA AHB bus while a CAN message is being fetched will result in a TxAHBErr interrupt.

If the CanCONF.ABORT bit is set to 0b, the channel causing the AHB error will skip the message being fetched from memory and will increment the read pointer. No message will be transmitted.

If the CanCONF.ABORT bit is set to 1b, the channel causing the AHB error will be disabled (CanTxCTRL.ENABLE is cleared automatically to 0 b). The read pointer can be used to determine which message caused the AHB error. Note that it could be any of the four word accesses required to read a message that caused the AHB error.

If the CanCONF.ABORT bit is set to 1b, all accesses to the AMBA AHB bus will be disabled after an AMBA AHB error occurs, as indicated by the CanSTAT.AHBErr bit being 1b. The accesses will be disabled until the CanSTAT register is read, and automatically clearing bit CanSTAT.AHBErr.

An AHB error response occurring on the AMBA AHB bus while a CAN message is being prefetched will not cause an interrupt, but will stop the ongoing prefetch and further prefetch will be prevented temporarily. The ongoing transmission of a CAN message from the fetch buffer will not be affected. When the fetch buffer is freed after a successful transmission, a new fetch will be initiated, and if this fetch results in an AHB error response occurring on the AMBA AHB bus, this will be handled as for the case above. If no AHB error occurs, prefetch will be allowed again.

42.5.7 Enable and disable

When an enabled transmit channel is disabled (CanTxCTRL.ENABLE=0b), any ongoing CAN message transfer request will not be aborted until a CAN bus arbitration is lost or the message has been sent successfully. If the message is sent successfully, the read pointer (CanTxRD.READ) is automatically incremented. Any associated interrupts will be generated.

The progress of the any ongoing access can be observed via the CanTxCTRL.ONGOING bit. The CanTxCTRL.ONGOING must be 0b before the channel can be re-configured safely (i.e. changing

GRIP

Apr 2024, Version 2024.1

508

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

address, size or read pointer). It is also possible to wait for the Tx and TxLoss interrupts described hereafter.

The channel can be re-enabled again without the need to re-configure the address, size and pointers.

Priority inversion is handled by disabling the transmitting channel, i.e. setting CanTxC-TRL.ENABLE=0b as described above, and observing the progress, i.e. reading via the CanTxC-TRL.ONGOING bit as described above. When the transmit channel is disabled, it can be re-configured and a higher priority message can be transmitted. Note that the single shot mode does not require the channel to be disabled, but the progress should still be observed as above.

No message transmission is started while the channel is not enabled.

42.5.8 Interrupts

During transmission several interrupts can be generated:

*   TxLoss: Message arbitration lost for transmit (could be caused by communications error, as indicated by other interrupts as well)

*   TxErrCntr: Error counter incremented for transmit

*   TxSync: Synchronization message transmitted

*   Tx: Successful transmission of one message

*   TxEmpty: Successful transmission of all messages in buffer

*   TxIrq: Successful transmission of a predefined number of messages

*   TxAHBErr: AHB access error during transmission

*   Off: Bus-off condition

*   Pass: Error-passive condition

The Tx, TxEmpty and TxIrq interrupts are only generated as the result of a successful message transmission, after the CanTxRD.READ pointer has been incremented.

42.6   Reception

The receive channel is defined by the following parameters:

*   base address
*   buffer size
*   write pointer
*   read pointer

The receive channel can be enabled or disabled.

42.6.1 Circular buffer

The receive channel operates on a circular buffer located in memory external to the CAN controller. The circular buffer can also be used as a straight buffer. The buffer memory is accessed via the AMBA AHB master interface.

Each CAN message occupies 4 consecutive 32-bit words in memory. Each CAN message is aligned to 4 words address boundaries (i.e. the 4 least significant byte address bits are zero for the first word in a CAN message).

The size of the buffer is defined by the CanRxSIZE.SIZE field, specifying the number of CAN messages * 4 that fit in the buffer.

E.g. CanRxSIZE.SIZE=2 means 8 CAN messages fit in the buffer.

Note however that it is not possible to fill the buffer completely, leaving at least one message position in the buffer empty. This is to simplify wrap-around condition checking.

E.g. CanRxSIZE.SIZE=2 means that 7 CAN messages fit in the buffer at any given time.

42.6.2 Write and read pointers

The write pointer (CanRxWR.WRITE) indicates the position+1 of the last CAN message written to the buffer. The write pointer operates on number of CAN messages, not on absolute or relative addresses.

The read pointer (CanRxRD.READ) indicates the position+1 of the last CAN message read from the buffer. The read pointer operates on number of CAN messages, not on absolute or relative addresses.

The difference between the write and the read pointers is the number of CAN message positions available in the buffer for reception. The difference is calculated using the buffer size, specified by the CanRxSIZE.SIZE field, taking wrap around effects of the circular buffer into account.

Examples:

*   There are 2 CAN messages available for read-out when CanRxSIZE.SIZE=2, Can-RxWR.WRITE=2 and CanRxRD.READ=0.

*   There are 2 CAN messages available for read-out when CanRxSIZE.SIZE=2, Can-RxWR.WRITE =0 and CanRxRD.READ=6.

*   There are 2 CAN messages available for read-out when CanRxSIZE.SIZE=2, Can-RxWR.WRITE =1 and CanRxRD.READ=7.

*   There are 2 CAN messages available for read-out when CanRxSIZE.SIZE=2, Can-RxWR.WRITE =5 and CanRxRD.READ=3.

When a CAN message has been successfully received and stored, the write pointer (Can-RxWR.WRITE) is automatically incremented, taking wrap around effects of the circular buffer into account. Whenever the read pointer CanRxRD.READ equals (CanRxWR.WRITE+1) modulo (Can-RxSIZE.SIZE*4), there is no space available for receiving another CAN message.

The error behavior of the CAN core is according to the CAN standard, which applies to the error counter, buss-off condition and error-passive condition.

42.6.3 Location

The location of the circular buffer is defined by a base address (CanRxADDR.ADDR), which is an absolute address. The location of a circular buffer is aligned on a 1kbyte address boundary.

42.6.4 Reception procedure

When the channel is enabled (CanRxCTRL.ENABLE=1), and there is space available for a message in the circular buffer (as defined by the write and read pointer), as soon as a message is received by the CAN core, an AMBA AHB store access will be started. The received message will be temporarily stored in a local store-buffer in the CAN controller. Note that the channel should not be enabled until the write and read pointers are configured, to avoid the message reception to start prematurely

After a message has been successfully stored the CAN controller is ready to receive a new message. The write pointer (CanRxWR.WRITE) is automatically incremented, taking wrap around effects of the circular buffer into account.

Interrupts are provided to aid the user during reception, as described in detail later in this section. The main interrupts are the Rx, RxFull and RxIrq which are issued on the successful reception of a message, when the message buffer has been successfully filled and when a predefined number of messages have been received successfully. The RxMiss interrupt is issued whenever a message has been received but does not match a message filtering setting, i.e. neither for the receive channel nor for the SYNC message described hereafter.

The RxSync interrupt is issued when a message matching the SYNC Code Filter Register.SYNC and SYNC Mask Filter Register.MASK registers has been successfully received. Additional interrupts are provided to signal error conditions on the CAN bus and AMBA bus.

42.6.5 Straight buffer

It is possible to use the circular buffer as a straight buffer, with a higher granularity than the 1kbyte address boundary limited by the base address (CanRxADDR.ADDR) field.

While the channel is disabled, the write pointer (CanRxWR.WRITE) can be changed to an arbitrary value pointing to the first message to be received, and the read pointer (CanRxRD.READ) can be changed to an arbitrary value.

When the channel is enabled, the reception will start from the write pointer and continue to the read pointer.

42.6.6 AMBA AHB error

An AHB error response occurring on the AMBA AHB bus while a CAN message is being stored will result in an RxAHBErr interrupt.

If the CanCONF.ABORT bit is set to 0b, the channel causing the AHB error will skip the received message, not storing it to memory. The write pointer will be incremented.

If the CanCONF.ABORT bit is set to 1b, the channel causing the AHB error will be disabled (Can-RxCTRL.ENABLE is cleared automatically to 0b). The write pointer can be used to determine which message caused the AHB error. Note that it could be any of the four word accesses required to writ a message that caused the AHB error.

If the CanCONF.ABORT bit is set to 1b, all accesses to the AMBA AHB bus will be disabled after an AMBA AHB error occurs, as indicated by the CanSTAT.AHBErr bit being 1b. The accesses will be disabled until the CanSTAT register is read, and automatically clearing bit CanSTAT.AHBErr.

42.6.7 Enable and disable

When an enabled receive channel is disabled (CanRxCTRL.ENABLE=0b), any ongoing CAN message storage on the AHB bus will not be aborted, and no new message storage will be started. Note that only complete messages can be received from the CAN core. If the message is stored successfully, the write pointer (CanRxWR.WRITE) is automatically incremented. Any associated interrupts will be generated.

The progress of the any ongoing access can be observed via the CanRxCTRL.ONGOING bit. The CanRxCTRL.ONGOING must be 0b before the channel can be re-configured safely (i.e. changing address, size or write pointer). It is also possible to wait for the Rx and RxMiss interrupts described hereafter.

The channel can be re-enabled again without the need to re-configure the address, size and pointers.

No message reception is performed while the channel is not enabled

42.6.8 Interrupts

During reception several interrupts can be generated:

- RxMiss: Message filtered away for receive
- RxErrCntr: Error counter incremented for receive
- RxSync: Synchronization message received
- Rx: Successful reception of one message
- RxFull: Successful reception of all messages possible to store in buffer

GRIP

Apr 2024, Version 2024.1

511

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- RxIrq: Successful reception of a predefined number of messages
- RxAHBErr: AHB access error during reception
- OR: Over-run during reception
- OFF: Bus-off condition
- PASS: Error-passive condition

The Rx, RxFull and RxIrq interrupts are only generated as the result of a successful message reception, after the CanRxWR.WRITE pointer has been incremented.

The OR interrupt is generated when a message is received while a previously received message is still being stored. A full circular buffer will lead to OR interrupts for any subsequently received messages. Note that the last message stored which fills the circular buffer will not generate an OR interrupt. The overrun is also reported with the CanSTAT.OR bit, which is cleared when reading the register.

The error behavior of the CAN core is according to the CAN standard, which applies to the error counter, buss-off condition and error-passive condition.

42.7   Global reset and enable

When the CanCTRL.RESET bit is set to 1b, a reset of the core is performed. The reset clears all the register fields to their default values. Any ongoing CAN message transfer request will be aborted, potentially violating the CAN protocol.

When the CanCTRL.ENABLE bit is cleared to 0b, the CAN core is reset and the configuration bits CanCONF.SCALER, CanCONF.PS1, CanCONF.PS2, CanCONF.RSJ and CanCONF.BPR may be modified. When disabled, the CAN controller will be in sleep mode not affecting the CAN bus by only sending recessive bits. Note that the CAN core requires that 10 recessive bits are received before any reception or transmission can be initiated. This can be caused either by no unit sending on the CAN bus, or by random bits in message transfers.

42.8   Interrupt outputs

Three interrupts are implemented by the CAN interface:

Index:	Name:	Description:
0	IRQ	Common output from interrupt handler
1	TxSYNC	Synchronization message transmitted (optional)
2	RxSYNC	Synchronization message received (optional)

The interrupts are configured by means of the *pirq* VHDL generic and the *singleirq* VHDL generic.

Unlike other IPs in the GRLIB IP core library, GRCAN generates level-based interrupts. This means that the output interrupt, pirq, will be asserted for as long as the core interrupt registers contain unmasked events. It is therefore recommended to clear the content of the interrupt registers after attending the interrupt in order to guarantee that pirq gets properly deasserted.

42.9   Endianness

The core is designed for big-endian systems.

42.10   AXI support

The core is designed for an AMBA system but can be adapted for AXI using the AHBM2AXI adapter.

42.11 Registers

The core is programmed through registers mapped into APB address space.

*Table 542.*GRCAN registers

	0					0				0	0	0	0	0	0
	rw					rw				rw	rw	rw	rw	rw	rw

31-24: SCALER   Prescaler setting, 8-bit: system clock / (SCALER +1)
23-20: PS1   Phase Segment 1, 4-bit: (valid range 1 to 15)
19-16: PS2   Phase Segment 2, 4-bit: (valid range 2 to 8)
14-12: RSJ   ReSynchronization Jumps, 3-bit: (valid range 1 to 4)

GRIP

Apr 2024, Version 2024.1

513

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

9:8:	BPR	Baud rate, 2-bit:
		00b = system clock / (SCALER +1) / 1
		01b = system clock / (SCALER +1) / 2
		10b = system clock / (SCALER +1) / 4
		11b = system clock / (SCALER +1) / 8
5:	SAM	Single sample when 0b. Triple sample when 1b.
4:	SILENT	Listen only to the CAN bus, send recessive bits.
3:	SELECT	Selection receiver input and transmitter output:
		Select receive input 0 as active when 0b,
		Select receive input 1 as active when 1b
		Select transmit output 0 as active when 0b,
		Select transmit output 1 as active when 1b
2:	ENABLE1	Set value of output 1 enable
1:	ENABLE0	Set value of output 0 enable
0:	ABORT	Abort transfer on AHB ERROR

All bits are cleared to 0 at reset.

Note that constraints on PS1, PS2 and RSJ are defined as:

- PS1 +1 >= PS2

- PS1 > PS2

- PS2 >= RSJ

Note that CAN standard TSEG1 is defined by PS1+1.

Note that CAN standard TSEG2 is defined by PS2.

Note that the SCALER setting defines the CAN time quantum, together with the BPR setting:

system clock / ((SCALER+1) * BPR)

where SCALER is in range 0 to 255, and the resulting division factor due to BPR is 1, 2, 4 or 8.

For a quantum equal to one system clock period, an additional quantum is added to the node delay. Note that for minimizing the node delay, then set either SCALER > 0 or BRP > 0.

Note that the resulting bit rate is:

system clock / ((SCALER+1) * BPR * (1+ PS1+1 + PS2))

where PS1 is in the range 1 to 15, and PS2 is in the range 2 to 8.

Note that RSJ defines the number of allowed re-synchronization jumps according to the CAN standard, being in the range 1 to 4.

For SAM = 0b (single), the bus is sampled once; recommended for high speed buses (SAE class C).

For SAM = 1b (triple), the bus is sampled three times; recommended for low/medium speed buses (SAE class A and B) where filtering spikes on the bus line is beneficial.

Note that the transmit or receive channel active during the AMBA AHB error is disabled if the ABORT bit is set to 1b. Note that all accesses to the AMBA AHB bus will be disabled after an AMBA AHB error occurs while the ABORT bit is set to 1b. The accesses will be disabled until the CanSTAT register is read.

42.11.2 Status Register

Table 544.0x004 - STAT - Status register

31		28	27		24	23								16
TxChannels			RxChannels			TxErrCntr								
0			0			0								
r			r			r								

15								8	7	6	5	4	3	2	1	0
RxErrCntr												Active	AHB Err	OR	Off	Pass
0												0	0	0	0	0
r												r	r	r	r	r

31-28:	TxChannels	Number of TxChannels -1, 4-bit
27-24:	RxChannels	Number of RxChannels -1, 4-bit
23-16:	TxErrCntr	Transmission error counter, 8-bit
15-8:	RxErrCntr	Reception error counter, 8-bit
4:	ACTIVE	Transmission ongoing
3:	AHBErr	AMBA AHB master interface blocked due to previous AHB error
2:	OR	Overrun during reception
1:	OFF	Bus-off condition
0:	PASS	Error-passive condition

All bits are cleared to 0 at reset.

The OR bit is set if a message with a matching ID is received and cannot be stored via the AMBA AHB bus, this can be caused by bandwidth limitations or when the circular buffer for reception is already full.

The OR and AHBErr status bits are cleared when the register has been read.

Note that TxErrCntr and RxErrCntr are defined according to CAN protocol.

Note that the AHBErr bit is only set to 1b if an AMBA AHB error occurs while the Can-CONF.ABORT bit is set to 1b.

42.11.3 Control Register

Table 545.0x008 - CTRL - Control Register

31		2	1	0
			Reset	Enable
			0	0
			rw	rw

1:	RESET	Reset complete core when 1
0:	ENABLE	Enable CAN controller, when 1. Reset CAN controller, when 0

All bits are cleared to 0 at reset.

Note that RESET is read back as 0b.

Note that ENABLE should be cleared to 0b to while other settings are modified, ensuring that the CAN core is properly synchronized.

											Sin-gle	Ong oing	Ena ble
											0	0	0
											rw	rw	rw

2:      SINGLE   Single shot mode
1:      ONGOING Transmission ongoing
0:      ENABLE   Enable channel

All bits are cleared to 0 at reset.

GRIP
Apr 2024, Version 2024.1

516

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Note that if the SINGLE bit is 1b, the channel is disabled (i.e. the ENABLE bit is cleared to 0b) if the arbitration on the CAN bus is lost.

Note that in the case an AHB bus error occurs during an access while fetching transmit data, and the CanCONF.ABORT bit is 1b, then the ENABLE bit will be reset automatically.

At the time the ENABLE is cleared to 0b, any ongoing message transmission is not aborted, unless the CAN arbitration is lost or communication has failed.

Note that the ONGOING bit being 1b indicates that message transmission is ongoing and that configuration of the channel is not safe.

42.11.7 Transmit Channel Address Register

*Table 549.*0x204 - TXADDR - Transmit Channel Address Register

31	10	9	0
ADDR			
0			
rw			

31-10:   ADDR   Base address for circular buffer

All bits are cleared to 0 at reset.

42.11.8 Transmit Channel Size Register

*Table 550.*0x208 - TXSIZE - Transmit Channel Size Register

31	21	20	6	5	0
		SIZE			
		0			
		rw			

20-6:   SIZE   The size of the circular buffer is SIZE*4 messages

All bits are cleared to 0 at reset.

Valid SIZE values are between 0 and 16384.

Note that each message occupies four 32-bit words.

Note that the resulting behavior of invalid SIZE values is undefined.

Note that only (SIZE*4)-1 messages can be stored simultaneously in the buffer. This is to simplify wrap-around condition checking.

The width of the SIZE field may be made configurable by means of a VHDL generic. In this case it should be set to 16-1 bits width.

42.11.9 Transmit Channel Write Register

*Table 551.*0x20C - TXWR - Transmit Channel Write Register

31	20	19	4	3	0
		WRITE			
		0			
		rw			

19-4:   WRITE   Pointer to last written message +1

All bits are cleared to 0 at reset.

The WRITE field is written to in order to initiate a transfer, indicating the position +1 of the last message to transmit.

Note that it is not possible to fill the buffer. There is always one message position in buffer unused. Software is responsible for not over-writing the buffer on wrap around (i.e. setting WRITE=READ).

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

42.11.10 Transmit Channel Read Register

Table 552. 0x210 - TXRD - Transmit Channel Read Register

31	20	19	4	3	0
		READ			
		0			
		rw			

19-4:   READ   Pointer to last read message +1

All bits are cleared to 0 at reset.

The READ field is written to automatically when a transfer has been completed successfully, indicating the position +1 of the last message transmitted.

Note that the READ field can be use to read out the progress of a transfer.

Note that the READ field can be written to in order to set up the starting point of a transfer. This should only be done while the transmit channel is not enabled.

Note that the READ field can be automatically incremented even if the transmit channel has been disabled, since the last requested transfer is not aborted until CAN bus arbitration is lost.

When the Transmit Channel Read Pointer catches up with the Transmit Channel Write Register, an interrupt is generated (TxEmpty). Note that this indicates that all messages in the buffer have been transmitted.

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

42.11.11 Transmit Channel Interrupt Register

Table 553. 0x214 - TXIRQ - Transmit Channel Interrupt Register

31	20	19	4	3	0
		IRQ			
		0			
		rw			

19-4:   IRQ   Interrupt is generated when CanTxRD.READ=IRQ, as a consequence of a message transmission

All bits are cleared to 0 at reset.

Note that this indicates that a programmed number of messages have been transmitted.

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

42.11.12 Receive Channel Control Register

Table 554. 0x300 - RXCTRL - Receive Channel Control Register

31		2	1	0
			OnGoing	Enable
			0	0
			r	rw

1:    ONGOING   Reception ongoing (read-only)
0:    ENABLE   Enable channel

All bits are cleared to 0 at reset.

Note that in the case an AHB bus error occurs during an access while fetching transmit data, and the CanCONF.ABORT bit is 1b, then the ENALBE bit will be reset automatically.

At the time the ENABLE is cleared to 0b, any ongoing message reception is not aborted

Note that the ONGOING bit being 1b indicates that message reception is ongoing and that configuration of the channel is not safe.

42.11.13 Receive Channel Address Register

Table 555. 0x304 - RXADDR - Receive Channel Address Register

31	10	9	0
ADDR			
0			
rw			

31-10:   ADDR   Base address for circular buffer

All bits are cleared to 0 at reset.

42.11.14 Receive Channel Size Register

Table 556. 0x308 - RXSIZE - Receive Channel Size Register

31	21	20	6	5	0
		SIZE			
		0			
		rw			

20-6:   SIZE   The size of the circular buffer is SIZE*4 messages

All bits are cleared to 0 at reset.

Valid SIZE values are between 0 and 16384.

Note that each message occupies four 32-bit words.

Note that the resulting behavior of invalid SIZE values is undefined.

Note that only (SIZE*4)-1 messages can be stored simultaneously in the buffer. This is to simplify wrap-around condition checking.

The width of the SIZE field may be made configurable by means of a VHDL generic. In this case it should be set to 16-1 bits width.

28-0:   AC   Acceptance Code, used in comparison with the received message

All bits are cleared to 0at reset.

Note that Base ID is bits 28 to 18 and Extended ID is bits 17 to 0.

A message ID is matched when:

$$((Received\text{-}ID\ XOR\ CanRxCODE.AC)\ AND\ CanRxMASS.AM) = 0$$

42.11.20 Interrupt registers

The interrupt registers give complete freedom to the software, by providing means to mask interrupts, clear interrupts, force interrupts and read interrupt status.

When an interrupt occurs the corresponding bit in the Pending Interrupt Register is set. The normal sequence to initialize and handle a module interrupt is:

• Set up the software interrupt-handler to accept an interrupt from the module.

• Read the Pending Interrupt Register to clear any spurious interrupts.

• Initialize the Interrupt Mask Register, unmasking each bit that should generate the module interrupt.

• When an interrupt occurs, read the Pending Interrupt Status Register in the software interrupt-handler to determine the causes of the interrupt.

• Handle the interrupt, taking into account all causes of the interrupt.

• Clear the handled interrupt using Pending Interrupt Clear Register.

Masking interrupts: After reset, all interrupt bits are masked, since the Interrupt Mask Register is zero. To enable generation of a module interrupt for an interrupt bit, set the corresponding bit in the Interrupt Mask Register.

Clearing interrupts: All bits of the Pending Interrupt Register are cleared when it is read or when the Pending Interrupt Masked Register is read. Reading the Pending Interrupt Masked Register yields the

contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register. Selected bits can be cleared by writing ones to the bits that shall be cleared to the Pending Interrupt Clear Register.

Forcing interrupts: When the Pending Interrupt Register is written, the resulting value is the original contents of the register logically OR-ed with the write data. This means that writing the register can force (set) an interrupt bit, but never clear it.

Reading interrupt status: Reading the Pending Interrupt Status Register yields the same data as a read of the Pending Interrupt Register, but without clearing the contents.

Reading interrupt status of unmasked bits: Reading the Pending Interrupt Masked Status Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register, but without clearing the contents.

The interrupt registers comprise the following:

- Pending Interrupt Masked Status Register   [CanPIMSR]   R
- Pending Interrupt Masked Register   [CanPIMR]   R
- Pending Interrupt Status Register   [CanPISR]   R
- Pending Interrupt Register   [CanPIR]   R/W
- Interrupt Mask Register   [CanIMR]   R/W
- Pending Interrupt Clear Register   [CanPICR]   W

Table 562. Interrupt registers

42.13 Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x03D. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

42.14 Implementation

42.14.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

42.14.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

42.15 Configuration options

Table 564 shows the configuration options of the core (VHDL generics).

*Table 564.*Configuration options

Generic name	Function	Allowed range	Default
hindex	AHB master index.	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar.	0 - 16#FFF#	0
pmask	Mask field of the APB bar.	0 - 16#FFF#	16#FFC#
pirq	Interrupt line used by the GRCAN.	0 - NAHBIRQ-1	0
singleirq	Implement only one common interrupt	0 - 1	0
txchannels	Number of transmit channels	1 - 1	1
rxchannels	Number of receive channels	1 - 1	1
ptrwidth	Width of message pointers	16 - 16	16

43   GRCANFD - CAN Flexible Data-Rate Controller with CANOpen support

43.1   Overview

GRCANFD implements a CAN-FD controller with a top DMA layer handling the configuration of the IP and the communication between the internal CAN-FD controller and a memory external to the IP. It features a generic bus master interface and an AMBA 2.0 APB slave interface. The first one is used for fetching and storing CAN frames from/to external memory. Wrappers adapting this interface to both AMBA 2.0 AHB and AXI4 are available. The APB interface is used for the configuration of the IP.

The internal codec is the CAN-FD controller implementing the MAC and PL sub-layers of the protocol: transmission and reception of frames, error detection and signaling, frame acknowledgment, bit resynchronization, etc. This functionality is compliant with the ISO standard 11898-1:2015 (2nd edition).

Additionally, GRCANFD implements the CANOpen Minimal Set Protocol as per the ECSS-E-ST-50-15C specification, section 9. The IP acts as a slave node (i.e. cannot operate as a CANOpen master). This functionality allows an external CAN node to access the AMBA address space of the device by means of CANOpen PDOs, similarly to RMAP in SpaceWire. The functionality can be configured upon start-up to enable automatic operation in simple applications without need of software intervention. The user can switch between the standard and the CANOpen mode in run-time via the APB interface.

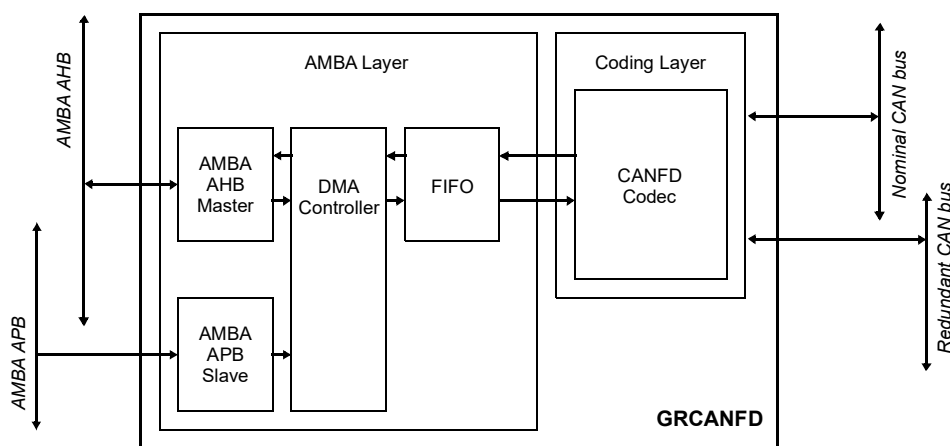
The following block diagram depicts the main components of GRCANFD. The diagram assumes that the AHB wrapper is used, but the functionality is equivalent if the generic bus master or the AXI wrapper are chosen instead.


Figure 128. Block diagram

The top AMBA layer contains the memory-mapped registers for the configuration of the IP, accessible through the APB interface. It also controls the global functionality of the IP by fetching frames to be transmitted from the external memory (TX channel) and by storing received frames into the external memory (RX channel) in standard mode, and by processing any input CANOpen commands and providing the reply when applicable in CANOpen mode.

This layer also includes 2 internal SRAMs for the transmit and receive channels. These buffers are used to store the data bytes of a frame, whereas the control bits are stored in registers. The size of each buffer is separately configured via generics, expressed as the number of CAN-FD messages that can be fitted, resulting in memories ranging from 64 to 512 bytes. Note that these buffers are only used in standard mode, no additional memory is required in CANOpen mode.

GRIP

Apr 2024, Version 2024.1

528

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The external memory where the frames are stored in standard mode is commonly referred to as the circular buffers, and it may be located on-chip or external to the chip. The IP will write and read from this memory through the master interface. There is a separate buffer for the TX and for the RX channels. Although the default topology is circular, straight buffers are also supported. The content of the circular buffers is handled by pointers.

In standard mode, the frames are temporarily buffered in the internal SRAMs. For transmission, the DMA engine fetches frames from the TX circular buffer and the CAN-FD codec transmits them as soon as the SRAM contains a full frame. Likewise, frames received by the codec are temporarily stored in the internal SRAM, and written to the RX circular buffer as soon as the reception is complete. The communication with the circular buffer takes place via the bus master interface.

In CANOpen mode, GRCANFD receives and acknowledges any incoming frame according to the ISO standard, regardless of its format. The frame is then decoded to identify if it is a PDO, SYNC or Heartbeat command, otherwise it is discarded. The CANOpen master node can therefore issue read and write commands, as well as to trigger interrupts in the slave via the CAN interface.

The IP may have up to 3 separate interrupt lines. The first one is the common line, which comprises interrupts for reception and transmission of frames, update on the status of the IP and events on the CAN bus. The other two interrupt lines are used for SYNC messages (for TX and RX channel, respectively) in standard mode. All interrupts are maskable by accessing the APB registers.

GRCANFD implements bus redundancy: its interface includes two RX and two TX lines. The pair of lines to be used can be selected via the AMBA APB interface. The transmission and reception of frames can only occur on one bus at a time. An additional signal is included to enable or disable the output of the external CAN-FD transceiver.

43.1.1 Function

The core implements the following functions:

- CAN-FD core functionality

- TX channel: frame fetching, buffering and transmission

- RX channel: frame reception, filtering, buffering and storage

- CANOpen interpreter supporting PDOs 1-4, SYNC and Heartbeat commands

- SYNC message detection for both TX and RX channels

- Status and monitoring of the IP

- Interrupt generation

- Redundancy selection

43.1.2 Interfaces

The IP core contains the following interfaces:

- 2 CAN interfaces (nominal and redundant)

- Generic bus master interface. If connected to the AMBA AHB wrapper, it includes the sideband signals as per [GRLIB] including:

  - cacheability information

  - interrupt bus

  - configuration information

  - diagnostic information

- AMBA APB slave interface, with sideband signals as per [GRLIB] including:

  - interrupt bus

GRIP

529

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- configuration information

- diagnostic information

• Configuration interface to set the values of some critical registers after reset.

43.1.3 Hierarchy

GRCANFD can be partitioned in the following main hierarchical elements:

• CAN-FD controller/codec

• CAN bus selector

• Internal SRAM (FIFO)

• Direct Memory Access controller with CANOpen support

• AMBA APB slave

• Generic bus master

• (Optional) Bridges adapting the generic bus master to AMBA 2.0 AHB or AXI4

43.2 CAN Interface

The external interface towards the CAN bus features two redundant pairs of transmit output and receive input (i.e. 0 and 1).

The active pair (i.e. 0 or 1) is selectable by means of a configuration register bit. Note that all reception and transmission is made over the active pair.

For each pair, there is one enable output (i.e. 0 and 1), each being individually programmable. The enable outputs can be used for enabling an external physical driver. Note that both pairs can be enabled simultaneously. The polarity for the enable/inhibit inputs on physical interface drivers may differ, thus the meaning of the enable output is undefined.

Redundancy is implemented by means of Selective Bus Access. Note that the active pair selection above provides means to meet this requirement.

43.3 Protocol compliance

The CAN-FD controller included in GRCANFD is a VHDL core compliant with the ISO standard for CAN with the FD extension: ISO 11898-1:2015 (2nd edition). The minimal CANOpen implementation is compatible with the ECSS-E-ST-50-15C specification.

43.4 Status and monitoring

The GRCANFD register interface provides status and monitoring data, including:

• Operational mode (standard or CANOpen)

• Ongoing transmission

• Bus-off state

• Error-passive mode

• Overrun during reception

• Transmitter error counter (8 bits)

• Receiver error counter (8 bits)

Some of the previous indicators are also written to the circular buffer every time a frame is received and stored in standard mode. This is described later in 43.5.2. Note that this only applies to the RX channel.

43.5 CAN and CAN-FD frames

43.5.1 Frame formats

As defined in the CAN-FD standard, GRCANFD supports the following formats for the transmission and reception of data frames:

•   Classical Base Frame Format (CBFF)

•   Classical Extended Frame Format (CEFF)

•   FD Base Frame Format (FBFF)

•   FD Extended Frame Format (FEFF)

Remote frames are compatible with the classical CAN formats (CBFF and CEFF), but not with the new FD formats (FBFF and FEFF), as per the standard. Error Frames (EF) and Overload Frames (OL) are fully supported too.

The following parameters define the format of a frame. A brief description and additional considerations when working with the IP are included. For a complete overview on the formats and their corresponding fields, please refer to the ISO standard for CAN-FD.

•   ID: identifier of the frame. It consists of two parts: the base ID (11 bits) and the extended ID (18 bits, optional). Frames with Base format (CBFF and FBFF) only use the base ID, whereas frames with Extended format (CEFF and FEFF) use both.

•   IDE: this parameter selects between Base (0b) and Extended Format (1b). It determines if the extended ID shall be appended to the base ID when building a frame, as described above. This parameter does not depend on whether it is an FD frame or not, so the value of other bits such as FDF or BRS is irrelevant.

•   RTR: this parameter selects between Data (0b) and Remote frames (1b). Remote frames are only compatible with classical CAN frames. This means that it must be avoided to set both RTR and FDF to 1b when describing a frame, as the behavior is undefined.

•   FDF: this parameter determines if the frame has classical (0b: CBFF and CEFF) or FD format (1b: FBFF and FEFF). The FD format allows to transmit larger payloads of up to 64 bytes, and features a more robust CRC algorithm: CRC-17 or CRC-21, depending on the data length. Optionally, it also enables the possibility of switching to a higher bit-rate. This depends on the configuration of the BRS bit, as described below. When setting FDF to 1b, no Remote frames shall be requested (i.e. RTR should be set to 0b).

•   BRS: this bit determines whether the bit-rate shall be switched for the data phase of a frame. It is only meaningful for FD frames (FDF set to 1b). Therefore, the bit is ignored for classical CAN frames (FDF to 0b).

•   DLC: it selects the data length of the frame. Its encoding varies depending on whether FD format is used or not. For classical frames, the maximum payload is 8 bytes, whereas FD formats may contain up to 64 bytes of data.

It is important to remark that it is optional to enable the BRS bit for FD frames. FD frames with no bit-rate switching still present the advantage of enabling larger data payloads than in classical CAN frames with more robust CRC algorithms, although the full frame would be transmitted at a constant, nominal bit-rate.

43.5.2 Frame memory mapping (standard mode only)

A descriptor is the minimum unit used to represent a frame. It consists of four 32-bit words. The number of descriptors needed to represent a frame varies from 1 to 5. For classical CAN frames (CBFF and CEFF formats) only one descriptor is needed. For CAN-FD frames (FBFF and FEFF formats) the number of descriptors depends on the data length of the frame: whereas frames with up to 8 bytes only

GRIP
Apr 2024, Version 2024.1

531

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

require 1 descriptor, as with classical CAN frames, frames with 64 bytes of data payload require 5 descriptors.

The first descriptor in a frame always includes the control bits describing the frame, as well as information regarding the status of the bus and the IP. This is applicable to both classical CAN and CAN-FD frames. If a frame requires more than one descriptor, the successive descriptors (from 2 up to 5) do not replicate the control and status bits, but only include data bytes. Therefore, each of these descriptors may contain up to 16 bytes of data. Descriptors belonging to the same frame shall always appear consecutively in the circular buffer, taking into account wrap-around conditions.

Each CAN descriptor is aligned to 4 words address boundaries, i.e. the 4 least significant byte address bits are zero for the first word in a CAN descriptor. Note that this frame representation and memory mapping is backwards compatible with GRCAN, which only supports classical CAN format.

Table 569 describes the memory mapping for the first descriptor of a frame, including both control and status bits (first half of the descriptor) and data bytes (second half).

*Table 569.*CAN message representation in memory.

		1011b	20 bytes (only CAN-FD)
		1100b	24 bytes (only CAN-FD)
		1101b	32 bytes (only CAN-FD)
		1110b	48 bytes (only CAN-FD)
		1111b	64 bytes (only CAN-FD)
FDF	Flexible-Data Rate Frame		1b for FD Format, 0b for Classic Format
BRS	Switch Data Bit Rate		1b for bit-rate switch (only CAN-FD frames), 0b for constant bit-rate
TxErrCntr	Transmission Error Counter		
RxErrCntr	Reception Error Counter		
BMErr	Bus Master Error during previous accesses to the bus when 1b		
OR	Reception Overrun when 1b		
OFF	Bus-Off mode when 1b		
PASS	Error-Passive mode when 1b		
Byte 00 to 07	Transmit/Receive data, Byte 00 first Byte 07 last		

Status bits (TxErrCntr, RxErrCntr, BMErr, OR, OFF, PASS) only apply to the RX channel. The IP will write these bits to the circular buffer together with the received frame. For transmission, these bits are not used, therefore they can be simply set to 0b when setting up a frame.

Frames with DLC > 1000b will only result in more than 8 bytes of data for FD frames (FDF set to 1b). For classical CAN frames, the maximum data size is limited to 8 bytes, even if DLC is higher than 1000b. Note also that GRCANFD will ignore the BRS bit if FDF is set to 0b (classical CAN format), so that the Nominal Bit Rate would be used for the entire frame.

If an FD frame contains more than 8 data bytes, it requires additional descriptors to be fully represented in the circular buffer. These descriptors only contain data bytes, and its memory representation is the continuation of the second half of the first descriptor:

- Descriptor #2: data bytes 8 to 23.

- Descriptor #3: data bytes 24 to 39.

- Descriptor #4: data bytes 40 to 55.

- Descriptor #5: data bytes 56 to 63 (second half of the descriptor is unused).

For more information regarding the format of the frame and the content of a descriptor, please refer to 43.5.1 and the CAN-FD ISO standard.

43.6 Operational modes

GRCANFD supports two modes of operation: standard and CANOpen. In standard mode, the IP splits the frame in descriptors, as explained in 43.5.2, and the transmission and reception is controlled by hardware pointers handling the TX and RX circular buffers. In CANOpen mode the IP becomes a CANOpen interpreter, decoding any incoming frame and reacting accordingly. This mode interacts with neither the circular buffers nor the internal SRAM memories.

The operational mode shall be selected, i.e. GRCANFD cannot operate in standard mode and CANOpen mode simultaneously. This section describes how to set the default mode after reset and how to switch between modes.

GRIP

Apr 2024, Version 2024.1

533

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

Note that the operational mode only affects the top DMA layer of the IP. The internal CAN-FD controller shall handle all frames in any case, regardless of its format.

43.6.1 Default configuration

The IP features a group of input signals to set the reset value of the most critical registers. This is mainly used in CANOpen mode, since it configures the CAN timing parameters so that communication can be established automatically without software intervention. These reset values are sampled only when the generic *canopen* is set. The parameters that can be configured are:

- Internal CAN-FD controller enable.
- Active CAN bus selection and transceivers output enable.
- CAN bit time parameters (only for classical bit-rate).
- CANOpen mode enable.
- CANOpen node ID.

Note that any changes in these signals are ignored if the IP is not reset.

43.6.2 Switching between standard and CANOpen mode

In order to switch between standard and CANOpen mode, several conditions shall be met before the IP can effectively switch to the requested mode. This prevents the IP from entering any unexpected state if the mode is switched during an ongoing operation.

To switch from standard to CANOpen mode, the following conditions shall be met:

- CANOpen mode enabled: set the Enable bit in the CANOpen Control Register to 1b.
- Transmitter disabled: set the Enable bit in the Transmit Channel Control Register to 0b.
- Receiver disabled: set the Enable bit in the Receive Channel Control Register to 0b.

Any ongoing operation shall finalize (i.e. all FSMs related to the TX and RX channels shall be in idle state) before the request to change to CANOpen mode is granted.

To switch from CANOpen to standard mode, the following conditions shall be met:

- CANOpen mode disabled: set the Enable bit in the CANOpen Control Register to 0b.

Any ongoing operation shall finalize (i.e. the CANOpen FSM shall be in idle state) before the request to change to standard mode is granted.

The status of the IP can be monitored at any time by sampling the Mode bit in the Status Register.

43.7 Standard Mode - Transmission

The circular buffer for the transmit channel is defined by the following parameters:

- base address
- buffer size
- write pointer
- read pointer

The transmit channel can be enabled or disabled.

43.7.1 Circular buffer

The transmit channel operates on a circular buffer located in memory external to GRCANFD. The circular buffer can also be used as a straight buffer. The buffer memory is accessed via the bus master interface (such as AMBA AHB or AXI).

GRIP

Apr 2024, Version 2024.1

534

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The size of the buffer is defined by the SIZE field in the Transmission Channel Size Register, specifying the number of CAN descriptors * 4 that fit in the buffer.

E.g. CanTxSIZE.SIZE =2 means 8 CAN descriptors fit in the buffer.

Note however that it is not possible to fill the buffer completely, leaving at least one descriptor position in the buffer empty. This is to simplify wrap-around condition checking.

E.g. CanTxSIZE.SIZE =2 means that 7 CAN descriptors fit in the buffer at any given time.

43.7.2 Write and read pointers

The write pointer (WRITE field in the Transmission Channel Write Register) indicates the position +1 of the last CAN descriptor written to the buffer. The write pointer operates on number of CAN descriptors, not on absolute or relative addresses.

The read pointer (READ field in the Transmission Channel Read Register) indicates the position +1 of the last CAN descriptor read from the buffer. The read pointer operates on number of CAN descriptors, not on absolute or relative addresses.

The difference between the write and the read pointers is the number of CAN descriptors available in the buffer for transmission. The difference is calculated using the buffer size, specified by the CanTxSIZE.SIZE field, taking wrap around effects of the circular buffer into account.

Examples:

- There are 2 CAN descriptors available for transmit when CanTxSIZE.SIZE=2, CanTxWR.WRITE=2 and CanTxRD.READ=0.

- There are 2 CAN descriptors available for transmit when CanTxSIZE.SIZE=2, CanTxWR.WRITE =0 and CanTxRD.READ =6.

- There are 2 CAN descriptors available for transmit when CanTxSIZE.SIZE=2, CanTxWR.WRITE =1 and CanTxRD.READ =7.

- There are 2 CAN descriptors available for transmit when CanTxSIZE.SIZE=2, CanTxWR.WRITE =5 and CanTxRD.READ =3.

When a frame has been successfully transmitted, the read pointer (CanTxRD.READ) is automatically updated, taking wrap-around effects of the circular buffer into account. If a frame consists of more than one descriptor, the pointer is not incremented one by one, but it is updated to the next descriptor to be read from the buffer.

Whenever the write pointer CanTxWR.WRITE and read pointer CanTxRD.READ are equal, there are no CAN descriptors available for transmission.

43.7.3 Location

The location of the circular buffer is defined by a base address in Transmission Channel Address Register, which is an absolute address. The location of a circular buffer is aligned on a 1kbyte address boundary.

43.7.4 Transmission procedure

When the channel is enabled (ENABLE bit in the Transmission Channel Control Register equal to 1b), as soon as there is a difference between the write and read pointer, GRCANFD will start fetching the first descriptor of a frame, whose position is indicated by the read pointer. If a frame consists of more than one descriptor, GRCANFD will continue fetching them until the full frame has been read. GRCANFD will decode the DLC field, available in the first descriptor, in order to know how many descriptors shall be fetched in total.

The generic *txbufsize* configures how many frames can be buffered by the core prior to transmission; possible values are between 1 and 8. The data bytes of a frame are stored in the internal TX SRAM,

GRIP

Apr 2024, Version 2024.1

535

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

whereas the control bits are stored in registers. Note that the core will fetch as many frames as the value of *txbufsize* (if available in the circular buffer) regardless of their data length. The core will stop fetching frames if there are no more frames initialized in the circular buffer.

The transmission of a frame does not start until a full frame has been fetched. Buffering the frame minimizes the number of accesses to the circular buffer and allows pre-fetching of additional frames before completing the transmission of the first one, thus increasing the efficiency of the transmitter channel. If *txbufsize* is set to 1, pre-fetching is disabled and the IP will not fetch a new frame until the current transmission has finished.

Note that the TX channel should not be enabled if a potential difference between the write and read pointers could be created, to avoid the descriptor fetching to start prematurely. The TX write pointer shall not be updated until all the descriptors forming the frame are ready to be fetched from the circular buffer.

The read pointer (CanTxRD.READ) is automatically updated after a successful transmission, taking into account wrap around effects of the circular buffer. The content of the local SRAM may then be overwritten, so a new frame would be fetched as soon as the write and read pointers differ.

If the single-shot mode is enabled for the TX channel (CanTxCTRL.SINGLE=1), any frame for which the arbitration is lost, or failed for some other reason such as ACK missing, will lead to the TX channel being automatically disabled (CanTxCTRL.ENABLE=0). The frame will not be put up for re-arbitration and the local SRAM will be emptied, in order not to block future transmissions.

Interrupts are provided to aid the user during transmission, as described in detail later in this section. The main interrupts are the Tx, TxEmpty and TxIrq which are issued respectively after the successful transmission of a frame, when all frames in the circular buffer have been transmitted and when a pre-defined number of descriptors have been transmitted. The TxLoss interrupt is asserted whenever a transmission does not complete: examples of this are loss of arbitration or communication errors. The TxSync interrupt is issued when a frame matching the SYNC pattern is successfully transmitted. Additional interrupts are provided to signal error conditions on the CAN bus and the AMBA bus.

43.7.5 Straight buffer

It is possible to use the circular buffer as a straight buffer, with a higher granularity than the 1kbyte address boundary limited by the base address in the Transmit Channel Address Register.

While the channel is disabled, the read pointer (READ field in the Transmission Channel Read Register) can be changed to an arbitrary value pointing to the first descriptor to be transmitted, and the write pointer (WRITE field in the Transmission Channel Write Register) can be changed to an arbitrary value.

When the channel is enabled, the transmission will start from the read pointer and continue to the write pointer.

43.7.6 AMBA error

An error response occurring on the AMBA bus while a frame descriptor is being fetched will result in a BmRdErr interrupt. Consequently the bit BMErr of the Status Register is set to 1b, and can only be cleared by reading that register.

If the CanCONF.ABORT bit is set to 0b, GRCANFD will automatically try to fetch the same frame descriptor again.

If the CanCONF.ABORT bit is set to 1b, the TX channel will be disabled (ENABLE bit in the Transmission Channel Control register is cleared automatically to 0b). The read pointer can be used to determine which frame caused the bus master error (but not the specific descriptor, if the frame contains more than one). If the error occurs while the other frame in the local SRAM is being transmitted, the transmission is not interrupted, in order not to disrupt the CAN bus. If the transmission is acknowledged, the pointers are updated accordingly, even if the channel is already disabled.

GRIP

Apr 2024, Version 2024.1

536

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

43.7.7 Enable and disable

When the TX channel is disabled (ENABLE bit in the Transmission Channel Control Register cleared to 0b) during an ongoing transmission, the internal CAN-FD codec will not abort the transmission, but attempt to finish it until the frame is acknowledged, the arbitration is lost or any error is detected. If the frame is sent successfully, the read pointer (CanTxRD.READ) is automatically incremented. Any associated interrupt will be generated.

The progress of any ongoing access can be observed via the ONGOING bit in the Transmission Channel Control Register. The ONGOING bit must be 0b before the channel can be re-configured safely (i.e. changing address, size or read pointer). It is also possible to monitor the Tx and TxLoss interrupts described hereafter.

GRCANFD includes a status bit in the TX channel control register called DisACK. This bit is used to indicate that the TX channel disable request has been acknowledged, and it will take effect as soon as the ongoing transmission finishes or fails to complete. The TX channel is not completely disabled until both ENABLE and DisACK are both 0b.

The channel can be re-enabled again without the need to re-configure the address, size and pointers.

Priority inversion is handled by disabling the transmitting channel, i.e. setting CanTxC-TRL.ENABLE=0b as described above, and observing the progress, i.e. reading via the CanTxC-TRL.ONGOING and CanTxCTRL.DisACK bits as described above. When the transmit channel is disabled, it can be re-configured and a higher priority frames can be transmitted. Note that the single shot mode does not require the channel to be disabled, but the progress should still be observed as above.

43.7.8 Interrupts

During transmission several interrupts can be generated:

- TxLoss: Frame transmission interrupted due to lost of arbitration, ACK not detected by the transmitter or errors during the transmission.
- TxErrCntr: Increment of the transmitter error counter.
- TxSync: Frame matching the SYNC filter transmitted.
- Tx: Successful transmission of a frame.
- TxEmpty: Successful transmission of all the frames in the circular buffer.
- TxIrq: Successful transmission of a predefined number of frame descriptors. One of the descriptors matches the position programmed by the Transmit Channel Interrupt Register.
- BmRdErr: Bus error while fetching a descriptor via the bus master interface.
- Off: Bus-off condition.
- Pass: Error-passive condition.

The Tx, TxEmpty and TxIrq interrupts are only generated as the result of a successful frame transmission, only once the CanTxRD.READ pointer has been incremented.

43.8 Standard Mode - Reception

The receive channel is defined by the following parameters:

- base address
- buffer size
- write pointer
- read pointer

GRIP

Apr 2024, Version 2024.1

537

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

The receive channel can be enabled or disabled.

43.8.1 Circular buffer

The reception channel operates on a circular buffer located in memory external to GRCANFD. The circular buffer can also be used as a straight buffer. The buffer memory is accessed via the bus master interface (such as AMBA AHB or AXI).

The size of the buffer is defined by the SIZE field in the Reception Channel Size Register, specifying the number of CAN descriptors * 4 that fit in the buffer.

E.g. CanRxSIZE.SIZE =2 means 8 CAN descriptors fit in the buffer.

Note however that it is not possible to fill the buffer completely, leaving at least one descriptor position in the buffer empty. This is to simplify wrap-around condition checking.

E.g. CanRxSIZE.SIZE =2 means that 7 CAN descriptors fit in the buffer at any given time.

43.8.2 Write and read pointers

The write pointer (WRITE field in the Reception Channel Write Register) indicates the position +1 of the last CAN descriptor written to the buffer. The write pointer operates on number of CAN descriptors, not on absolute or relative addresses.

The read pointer (READ field in the Reception Channel Read Register) indicates the position +1 of the last CAN descriptor read from the buffer. The read pointer operates on number of CAN descriptors, not on absolute or relative addresses.

The difference between the write and the read pointers is the number of CAN descriptors available in the buffer for read-out after having received a set of frames. The difference is calculated using the buffer size, specified by the CanRxSIZE.SIZE field, taking wrap around effects of the circular buffer into account.

Examples:

- There are 2 CAN descriptors available for read-out when CanRxSIZE.SIZE=2, CanRxWR.WRITE=2 and CanRxRD.READ=0.

- There are 2 CAN descriptors available for read-out when CanRxSIZE.SIZE=2, CanRxWR.WRITE =0 and CanRxRD.READ=6.

- There are 2 CAN descriptors available for read-out when CanRxSIZE.SIZE=2, CanRxWR.WRITE =1 and CanRxRD.READ=7.

- There are 2 CAN descriptors available for read-out when CanRxSIZE.SIZE=2, CanRxWR.WRITE =5 and CanRxRD.READ=3.

When a frame has been successfully received and all its descriptors have been stored into the circular buffer, the write pointer (CanRxWR.WRITE) is automatically updated, taking wrap-around effects of the circular buffer into account. If a frame consists of more than one descriptor, the pointer is not incremented one by one, but it is updated to the next position to be written to the buffer.

Whenever the read pointer CanRxRD.READ equals (CanRxWR.WRITE+1) modulo (CanRxSIZE.SIZE*4), there is no space available for storing another descriptor. This is signaled by an interrupt (RxFull). If a frame consists of more than one descriptor, GRCANFD will attempt to store each descriptor as long as there is space in the buffer. If there is no space for the next descriptor, the interrupt will be asserted, and GRCANFD will wait until the read pointer is updated to continue storing the frame.

GRIP

Apr 2024, Version 2024.1

538

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

43.8.3 Location

The location of the circular buffer is defined by a base address in the Reception Channel Address Register, which is an absolute address. The location of a circular buffer is aligned on a 1kbyte address boundary.

43.8.4 Reception procedure

When the channel is enabled (ENABLE bit in the Reception Channel Control Register equal to 1b), GRCANFD will evaluate whether any incoming frame shall be stored into the local SRAM. To store a frame, the frame shall match the acceptance filter, which is programmable through the Acceptance Code and Acceptance Mask registers, and there shall be space available in the RX SRAM.

The generic *rxbufsize* configures hoy many frames can be buffered by the core prior to writing them to the circular buffer; possible values are between 1 and 8. The data bytes of a frame are stored in the internal RX SRAM, whereas the control bits are stored in registers. Note that the core will buffer as many frames as the value of *rxbufsize* regardless of their data length.

Once a complete frame is available, GRCANFD will split it into descriptors, as many as needed to represent the full frame. Then the IP will attempt to write each descriptor to the circular buffer, as long as the write and read pointers differ. This process will continue until the full frame is written to the buffer, which is signaled by the Rx interrupt and the write pointer being updated (Can-RxWR.WRITE).

By having a local SRAM with capacity for multiple CAN-FD frames, GRCANFD minimizes the risk of missing frames due to conflicts accessing the AHB (or AXI) bus or due to the RX buffer being full. Once a frame is written to the circular buffer and the write pointer is updated, the content of the SRAM can be replaced with a new frame.

Note that the channel should not be enabled until the write and read pointers are configured, to avoid the message reception to start prematurely.

The core supports generation of Overload Frames when the internal buffer is full in order to request other nodes to delay the next transmission. This feature is only available if the size of the RX SRAM is larger than 1 frame (i.e. *rxbufsize* from 2 to 8). If so, the core will transmit Overload Frames if the Overload Frames bit is set in the Receive Channel Control Register and the buffer is full. Up to 2 consecutive Overload Frames will be issued, according to the CAN-FD standard.

If a new frame is received before there being space available in the SRAM, the frame cannot be internally stored and the Overrun condition is detected and signaled via the corresponding interrupt (OR) and the Overrun bit in the Status Register. The OR interrupt is raised only upon the reception of the first frame which causes Overrun. If more frames are received, the OR interrupt is not raised until the Overrun condition is resolved.

Interrupts are provided to aid the user during reception, as described in detail later in this section. The main interrupts are Rx and RxIrq which are issued on the successful reception of a frame and when a predefined number of frame descriptors have been received successfully. The RxMiss interrupt is asserted whenever a frame has been received but does not match any filters (i.e. neither the acceptance nor the SYNC filters) or when a frame is received by the codec but the RX channel is disabled and consequently the frame is not stored in the circular buffer.

The RxFull interrupt is raised when there is no space in the circular buffer for storing the next descriptor. This does not only occur when a complete frame has been received and stored, but also when an individual descriptor has been stored and there is no space in the RX buffer for the following one belonging to the same frame (only applicable to FD frames). In this case, the RX Write Pointer would not represent the position currently being written, as it is only updated after all the descriptors of the frame have been stored.

The RxSync interrupt is issued when a frame matching the SYNC filter has been successfully received. Note that the frame does not need to match the acceptance filter. The interrupt is generated

GRIP

Apr 2024, Version 2024.1

539

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

as soon as the CAN-FD controller finishes receiving the frame. Additional interrupts are provided to signal error conditions on the CAN bus and AMBA bus.

Regardless of the status of the RX channel, the internal CAN-FD codec will check for errors and acknowledge any incoming frames. The codec shall also evaluate frames with any identifier, even if they do not match the Acceptance or SYNC filters. The only way to prevent the internal codec from checking and acknowledging any incoming frames is to disable it via the Control Register (ENABLE bit).

43.8.5 Straight buffer

It is possible to use the circular buffer as a straight buffer, with a higher granularity than the 1kbyte address boundary limited by the base address (CanRxADDR.ADDR) field.

While the channel is disabled, the write pointer (CanRxWR.WRITE) can be changed to an arbitrary value pointing to the first frame to be received, and the read pointer (CanRxRD.READ) can be changed to an arbitrary value.

When the channel is enabled, the reception will start from the write pointer and continue to the read pointer.

43.8.6 AMBA error

An error response occurring on the AMBA bus while a frame descriptor is being stored will result in a BmWrErr interrupt. Consequently the bit BMErr of the Status Register is set to 1b, and it can only be cleared when that register is read.

If the CanCONF.ABORT bit is set to 0b, GRCANFD will retry to write the same descriptor to the circular buffer.

If the CanCONF.ABORT bit is set to 1b, the RX channel will be disabled (CanRxCTRL.ENABLE is cleared automatically to 0b). The write pointer can be used to determine which frame caused the bus master error (but not the specific descriptor, if the frame contains more than one). Any ongoing reception is aborted, and the local SRAM is emptied. The descriptor causing the error is not stored and the write pointer is therefore not updated.

43.8.7 Enable and disable

When the RX channel is disabled (ENABLE bit in the Reception Channel Control Register cleared to 0b) while a frame is being written to the circular buffer, the core will still complete this operation before effectively switching off the channel, thus updating the write pointer (CanRxWR.WRITE) and generating the corresponding interrupts.

When the Receive Channel is disabled, the content of the internal SRAM is emptied once any pending operations are finalized, so that the buffer is fully available once the channel is enabled again.

The progress of an ongoing reception can be observed via the ONGOING bit in the Reception Channel Control Register. The ONGOING bit must be 0b before the channel can be re-configured safely (i.e. changing address, size or write pointer).

GRCANFD includes a status bit in the RX channel control register called DisACK. This bit is used to indicate that the RX channel disable request has been acknowledged, and will take effect as soon as the ongoing reception finishes and the frame is stored into the circular buffer, or until it fails to complete. The RX channel is not completely disabled until both ENABLE and DisACK are both 0b.

The channel can be re-enabled again without the need to re-configure the address, size and pointers.

43.8.8 Interrupts

During reception several interrupts can be generated:

- RxMiss: Frame filtered away during reception

GRIP
Apr 2024, Version 2024.1

540

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- • RxErrCntr: Receive error counter incremented.

- • RxSync: Frame matching the SYNC filter received.

- • Rx: Successful reception of a frame and storage into the circular buffer.

- • RxFull: RX buffer full; no space for the next frame descriptor.

- • RxIrq: Successful reception of a predefined number of frame descriptors. One of the descriptors of the frame matches the position programmed by the Receive Channel Interrupt Register.

- • BmWrErr: Bus error while storing a frame descriptor via the bus master interface.

- • OR: Overrun during reception.

- • OFF: Bus-off condition.

- • PASS: Error-passive condition.

The Rx and RxIrq interrupts are only generated as the result of a successful frame reception, after the CanRxWR.WRITE pointer has been incremented. RxFull may be generated when a descriptor is stored, regardless of whether it is the last one within a frame or not.

The OR interrupt is generated when a frame is received but the internal SRAM already contains the maximum number of frames yet to be stored into the circular buffer. This may be due to a conflict accessing the bus via the bus master interface, or to the RX circular buffer being full. The assertion of this interrupt implies that one or more frames have already been missed. Once this occurs, the Overrun bit of the Status Register is set to 1b, and will only be cleared by reading the mentioned register.

43.9 CANOpen mode

43.9.1 General

GRCANFD features a minimal implementation of the CANOpen standard. This allows an external CAN node to access the internal address space of the device via specific messages defined in CANOpen.

The IP contains an FSM to handle CANOpen commands. GRCANFD will not transmit any frame spontaneously, it shall be triggered by the master node of the bus. Once a CAN frame is received, the IP will check its format and decode it. The frame shall be a classical CAN data frame, i.e. the bits RTR, FDF and BRS shall be all 0b. Frames not matching this criteria are silently discarded.

A separate bus master interface can be generated for all AMBA accesses performed in CANOpen mode if the generic *sepbus* is set to 1. The AHB index of this second bus is configured via the generic *hindexcopen*.

When decoding the frame, the IP checks the function code (bits 11-8 of the base ID) and the destination node ID (bits 7-0 of the base ID) of the command. If the command is supported by the IP, the corresponding process is triggered, otherwise the command is silently discarded. Supported commands include PDOs 1-4, SYNC and Heartbeat messages. A detailed description of each command and the usage of their data bytes can be found later in this section.

The PDOs 1 and 3 are mapped to write commands, in which the user shall indicate the target AMBA address and the data to write. The IP supports write accesses of 1-4 bytes, depending on the DLC field of the frame. Once the internal write access to the AMBA bus is finalized, the FSM returns to idle state and an interrupt is generated.

The PDOs 2 and 4 are mapped to read commands, in which the user shall indicate the target AMBA address and, optionally, the number of bytes to read. The IP supports read accesses of 0-8 bytes. If no reply length is indicated, the default access is 4 bytes. Once the internal read access to the AMBA bus is finalized, GRCANFD transmits the reply with the requested data. The FSM returns to idle state when the codec has successfully transmitted the frame, and an interrupt is generated.

GRIP
Apr 2024, Version 2024.1

541

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

For all PDOs, the IP supports the reception of RPDOs and, for read commands, the transmission of the corresponding TPDO with the reply.

The Heartbeat command is used to keep alive the bus. It enabled, GRCANFD features an internal counter that is incremented every CAN bit time (i.e. with the Sample Point of the CAN bus). Every time a Heartbeat command is received, the counter is reset. If the counter reaches the programmed timeout, the IP will generate an interrupt and, optionally, switch to the alternate CAN bus, by inverting the LineSel bit in the Configuration Register. This functionality can be enabled in the CANOpen Control Register with the Redundant Control bit.

The SYNC command is used to synchronize all nodes in the network. When GRCANFD receives a SYNC command, an interrupt is generated. Software is required to handle the node synchronization in this case.

If GRCANFD receives a frame which does not pass the preliminary format check (e.g. the frame has FD format or is a Remote Frame) or it does not match any CANOpen object supported, it generates the RxMiss interrupt and the frame is discarded. Then, the IP starts listening to the CAN bus again waiting for the next frame.

43.9.2 Write commands

Write commands are mapped to the CANOpen PDOs 1 and 3, and are used to trigger an internal AMBA write access. Both PDOs will result in the same functionality. The format of the incoming PDOs shall be as follows:

- Frame format: Classical CAN data frame.

- Function code: RPDO1 (0100b) or RPDO3 (1000b).

- Destination node: GRCANFD node ID (node ID field in the CANOpen Control Register).

- DLC: 5 - 8

The DLC field is used to indicate the size of the AMBA write access. The IP supports write accesses of 1 - 4 bytes per PDO. The AMBA address is mapped to the data bytes 1 - 4 of the frame (the first byte being the MSB and the fourth byte the LSB), whereas the data bytes 5 - 8 represent the data to write (the fifth byte being the MSB and the last byte the LSB).

Figure 129. Use of data bytes in write commands (RPDO1 and RPDO3)

Any write command with less than 5 data bytes is simply ignored, as it would not contain enough information to trigger an internal AMBA write access.

43.9.3 Read commands

Read commands are mapped to the CANOpen PDOs 2 and 4, and are used to trigger an internal AMBA read access. Both PDOs will result in the same functionality. The format of the incoming PDOs shall be as follows:

- Frame format: Classical CAN data frame.

- Function code: RPDO2 (0110b) or RPDO4 (1010b).

- Destination node: GRCANFD node ID (node ID field in the CANOpen Control Register).

- DLC: 4 or 5

GRIP
Apr 2024, Version 2024.1

542

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The size of the AMBA read access is configurable. If the frame contains 4 data bytes (DLC = 4), a standard 32-bit read access is performed. The AMBA address is mapped to these first 4 data bytes of the frame (the first byte being the MSB).

GRCANFD also supports AMBA read accesses of configurable size by means of frames with 5 data bytes (DLC = 5). The four data bytes are still the AMBA address, whereas the fifth byte indicates the size of the read access in number of bytes. Valid sizes range from 0 to 8 bytes, the IP will cap the value to the maximum of 8 bytes.
Figure 130. Use of data bytes in read commands (RPDO2 and RPDO4)

Any read command with DLC other than 4 or 5 is silently discarded by the IP.

Once GRCANFD has completed the internal AMBA read access, it will transmit a TPDO with the data requested as soon as the intermission time (3 bits of nominal CAN bit-rate) is over. The main characteristics of the reply are listed below:

- Frame format: Classical CAN data frame.
- Function code: TPDO2 (0101b) if replying to an RPDO2, or TPDO4 (1001b) for an RPDO4.
- Destination node: GRCANFD node ID (node ID field in the CANOpen Control Register).
- DLC: 0 - 8, according to the size field of the read command (4 by default).

The first data byte of the reply TPDO is the MSB and the last byte, the LSB. Note that it is possible to request the transmission of a TPDO without any data bytes by setting the size of the read access to 0. In this case, no internal read access is performed, and the DLC of the reply is set to 0 accordingly.

43.9.4 SYNC commands

The SYNC commands are employed to synchronize the slave nodes in a CAN bus. Once a frame is interpreted as a SYNC command, GRCANFD triggers an interrupt to be handled by software. The IP does not maintain any internal synchronization timer. The format of the incoming SYNC command is as follows:

- Frame format: Classical CAN data frame.
- Function code: SYNC (0001b).
- Destination node: broadcast (0000000b).

Note that the DLC and the data bytes of a SYNC command are neither checked nor used by the IP.

43.9.5 Heartbeat commands

The Heartbeat command is used as the NMT Error Control mechanism to keep the bus alive. GRCANFD features an internal counter incremented once per CAN bit time if the NMT Error Control functionality is enabled, which is done by setting the CANOpen Heartbeat Timeout Register to a value different from zero. The timeout is expressed in number of CAN bit times.

Every time a Heartbeat command is received, GRCANFD restarts the counter. If the timeout is reached, an interrupt is triggered and the IP may switch to the alternate bus by inverting the LineSel signal of the Configuration Register. This behavior is controlled via the Redundant Control bit in the CANOpen Control Register.

The format of the Heartbeat command shall be as follows:

- Frame format: Classical CAN data frame.

GRIP

- Function code: NMT Error Control / Heartbeat (1110b).
- Destination node: GRCANFD node ID (node ID field in the CANOpen Control Register).

Note that the DLC and the data bytes of a Heartbeat command are neither checked nor used by the IP.

43.9.6 AMBA errors

As in the standard mode, the IP will raise an interrupt if any access to the internal AMBA bus ends with errors. The CANOpen mode uses the same Bus Master Error interrupt bits as the standard mode. Therefore, if an AMBA write access triggered by a CANOpen write command ends with errors, the IP will raise the BmWrErr interrupt. On the other hand, if the errors are observed during a read access triggered by a CANOpen read command, the corresponding BmRdErr interrupt is raised.

The IP does not use the Abort bit of the Configuration Register, unlike the standard mode. In CANOpen mode, AMBA accesses are never retried (i.e. this corresponds to Abort bit set to 1b) in order to prevent the IP from locking if an external node targeted an invalid AMBA address. Therefore, the internal CANOpen FSM will automatically return to idle after any bus master errors without processing the command. The corresponding interrupt is generated as explained in the paragraph above.

43.9.7 Interrupts

GRCANFD includes four maskable interrupts exclusive to the CANOpen mode:

- CoHbErr: CANOpen Heartbeat timeout error
- CoSync: SYNC command received
- CoWrCmd: CANOpen write command processed
- CoRdCmd: CANOpen read command processed

Note that the IP can still produce other general interrupts in CANOpen mode, such as those related to the CAN error counters, loss of arbitration or bus master errors. More information can be found under the Register section, in 43.14.28.

43.10 Global reset and enable

When the RESET bit in the Control Register is set to 1b, a reset of the whole IP is performed, including the internal CAN-FD codec. The reset clears all the register fields to their default values. Any ongoing frame transfer request will be aborted, potentially violating the CAN protocol.

When the ENABLE bit in the Control Register is cleared to 0b, the CAN-FD codec is reset, so it is safe to modify the configuration registers. When disabled, the CAN-FD controller will be in sleep mode. It will only send recessive bits thus not affecting the CAN bus. It will neither receive nor acknowledge any frame on the bus.

Once the codec is enabled again, it will enter bus integration state before being able to transmit or receive frames. It requires that 11 consecutive recessive bits are detected in the CAN bus prior to starting the normal operation.

43.11 Interrupt outputs

GRCANFD features up to 3 separate output interrupt lines:

Index:	Name:	Description:
0	IRQ	Common output from interrupt handler
1	TxSYNC	Synchronization message transmitted (optional)
2	RxSYNC	Synchronization message received (optional)

The interrupts are configured by means of the *pirq* VHDL generic and the *singleirq* VHDL generic. If *singleirq* is set to 1 there will be only one interrupt line, whose number will be the one set by *pirq*.

GRIP
Apr 2024, Version 2024.1
544
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Otherwise, if *singleirq* is set to 0, there will be three interrupt lines, whose numbers will be *pirq, pirq+1 and pirq+2*. If *pirq+1 or pirq+2* exceed the maximum number of IRQ lines, the IP will not be able to generate 3 interrupt outputs, even if *singleirq* is set to 0.

Unlike other IPs in the GRLIB IP core library, GRCANFD generates level-based interrupts. This means that the output interrupt, pirq, will be asserted for as long as the core interrupt registers contain unmasked events. It is therefore recommended to clear the content of the interrupt registers after attending the interrupt in order to guarantee that pirq gets properly deasserted.

43.12   Endianness

The core is designed for big-endian and little-endian systems.

GRCANFD automatically detects the endianness of the system by reading a dedicated sideband signal included in the AMBA records. When accessing the generic bus master interface, the data may be realigned and/or swapped, depending on the selected endianness and the type of data involved in the transfer:

- In standard mode, the first 2 words of the first descriptor of a frame contain control and status information, and will always appear at address offsets 0x00 and 0x04, respectively. The core never swaps the bytes of these two words, so they are expected to be written/read in 32-bit accesses. From this point on, the descriptors contain the data bytes of the CAN frame. GRCANFD treats the data bytes as a stream of bytes, i.e. the first data byte of the first descriptor will always appear at offset 0x08, the second byte at offset 0x09 and so on, regardless of the endianness of the system. This implies that GRCANFD will internally swap data bytes in little-endian configurations.

- In CANOpen mode, GRCANFD does not swap the data bytes, so the user must take the endianness of the system into account when accessing the internal AMBA address space of the device via CAN and align the data bytes accordingly.

43.13   Bus master interface

43.13.1 Protocol support

The core features a generic bus master interface to increase the flexibility of the IP. A second bus master interface can be generated for CANOpen transactions by setting the generics *canopen* and *sepbus* to 1. Additionally Frontgrade Gaisler provides wrappers for both AMBA AHB 2.0 and AXI4.

43.13.2 Bus access

In standard mode, GRCANFD uses the generic bus master interface to access the bus in order to fetch and store frame descriptors from/to the corresponding circular buffer. Each access involves a full descriptor. As explained in previous sections, a frame descriptor is formed by four 32-bit words, therefore the access width is always 128 bits for both writing and reading.

When the IP operates in CANOpen mode, the size of the AMBA accesses depend on the write and read commands. Read accesses consist of 1 to 8 bytes, whereas write accesses are of 1 - 4 bytes.

The wrapper for AMBA AHB 2.0 features a bridge to convert the generic bus master into an AHB bus master interface. The 128-bit accesses are split into a burst of 4 incremental 32-bit accesses.

The wrapper for AXI4 features a bridge to convert the generic bus master into an AXI4 bus master interface. For further information regarding the accesses contact Frontgrade Gaisler.

Apr 2024, Version 2024.1

546

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

43.14.1 Configuration Register

*Table 571.*0x000 - CONF - Configuration Register

31										8	7	6	5	4	3	2	1	0
Reserved											LBS	LB	Res	Silent	Select	Enable1	Enable0	Abort
0x000000											0	0	0	0	0*	0*	0*	0
r											rw	rw	r	rw	rw	rw	rw	rw

7:	LBS	Loop-back selector. Selects between external (0b) and internal (1b) loop-back. Used only if LB is set.
6:	LB	Loop-back mode. When transmitting a frame, the core will drive the ACK bit and store its own frames.
4:	SILENT	Listen only to the CAN bus, send recessive bits.
3:	SELECT	Line selector for transmitter and receiver:
		Select receiver input 0 and transmitter output 0 as active when 0b,
		Select receiver input 1 and transmitter output 1 as active when 1b.
2:	ENABLE1	Set value of output 1 enable. Its polarity depends on the physical transceiver.
1:	ENABLE0	Set value of output 0 enable. Its polarity depends on the physical transceiver.
0:	ABORT	Abort transfer after AMBA bus errors (standard-mode only).

* The reset value of these fields may be overwritten with the input configuration signals (cfg record) if the generic *canopen* is set to 1.

By setting the ABORT bit to 1b, the TX and RX channels are automatically disabled upon detection of an AMBA bus error. Otherwise, the transfer causing the error is issued again. Note that in CANOpen mode, any AMBA accesses resulting in errors are always aborted, regardless of the value of this bit. This prevents any external CAN node from locking the IP if accessing an invalid or protected AMBA address.

When the loop-back mode is enabled, GRCANFD will drive the ACK bit of its own frames. Additionally, these frames will be stored in the RX circular buffer as received frames. The loop-back selector allows to connect the TX and RX bits inside the IP, thus bypassing the external CAN transceiver (internal loop-back), and to have a standard connection to the CAN bus (external loop-back).

The core will only transmit recessive bits over the CAN bus when either the internal loop-back or the Silent mode is activated.

43.14.2 Status Register

*Table 572.*0x004 - STAT - Status Register

31							24	23							16
Reserved								TxErrCntr							
0x00								0x00							
r								r							

15							8	7	6	5	4	3	2	1	0
RxErrCntr								Reserved		MD	Active	BMErr	OR	Bus Off	Err Pass
0x00								0x0		0	0	0	0	0	0
r								r		r	r	r	r	r	r

23-16:	TxErrCntr	Transmission error counter, 8-bit
15-8:	RxErrCntr	Reception error counter, 8-bit
5:	MD	GRCANFD operational mode: standard (0b) or CANOpen (1b)
4:	ACTIVE	Transmission ongoing
3:	BMErr	Errors detected during a previous transfer via the bus master interface
2:	OR	Overrun during reception

GRIP
Apr 2024, Version 2024.1

547

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

| 1: | Bus Off | Bus-off condition |
| 0: | Err Pass | Error-passive condition |

The OR bit is set if a frame with an ID matching the acceptance filter cannot be stored within the local SRAM due to lack of space, i.e. the SRAM already is full of CAN messages yet to be stored into the circular buffer (the number of received messages is determined by the generic *rxbufsize*).

The OR and BMErr status bits are cleared when the Status Register is read.

Note that TxErrCntr and RxErrCntr are defined and updated according to the CAN protocol.

Additionally, the fields TxErrCntr, RxErrCntr, BMErr, OR, Bus Off and Error Passive are stored in the circular buffer during reception as part of the first descriptor of every frame.

The MD bit indicates the mode in which GRCANFD operates. This bit only changes once all conditions to switch from one mode to the other are satisfied.

43.14.3 Control Register

*Table 573.*0x008 - CTRL - Control Register

31		2	1	0
	Reserved		Reset	Enable
	0x00000000		0	0*
	r		w	rw

| 1: | RESET | Reset complete core when 1. Self-clearing. |
| 0: | ENABLE | Enable CAN-FD codec when 1. Disable CAN-FD codec when 0. |

* The reset value of this field may be overwritten with the input configuration signals (cfg record) if the generic *canopen* is set to 1.

RESET takes effect on the whole IP, including the internal codec. Self-clearing (read back as 0b).

The internal codec shall be disabled by setting ENABLE to 0 before modifying any CAN-related settings, such as the configuration of the bit times. This ensures that the integration with the CAN bus is correctly performed.

When ENABLE is cleared to 0b, the CAN interface is in sleep mode, only outputting recessive bits.

Once the CAN-FD codec is enabled again, it needs to detect 11 consecutive recessive bits on the CAN bus prior to starting the normal operation, i.e. transmit or receive any frame.

43.14.4 Capability Register

*Table 574.*0x00C - CAP - Capability Register

31	30	29	11	10	8	7	6	4	3	2	1	0
Rev1	Rev2	Res		TxBufSize		Res	RxBufSize		Res	SepBus	COpen	SingIRQ
-	-	0x00000		-		0	-		0	-	-	-
r	r	r		r		r	r		r	r	r	r

31:	Rev1	Revision 1 implemented: support for configurable buffers, FT and scantest, loop-back mode, etc.
30:	Rev2	Revision 2 implemented: CANOpen support.
10-8:	TxBufSize	Size of the internal TX buffer, expressed in number of frames - 1. Determined by the generic *txbufsize*.
6-4:	RxBufSize	Size of the internal RX buffer, expressed in number of frames - 1. Determined by the generic *rxbufsize*.
2:	SepBus	Separate bus master interface for CANOpen accesses. Determined by the generic *sepbus*.
1:	COpen	CANOpen FSM implemented. Determined by the generic *canopen*.
0:	SingIRQ	The IP has a single IRQ output if SingIRQ is set to 1b, otherwise there are three different interrupts.

The capability register contains general information about the instantiation of the IP, specifically concerning the generics.

If SingIRQ is set to 1b, the IP combines all the interrupts in a single interrupt output. If set to 0b, GRCANFD features up to 3 interrupt outputs: a common line, together with dedicated lines for TxSYNC and RxSYNC interrupts, respectively.

If the bit 31 is set to 1b, the IP implements the Revision 1 of the core, including new generics (txbufsize, rxbufsize, ft, scantest) and control bits (Loop-back mode, Loop-back selector, Overload Frame Enable).

If the bit 30 is set to 1b, the IP implements the Revision 2 of the core, including CANOpen support.

43.14.5 SYNC Mask Filter Register

*Table 575.*0x018 - SYNCMASK - SYNC Mask Filter Register

31 30 29	28 0
Reserved	MASK
0x0	0x1FFFFFFF
r	rw

28-0:   MASK   Mask for SYNC filter

All bits of the MASK field are set to 1 at reset.

Note that Base ID corresponds to the bits 28 to 18 and Extended ID corresponds to bits 17 to 0.

43.14.6 SYNC Code Filter Register

*Table 576.*0x01C - SYNCCODE - SYNC Code Filter Register

31 30 29	28 0
Reserved	CODE
0x0	0x00000000
r	rw

28-0:   CODE   Code for SYNC filter

The CAN Base ID corresponds to the bits 28 to 18 and Extended ID corresponds to bits 17 to 0.

The SYNC filter is applied to the transmitted frames as soon as the codec transmits the frame. For the RX channel, the filter is applied as soon as the codec receives the frame, regardless of whether the frame is to be stored into the circular buffer afterwards, so it does not depend on the configuration of the Acceptance filter. Specific interrupts are available for both SYNC filters.

An ID matches the RxSYNC filter when:

$$((\text{Received-ID}) \text{ XOR } (\text{SYNC CODE})) \text{ AND } (\text{SYNC MASK}) = 0$$

An ID matches the TxSYNC filter when:

$$((\text{Transmitted-ID}) \text{ XOR } (\text{SYNC CODE})) \text{ AND } (\text{SYNC MASK}) = 0$$

43.14.7 Nominal Bit-Rate Configuration Register

Table 577. 0x040 - NOMBR - Nominal Bit-Rate Configuration Register

31		24	23		16
Reserved			SCALER		
0x00			0x00*		
r			rw		

15		10	9		5	4		0
PS1			PS2			SJW		
0x00*			0x00*			0x00*		
rw			rw			rw		

23-16:	SCALER	Prescaler setting for nominal bit rate, 8-bit: system clock / (SCALER +1)
15-10:	PS1	Phase Segment 1 for nominal bit rate, 6-bit
9-4:	PS2	Phase Segment 2 for nominal bit rate, 5-bit
3-0:	SJW	Synchronization Jump Width, 5-bit

* The reset value of these fields may be overwritten with the input configuration signals (cfg record) if the generic *canopen* is set to 1.

The prescaler sets the number of clock cycles per nominal time quantum (plus an offset of 1). PS1, PS2 and SJW define the number of nominal quantum within the Phase Segment 1, Phase Segment 2 and Synchronization Jump Width, respectively.

Certain constraints apply to the previous parameters. Since GRCANFD is an FD enabled implementation with separate prescalers for the nominal and the data bit rate, the valid ranges are as follows:

*   Prescaler: 0 - 255

*   PS1: 2 - 63

*   PS2: 2 - 16

*   SJW: 1 - 16

Additional considerations must be taken when defining the parameters:

*   PS2 >= SJW

*   SJW <= min (PS1, PS2)

For more information regarding the parameters defining the nominal bit time, please refer to the ISO standard 11898-1:2015 (2nd edition).

Therefore, the Nominal time quantum can be obtained as follows:

$$(system\ clock\ period) * (SCALER+1)$$

whereas the resulting Nominal bit rate is:

$$(system\ clock\ frequency) / ((SCALER+1) * (1+ PS1 + PS2))$$

43.14.8 Data Bit-Rate Configuration Register

*Table 578.*0x044 - DATABR - Data Bit-Rate Configuration Register

31					24	23			16
Reserved						SCALER			
0x00						0x00			
r						rw			

15	14	13		10	9	8		5	4	3		0
Reserved		PS1			Res.	PS2			Res.	SJW		
00		0x0			0	0x0			0	0x0		
r		rw			r	rw			r	rw		

23-16: SCALER Prescaler setting for data bit rate, 8-bit: system clock / (SCALER +1)
13-10: PS1 Phase Segment 1 for data bit rate, 4-bit
8-5: PS2 Phase Segment 2 for data bit rate, 4-bit
3-0: SJW Synchronization Jump Width, 4-bit

The prescaler sets the number of clock cycles per data time quantum (plus an offset of 1). PS1, PS2 and SJW define the number of data quantum within the Phase Segment 1, Phase Segment 2 and Synchronization Jump Width, respectively.

Certain constraints apply to the previous parameters. Since GRCANFD is an FD enabled implementation with separate prescalers for the nominal and the data bit rate, the valid ranges are as follows:

- Prescaler: 0 - 255
- PS1: 1 - 15
- PS2: 2 - 8
- SJW: 1 - 8

Additional considerations must be taken when defining the parameters:

- SJW <= min (PS1, PS2)
- Data bit-rate >= Nominal bit-rate

For more information regarding the parameters defining the data bit time, please refer to the ISO standard 11898-1:2015 (2nd edition).

Therefore, the Data time quantum can be obtained as follows:

$$(\text{system clock period}) * (\text{SCALER}+1)$$

whereas the resulting Data bit rate is:

$$(\text{system clock frequency}) / ((\text{SCALER}+1) * (1+ \text{PS1} + \text{PS2}))$$

43.14.9 Transmitter Delay Compensation Register

43.14.13CANOpen Status Register

*Table 583.*0x08C - COSTS- CANOpen Status Register

31				4	3			0
Reserved					STS			
0x0000000					0x0			
r					r			

3-0:   STS   Status of the CANOpen FSM, encoded as follows:
    0x0: IDLE. Listening to the CAN bus while waiting for a new RX frame.
    0x1: RX_DATABYTES. A frame passing the preliminary format check is being received.
    0x2: DECODE. The reception has ended and the IP checks if the frame is a CANOpen object.
    0x3: INIT_WRITE. Initializing an AMBA write access after receiving a CANOpen write command.
    0x4: END_WRITE. Waiting for the end of the write access.
    0x5: INIT_READ. Initializing an AMBA read access after receiving a CANOpen read command.
    0x6: END_READ. Waiting for the end of the read access.
    0x7: INIT_REPLY. Initializing the TPDO as a reply to a CANOpen read command.
    0x8: TX_DATABYTES. Transmitting the TPDO.
    0x9: REPLY_NOK. The TPDO failed during transmission due to errors or loss of arbitration.

43.14.14 Transmit Channel Control Register

*Table 584.*0x200 - TXCTRL - Transmit Channel Control Register

31	4	3	2	1	0
Reserved		Dis Ack	Sin-gle	Ong oing	Ena ble
0x0000000		0	0	0	0
r		r	rw	r	rw

3:    DisAck   Disable request acknowledged
2:    SINGLE   Single shot mode
1:    Ongoing   Transmission ongoing
0:    ENABLE   Enable channel

The TX channel is enabled by setting ENABLE to 1b.

The Ongoing bit indicates whether the codec is transmitting a frame. If the TX channel is disabled while Ongoing is set to 1, the TX channel is disabled, but any ongoing transmission will continue until it finishes (either successfully or with errors). In this case, the DisACK bit is set to 1b to indicate the user that the TX channel will be completely disabled as soon as the ongoing transmission ends.

Changing the configuration of the TX channel (pointers, parameters of the buffer) is not safe when ongoing is set to 1b. The user shall wait until the TX channel is effectively disabled by monitoring both DisACK and ENABLE. When both are set to '0', the codec is no longer transmitting a frame, so the TX channel can be safely reconfigured.

If the single shot mode is enabled, the TX channel will be automatically disabled when a transmission does not complete successfully. This may be due to loss of arbitration, transmission errors, ACK not being sent by the receivers, etc. In this case, the content of the SRAM is removed to avoid blocking any future transmission and GRCANFD does not update the TX read pointer.

The TX channel will also be automatically disabled if the ABORT bit is set to 1b in the Configuration Register, and an AMBA error occurs while fetching a descriptor from the circular buffer. If the codec is transmitting a frame in parallel, the transmission is not interrupted, since that frame did not cause the error accessing the bus (a transmission only starts when all the descriptors describing the frame are fetched).

r		rw		r	

19-4:   WRITE   Pointer to last written descriptor+1

The WRITE field is written to in order to initiate a transfer, indicating the position +1 of the last descriptor to transmit.

Note that it is not possible to fill the buffer. There is always one descriptor position in buffer unused. Software is responsible for not over-writing the buffer on wrap around (i.e. setting WRITE=READ).

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

GRCANFD reads this register to know if there are more descriptors to fetch. While operating, it will never modify the write pointer, unless the core is being reset.

43.14.18 Transmit Channel Read Register

*Table 588.*0x210 - TXRD - Transmit Channel Read Register

31	20	19	4	3	0
Reserved		READ		Reserved	
0x000		0x0000		0x0	
r		rw		r	

19-4:   READ   Pointer to last read descriptor+1

The READ field is written to automatically by the core when a transfer has been completed successfully, indicating the position +1 of the last descriptor transmitted. If a frame consists of more than 1 descriptor, GRCANFD will not increment the pointer one by one, but update it with the final position directly.

Note that the READ field can be use to read out the progress of a transfer of a set of frames.

Note that the READ field can be written to in order to set up the starting point of a transfer. This should only be done while the transmit channel is not enabled and the codec is not transmitting any frame.

Note that the READ field may be incremented even if the transmit channel has been disabled, in case the codec was already transmitting a frame when the ENABLE was set to 0b. As explained previously, this is indicated by both the Ongoing and the DisACK bits of the TX control register.

When the Transmit Channel Read Pointer catches up with the Transmit Channel Write Register, an interrupt is generated (TxEmpty). Note that this implies that all descriptors stored in the buffer have been transmitted.

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

43.14.19 Transmit Channel Interrupt Register

*Table 589.*0x214 - TXIRQ - Transmit Channel Interrupt Register

31	20	19	4	3	0
Reserved		IRQ		Reserved	
0x000		0x0000		0x0	
r		rw		r	

19-4:   IRQ   Interrupt is generated when the value in the Tx Read register becomes equal to IRQ, as a consequence of the transmission of a frame

This register configures the interrupt TxIRQ, which indicates that a programmed number of descriptors have been transmitted.

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

Since CAN-FD frames may consist of up to 5 descriptors, the TX read pointer may be incremented internally several times per frame. The content of this register is therefore compared with the TX read pointer after each increment. This means that the interrupt will be asserted if the position of any of the descriptors conforming the frame matches the programmed position. Note that the interrupt is only generated once the transmission of the frame is successfully completed.

43.14.20 Receive Channel Control Register

*Table 590.*0x300 - RXCTRL - Receive Channel Control Register

31		4	3	2	1	0
Reserved			OF	Dis Ack	Ong oing	Ena ble
0x0000000			0	0	0	0
r			rw	r	r	rw

3:	OF	Overload Frame enable
2:	DisAck	Disable request acknowledged
1:	ONGOING	Reception ongoing (read-only)
0:	ENABLE	Enable channel

The RX channel is enabled by setting ENABLE to 1b.

The Ongoing bit indicates that a reception is taking place. There are two scenarios for this: the codec may be receiving the frame, or the frame has already been received, matches the acceptance filter and it is yet to be written to the circular buffer.

If the user disables the RX channel by setting ENABLE to 0b, any ongoing write access over the AMBA bus will finish. If it was the last descriptor of a frame, the reception is complete and the pointers, status registers and interrupts are updated accordingly. The DisACK bit is then set to 1b to acknowledge the disable request, and is cleared as soon as the RX channel is effectively disabled.

The RX channel may not be configured while Ongoing is 1b, as this may disrupt the status of the CAN bus. The user shall monitor both Ongoing and DisACK bits: when both are 0b and the channel has been disabled, it is safe to modify the configuration of the RX channel.

The RX channel is automatically disabled if the ABORT bit is set to 1b in the Configuration Register and an AMBA error is detected when accessing the bus.

The content of the RX SRAM is emptied whenever the RX channel is effectively disabled.

43.14.21 Receive Channel Address Register

*Table 591.*0x304 - RXADDR - Receive Channel Address Register

31	10	9	0
ADDR		Reserved	
0x000000		0x000	
rw		r	

31-10:	ADDR	Base address for RX circular buffer

43.14.22 Receive Channel Size Register

*Table 592.*0x308 - RXSIZE - Receive Channel Size Register

31	21	20	6	5	0
Reserved		SIZE		Reserved	
0x000		0x0000		0x00	
r		rw		r	

20-6:	SIZE	The size of the RX circular buffer is SIZE*4 descriptors

Valid SIZE values are between 0 and 16384.

GRIP
Apr 2024, Version 2024.1
556
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Note that each descriptor occupies four 32-bit words. A frame may consist of 1 to 5 descriptors depending on its format and data length.

Note that the resulting behavior of invalid SIZE values is undefined.

Note that only (SIZE*4)-1 descriptors can be stored simultaneously in the buffer. This is to simplify wrap-around condition checking.

43.14.23 Receive Channel Write Register

*Table 593.*0x30C - RXWR - Receive Channel Write Register

31	20	19	4	3	0
Reserved		WRITE		Reserved	
0x000		0x0000		0x0	
r		rw		r	

19-4:   WRITE   Pointer to last written descriptor +1

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

The WRITE field is written to automatically when a transfer has been completed successfully, indicating the position +1 of the last descriptor received. For frames consisting of more than 1 descriptor, GRCANFD will not increment the Write pointer one by one, but update it with the final position directly.

The Write pointer may be updated even after disabling the RX channel. This may be due to the fact that there was a frame being received or already in the local SRAM, and the storage takes place after the disable request.

Note that the WRITE field can be use to read out the progress of a transfer of a set of frames.

Note that the WRITE field can be written to in order to set up the starting point of a transfer. This should only be done while the receive channel is not enabled.

If the RX write pointer catches up with the read pointer, there is no space in the buffer for any additional descriptor. An interrupt is asserted informing that the buffer is full. GRCANFD will detect this and transmit up to 2 consecutive Overload Frames to delay the reception of the next frame. If a new frame arrives under this circumstance, the IP misses it and the Overrun bit in the Status Register is set, together with the Overrun interrupt.

43.14.24 Receive Channel Read Register

*Table 594.*0x310 - RXRD - Receive Channel Read Register

31	20	19	4	3	0
Reserved		READ		Reserved	
0x000		0x0000		0x0	
r		rw		r	

19-4:   READ   Pointer to last read descriptor +1

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

The READ field is written to in order to release the receive buffer, indicating the position +1 of the last descriptor that has been read out.

Note that it is not possible to fill the buffer. There is always one descriptor position in buffer unused. Software is responsible for not over-reading the buffer on wrap around (i.e. setting WRITE=READ).

GRCANFD will never modify the RX read pointer, unless the IP is being reset.

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

43.14.25 Receive Channel Interrupt Register

*Table 595.*0x314 - RXIRQ - Receive Channel Interrupt Register

31	20	19	4	3	0
Reserved		IRQ		Reserved	
0x000		0x0000		0x0	
r		rw		r	

19-4:	IRQ	Interrupt is generated when the value in the Rx Write register becomes equal to IRQ, as a consequence of reception of a message

This register configures the interrupt which indicates that a programmed number of descriptors have been received.

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

Since CAN-FD frames may consist of up to 5 descriptors, the RX write pointer may be incremented internally several times per frame. The content of this register is therefore compared with the RX write pointer after each increment. This means that the interrupt will be asserted if the position of any of the descriptors conforming the frame matches the programmed position. Note that the interrupt is only generated once the storage of the frame is successfully completed.

43.14.26 Receive Channel Acceptance Mask Register

*Table 596.*0x318 - RXMASK - Receive Channel Acceptance Mask Register

31	30	29	28	0
Reserved			AM	
000			0x1FFFFFFF	
r			rw	

28-0:	AM	Acceptance Mask: bits set to 1b are taken into account in the comparison between the received frame ID and the CanRxCODE.AC field

All bits are set to 1 at reset.

Note that Base ID corresponds to the bits 28 to 18 and Extended ID corresponds to the bits 17 to 0.

43.14.27 Receive Channel Acceptance Code Register

*Table 597.*0x31C - RXCODE - Receive Channel Acceptance Code Register

31	30	29	28	0
Reserved			AC	
000			0x00000000	
r			rw	

28-0:	AC	Acceptance Code, used in comparison with the received frame ID

Note that Base ID corresponds to the bits 28 to 18 and Extended ID corresponds to the bits 17 to 0.

When a frame is received by the internal CAN-FD codec, GRCANFD applies the Acceptance filter to decide whether it should be stored into the circular buffer. A frame matches the filter if the following condition is verified:

$$((\text{Received-ID}) \text{ XOR } (\text{ACCPT CODE})) \text{ AND } (\text{ACCPT MASK}) = 0$$

43.14.28 Interrupt registers

The interrupt registers give complete freedom to the software, by providing means to mask interrupts, clear interrupts, force interrupts and read interrupt status.

When an interrupt occurs the corresponding bit in the Pending Interrupt Register is set. The normal sequence to initialize and handle a module interrupt is:

- Set up the software interrupt-handler to accept an interrupt from the module.

- Read the Pending Interrupt Register to clear any spurious interrupts.

- Initialize the Interrupt Mask Register, unmasking each bit that should generate the module interrupt.

- When an interrupt occurs, read the Pending Interrupt Status Register in the software interrupt-handler to determine the causes of the interrupt.

- Handle the interrupt, taking into account all causes of the interrupt.

- Clear the handled interrupt using Pending Interrupt Clear Register.

Masking interrupts: After reset, all interrupt bits are masked, since the Interrupt Mask Register is zero. To enable generation of a module interrupt for an interrupt bit, set the corresponding bit in the Interrupt Mask Register.

Clearing interrupts: All bits of the Pending Interrupt Register are cleared when it is read or when the Pending Interrupt Masked Register is read. Reading the Pending Interrupt Masked Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register. Selected bits can be cleared by writing ones to the bits that shall be cleared to the Pending Interrupt Clear Register.

Forcing interrupts: When the Pending Interrupt Register is written, the resulting value is the original contents of the register logically OR-ed with the write data. This means that writing the register can force (set) an interrupt bit, but never clear it.

Reading interrupt status: Reading the Pending Interrupt Status Register yields the same data as a read of the Pending Interrupt Register, but without clearing the contents.

Reading interrupt status of unmasked bits: Reading the Pending Interrupt Masked Status Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register, but without clearing the contents.

The interrupt registers comprise the following:

- Pending Interrupt Masked Status Register   [CanPIMSR]   R
- Pending Interrupt Masked Register   [CanPIMR]   R
- Pending Interrupt Status Register   [CanPISR]   R
- Pending Interrupt Register   [CanPIR]   R/W
- Interrupt Mask Register   [CanIMR]   R/W
- Pending Interrupt Clear Register   [CanPICR]   W

0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
*	*	*	*	*	*	*	*	*	*	*	*	*	*	*	*

20:	COHbErr	CANOpen Heartbeat Timeout Error
19:	COSync	CANOpen SYNC command received
18:	COWrCmd	CANOpen write command processed
17:	CORdCmd	CANOpen read command processed
16:	TxLoss	Unsuccessful transmission (due to loss of arbitration or errors in the frame)
15:	RxMiss	Message filtered away during reception
14:	TxErrCntr	Transmission error counter incremented
13:	RxErrCntr	Reception error counter incremented
12:	TxSync	Synchronization message transmitted by the codec
11:	RxSync	Synchronization message received by the codec
10:	Tx	Successful transmission of message
9:	Rx	Successful reception of message
8:	TxEmpty	Successful transmission of all frames in TX circular buffer
7:	RxFull	Successful reception of all frames possible to store in RX circular buffer
6:	TxIRQ	The Tx Read Pointer is equal to the value stored in Tx IRQ register
5:	RxIRQ	The Rx Write Pointer is equal to the value stored in Rx IRQ register
4:	BmRdErr	Error during AMBA read access
3:	BmWrErr	Error during AMBA write access
2:	OR	Over-run during reception
1:	OFF	Bus-off condition
0:	PASS	Error-passive condition

All bits in all interrupt registers are reset to 0b after reset.

Note that the BmRdErr interrupt is generated in such way that the corresponding read and write pointers are valid for failure analysis in standard mode. The interrupt generation is independent of the Can-CONF.ABORT field setting.

Note that the BmWrErr interrupt is generated in such way that the corresponding read and write pointers are valid for failure analysis in standard mode. The interrupt generation is independent of the Can-CONF.ABORT field setting.

43.15 Backwards compatibility between GRCAN and GRCANFD

GRCANFD is designed following the same approach as GRCAN, but adapting the register interface to the new frame formats and data lengths. This section summarizes the main differences introduced by GRCANFD from the user's point of view:

- While frames in GRCAN were always represented by a single descriptor, FD frames in GRCANFD may require from 1 to 5 descriptors in the circular buffers due to the larger data pay-

GRIP
Apr 2024, Version 2024.1

560

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

load. Whereas the first descriptor of a frame is still compatible, the descriptors 2 to 5 (if applicable) only contain data bytes and do not replicate the bits describing the format of the frame.

- The first descriptor of a frame includes the FDF and BRS bits. These are both set to 0b for classical CAN frames, so it is fully compatible with the memory representation of CAN frames in GRCAN, as these bits were unused.

- The Configuration Register (APB offset 0x000) does not include the CAN timing parameters anymore. Two new registers are created for this purpose: the Nominal Bit-Rate Configuration Register (0x040) and Data Bit-Rate Configuration Register (0x044).

- BPR (Baud Rate) and SAM (Triple Sampling) not supported by GRCANFD. In GRCAN these features may be enabled in the Configuration Register (0x000).

- New control bits to enable the generation of Overload Frames (Receive Channel Control Register, 0x300) and the internal/external loop-back modes (Configuration Register 0x000).

- New Capability Register (0x00C) providing information about the configuration of the generics when instantiating GRCANFD.

- New register for configuring the Transmitter Delay Compensation (0x048). This only applies to the data phase of FD frames (i.e. when switching the bit-rate).

- Since multiple descriptors may be necessary for describing a frame, the interrupts TxIRQ and RxIRQ are asserted when **any** of the descriptors of a transmitted/received frame matches the position programmed via the registers.

- Different device identifier: 0x03D for GRCAN; 0x0B5 for GRCANFD.

- New CANOpen mode. This mode uses a different set of registers. By default the IP operates in standard mode, which is the same general behavior as in GRCAN.

43.16 Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0B5 (GRCANFD). For description of vendor and device identifiers see GRLIB IP Library User's Manual.

43.17 Implementation

43.17.1 Reset

The core changes its reset behavior depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

GRCANFD will feature a synchronous reset if the parameter *grlib_async_reset_enable* is not set in the GRLIB configuration package. On the contrary, it will implement an asynchronous reset if *grlib_async_reset_enable* is set.

The reset is applied to all the registers in GRCANFD, except for the synchronization registers.

43.17.2 Endianness

The core automatically changes its endianness behavior depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for both big-endian and little-endian systems.

43.18 Configuration options

Table 599 shows the configuration options of the core (VHDL generics).

*Table 599.*Configuration options

Generic name	Function	Allowed range	Default
tech	Technology for the syncram and the sync. registers	0 - NTECH	inferred (0)
hindex	AHB master index	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar	0 - 16#FFF#	0
pmask	Mask field of the APB bar	0 - 16#FFF#	16#FFC#
pirq	Interrupt line used by the GRCANFD	0 - NAHBIRQ-1	1
singleirq	Implement only one common interrupt	0 - 1	0
txbufsize	Size of the internal TX buffer expressed in number of frames. The size can be calculated as *txbufsize* * 64 bytes.	1 - 8	2
rxbufsize	Size of the internal RX buffer expressed in number of frames. The size can be calculated as *rxbufsize* * 64 bytes.	1 - 8	2
ft	Enable fault-tolerance against SEU errors. The core can optionally be implemented with fault-tolerance against SEU errors in the FIFO memories by setting this generic to 1, 2, 4 or 5. Possible options are byte parity protection (ft = 1), TMR registers (ft = 2), SECDED BCH (ft = 4) or technology specific protection (ft = 5). If set to 0, no protection is implemented.	0 - 2, 4 - 5	0
scantest	Enable Scan Test support.	0 - 1	0
canopen	Implement a CANOpen target as part of the DMA layer. Enable the CANOpen-specific APB registers and the CANOpen mode. If set, certain registers are automatically configured during reset by sampling the configuration record cfg. This allows to establish communication with the CAN bus automatically without software intervention.	0 - 1	0
sepbus	Generate a separate bus master interface for the AMBA accesses in CANOpen mode. If set to 0, the standard and the CANOpen mode share the same bus master interface. Only valid if the generic *canopen* is also set to 1.	0 - 1	0
hindexcopen	AHB master index of the CANOpen bus. Only valid if both generics *canopen* and *sepbus* are set to 1.	0 - NAHBMST-1	0
ahbbits	Width of AHB read/write data buses and maximum access size	32, 64, 128	AHBDW

If *singleirq* is set to 1 there will be only one interrupt line, whose number will be the one set by *pirq*. Otherwise, if *singleirq* is set to 0, there will be three interrupt lines (Paragraph 38.8), whose numbers will be *pirq, pirq+1 and pirq+2*.

44 GRCLKGATE / GRCLKGATE2X - Clock gating unit

44.1 Overview

The clock gating unit provides a means to save power by disabling the clock to unused functional blocks. The core provides a mechanism to automatically disabling the clock to LEON processors in power-down mode, and optionally also to disable the clock for floating-point units.

The core provides a register interface via its APB slave bus interface.

The clock gate unit has two main top-level units, GRCLKGATE and GRCLKGATE2X. GRCLK-GATE2X exposes the full functionality and is the recommended top-level for new designs.

44.2 Operation

The operation of the clock gating unit is controlled through four registers: the unlock, clock enable, core reset and CPU/FPU override registers. The clock enable register defines if a clock is enabled or disabled. A '1' in a bit location will enable the corresponding clock, while a '0' will disable the clock. The core reset register allows to generate a reset signal for each generated clock. A reset will be generated as long as the corresponding bit is set to '1'. The bits in clock enable and core reset registers can only be written when the corresponding bit in the unlock register is 1. If a bit in the unlock register is 0, the corresponding bits in the clock enable and core reset registers cannot be written.

To gate the clock for a core, the following procedure should be applied:

1. Disable the core through software to make sure it does not initialize any AHB accesses

2. Write a 1 to the corresponding bit in the unlock register

3. Write a 0 to the corresponding bit in the clock enable register

4. Write a 0 to the corresponding bit in the unlock register

To enable the clock for a core, the following procedure should be applied

1. Write a 1 to the corresponding bit in the unlock register

2. Write a 1 to the corresponding bit in the core reset register

3. Write a 1 to the corresponding bit in the clock enable register

4. Write a 0 to the corresponding bit in the clock enable register

5. Write a 0 to the corresponding bit in the core reset register

6. Write a 1 to the corresponding bit in the clock enable register

7. Write a 0 to the corresponding bit in the unlock register

The clock gating unit also provides gating for the processor core and, optionally, floating-point units. A processor core will be automatically gated off when it enters power-down mode.

With the GRCLKGATE and GRCLKGATE2X units, any shared FPU will be gated off when all processor cores connected to the FPU have floating-point disabled or when all connected processor cores are in power-down mode.

With the GRCLKGATE2X unit it is also possible to support dedicated FPU clock gating. In this case a FPU will be gated off when processor core connected to the FPU has floating-point disabled or when the processor core is in power down mode.

Processor/FPU clock gating can be disabled by writing '1' to bit 0 of the CPU/FPU override register.

44.2.1 Shared FPU

For systems with shared FPU, a processor may be clock gated off while the connected FPU continues to be clocked. The power-down instruction may overtake a previously issued floating-point instruc-

tion and cause the processor to be gated off before the floating-point operation has completed. This can in turn lead to the processor not reacting to the completion of the floating-point operation and to a subsequent processor freeze after the processor wakes up and continues to wait for the completion of the floating-point operation.

In order to avoid this, software must make sure that all floating-point operations have completed before the processor enters power-down. This is generally not a problem in real-world applications as the power-down instruction is typically used in a idle loop and floating-point results have been stored to memory before entering the idle loop. To make sure that there are no floating-point operations pending, software should perform a store of the %fsr register before the power-down instruction.

44.3 Registers

The core's registers are mapped into APB address space.

Table 603. Clock gate unit registers

+46 31 7758650 | frontgrade.com/gaisler

44.5 Implementation

44.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset for its internal registers.

44.5.2 Clock gate implementation

The clock gates are implemented using the CLKAND core in the techmap library, that instantiates the appropriate cell for the selected technology.

For ungated clocks, dummy clock gates are instantiated with the same technology but the isdummy generic set to 1. The technology mapping for the technology can decide whether to instantiate real clock gating cells for the technology or to pass the clock through as-is without any gating.

44.5.3 Scan test support

The test-enable signal is taken in through the APB input record and passed through to the techmap layer where it can be connected to the clock gating cell's test enable input or OR:ed into the normal enable if no test-enable input is available. Another alternative is to drive the cell's test enable input with constant 0 and hook it up to test-enable or scan-enable during the DFT implementation. Refer to the synthesis/DFT tools documentation for more details.

A separate ungate active-high input signal that also sets all clock gates to pass-through can be enabled in the core. This is passed in through the functional path.

44.5.4 Simulation

The underlying technology-specific gating in the techmap layer should ensure that all the gated and ungated clocks generated are delay and delta aligned to avoid zero-delay simulation problems. The standard solution is to add a 5 ps delay that gets removed on synthesis, however some technologies may use a different approach.

44.6 Configuration options

Table 608 shows the configuration options of the core (VHDL generics).

*Table 608.*Configuration options

Generic	Function	Allowed range	Default
tech	Clock/fabrication technology	0 to NTECH-1	0
pindex	Selects which APB select signal (PSEL) will be used to access the unit		
paddr	The 12-bit MSB APB address	0 to 16#FFF#	0
pmask	The APB address mask	0 to 16#FFF#	16#FFF#
ncpu	Number of processors that will connect to the unit	-	1
nclks	Number of peripheral units (clock/reset pairs) in addition to any processors and floating-point units that will connect to the unit.	0 - 31	8
emask	Bit mask where bit n (0 is the least significant bit) decides if a unit should be enabled (1) or disabled (0) after system reset.	0 - 16#FFFFFFFF#	0
extemask	If this generic is set to a non-zero value then the after-reset-enable-mask will be taken from the input signal epwen.	0 - 1	0
scantest	Enable scan test support	0 - 1	0

45 GRDMAC - DMA Controller with internal AHB/APB bridge

45.1 Overview

The GRDMAC core provides a flexible direct memory access controller. The core can perform burst transfers of data between AHB and APB peripherals at aligned or unaligned memory addresses. The core can be instantiated with one or two AHB master interfaces to perform transfers among different AHB buses.

The core's configuration registers are accessible through an APB interface. Up to 16 DMA channels are supported. Each channel can be configured flexibly by means of two descriptor chains residing in main memory: a Memory to Buffer (M2B) chain and a Buffer to Memory (B2M) chain. Each chain is composed of a linked list of descriptors, where each descriptor specifies an AHB address and the size of the data to read/write, supporting a scatter/gather behavior.

Once enabled, the core will proceed in reading the descriptor chains, then reading memory mapped addresses specified by the M2B chain and filling its internal buffer. It will then write the content of the buffer back to memory mapped addresses by elaborating the B2M descriptor chain.

The core supports a simplified mode of operation, with only one channel. In this mode of operation only one descriptor is present for each of the M2B and B2M chains. These two descriptors are written directly in the core's register via APB.

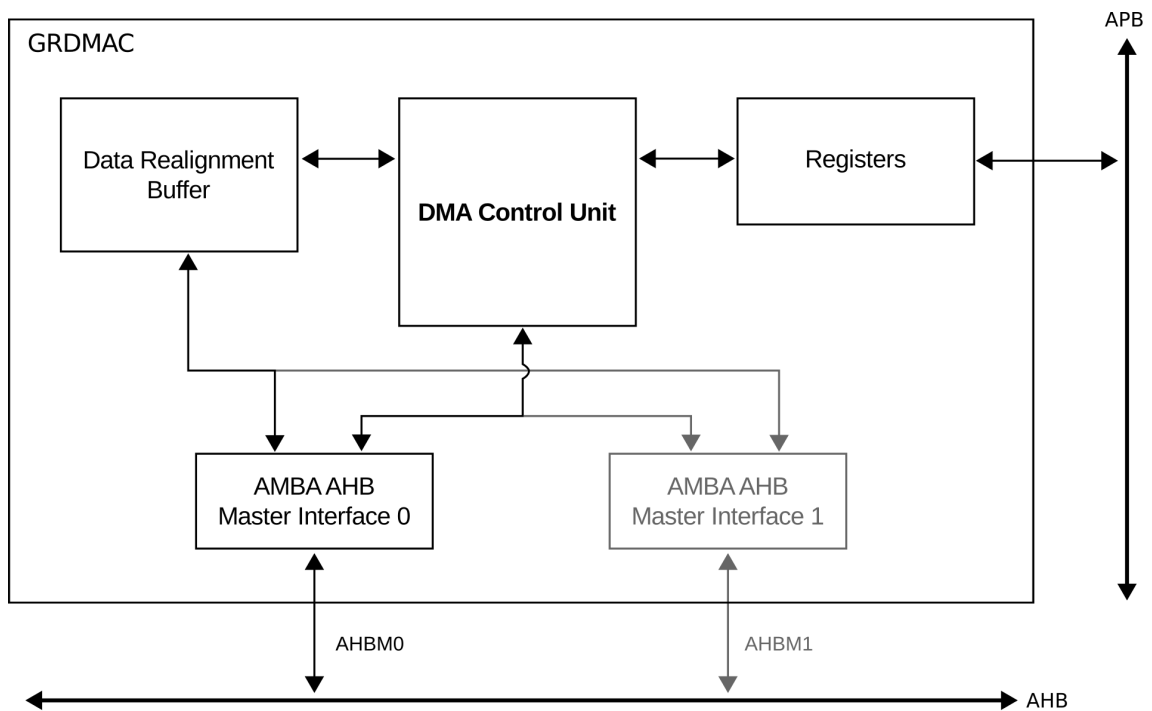
Note: This IP core is deprecated and should not be used for new designs. Please see the GRDMAC2 IP core instead.


Figure 131. Block diagram

45.2 Configuration

The GRDMAC core consists of four main components: the DMA control unit, the AHB Master interface, the internal buffer with realignment support and an optional second AHB Master interface. The core supports being attached to any AHB bus with a data width of 32-bit, 64-bit or 128-bit. For every DMA channel the core will perform two types of DMA transfers through one of the AMBA AHB

GRIP
Apr 2024, Version 2024.1

573

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Master interfaces: from memory to the internal buffer (M2B) and from the internal buffer to memory (B2M). The core will read data from memory until its internal buffer is filled or until the M2B descriptor chain is completed. When one of these two events is detected, GRDMAC will start writing the buffer content into memory, by switching to the B2M chain.

The internal buffer size is configurable through the generic *bufsize*. In case the buffer size is smaller that the total size of the M2B chain, the core will switch multiple times from the M2B chain to the B2M chain and vice versa.

The second AHB Master Interface is enabled by setting the *en_ahbm1* generic to 1. If the second interface is not enabled, all settings related to it will be ignored and the core will default to the main AHB Master Interface for all transfers.

45.2.1 Core setup

The GRDMAC core reads its configuration from any AHB mapped address (typically main memory) through its main AMBA AHB Master interface (AHBM0 if instantiated with support for two master interfaces). The core supports up to 16 DMA channels, a number configurable through the *ndmach* generic. For each channel, the M2B and B2M descriptor linked lists must be set up, and a pointer to the first descriptor in the two chains must be provided. These pointers are organized in a structure called Channel Vector. The Channel Vector is organized as in Table 611, below. For each of the GRDMAC channels there are two pointers: one pointer to the M2B descriptor linked list and one pointer to the B2M descriptor linked list. The Channel Vector array must be created at a 128-byte-aligned address. The GRDMAC core will read the Channel Vector entries for each channel up to *ndmach* channels.

Table 611. GRDMAC Channel Vector format

Address offset	Field
0x00	Channel 0: M2B descriptor pointer
0x04	Channel 0: B2M descriptor pointer
0x08	Channel 1: M2B descriptor pointer
0x0C	Channel 1: B2M descriptor pointer
...	...
...	...
0x78	Channel 15: M2B descriptor pointer
0x7C	Channel 15: B2M descriptor pointer

45.2.2 Descriptor types

Each descriptor consists of a four-field structure as provided in the tables below and must be created at a 16-byte-aligned address. There are three descriptor types: M2B descriptors, B2M descriptors and conditional descriptors.

The former two descriptors, categorized as data descriptors, are only allowed in the respective descriptor linked lists (M2B descriptor linked list and B2M descriptor linked list).

Conditional descriptors on the other hand, are required to be followed by a data descriptor, to which they bond to, and they can be specified in both the M2B and B2M descriptor linked lists. They are special descriptors that enable conditional behavior in a descriptor linked list and they are described in more detail in paragraph 45.3.2.

+46 31 7758650 | frontgrade.com/gaisler

45.2.3 Data descriptors

For data descriptors, the first field, the next_descriptor field, is the address of the next descriptor in the chain. The chain ends with a descriptor whose next_descriptor field is all zeroes (NULL pointer).

The second field of an M2B descriptor, the address field, defines the address to read the data from. It can be any address in the system, and there are no alignment requirements. The number of bytes to transfer from memory to the internal buffer is specified in the third field, the control field, as seen in the table below.

*Table 612.*GRDMAC M2B descriptor format

Address offset	Field
0x0	M2B next_descriptor
0x4	M2B address
0x8	M2B control
0xC	M2B status

Table 613. GRDMAC M2B descriptor next_descriptor field (address offset 0x00)

31		4	3	1	0
	NEXT_PTR		RESERVED		DT

31: 4	M2B Next descriptor pointer address (NEXT_PTR) - MSb of 16 Byte aligned address of the next descriptor in the M2B descriptor chain or NULL.
0	M2B descriptor type (DT) - Descriptor type field, '0' for data descriptors, '1' for conditional descriptors. Must be set to '0' for this type of descriptor.

Table 614. GRDMAC M2B descriptor address field (address offset 0x04)

31	0
ADDR	

31: 0	M2B Address (ADDR) - Starting address the core will read data from.

Table 615. GRDMAC M2B descriptor control field (address offset 0x08)

31	16	15	5	4	3	2	1	0
SIZE		RESERVED		FA	AN	IE	WB	EN

31: 16	M2B descriptor size (SIZE) - Size in Bytes of the data that will be fetched from the address specified in the M2B address register.
4	M2B descriptor Fixed Address (FA) - If set to '1', the data will be fetched from the same address for the entire size of the descriptor transfer. This is useful when reading from IO peripheral registers in combination with a conditional descriptor. If set to '0', normal operation mode is attained.
3	M2B descriptor AHB Master Interface Number (AN) - If set to '0', the descriptor's transfer will be performed by the main AHB Master Interface (AHBM0). If set to '1', the descriptor's transfer will be performed by the second AHB Master Interface (AHBM1). If this interface is not enabled by the configuration generic *en_ahbm1*, then the transfer will fall back to the main AHB Master Interface (AHBM0).
2	M2B descriptor Interrupt Enable (IE) - If set to one, an interrupt will be generated when the M2B descriptor is completed. Descriptor interrupt generation also depends on interrupt mask for channel 0 and global interrupt enable.

4	B2M descriptor Fixed Address (FA) - If set to '1', the data will be fetched from the same address for the entire size of the descriptor transfer. This is useful when writing to IO peripheral registers in combination with a conditional descriptor. If set to '0', normal operation mode is attained.
3	B2M descriptor AHB Master Interface Number (AN) - If set to '0', the descriptor's transfer will be performed by the main AHB Master Interface (AHBM0). If set to '1', the descriptor's transfer will be performed by the second AHB Master Interface (AHBM1). If this interface is not enabled by the configuration generic *en_ahbm1*, then the transfer will fall back to the main AHB Master Interface (AHBM0).
2	B2M descriptor Interrupt Enable (IE) - If set to one, an interrupt will be generated when the B2M descriptor is completed. Descriptor interrupt generation also depends on interrupt mask for channel 0 and global interrupt enable.
1	B2M descriptor write-back (WB) - If set to one, the descriptor's status field will be written back in main memory after completion.
0	B2M descriptor Enable (EN) - If set to one, the descriptor will be enabled, otherwise it will be skipped and the next descriptor fetched from memory.

Table 621. GRDMAC B2M descriptor status field (address offset 0x0C)

31	3	2	1	0
RESERVED		E	S	C

2	B2M descriptor error (E) - If set to one, an error was generated during execution of the B2M descriptor. See error register for more information.
1	B2M descriptor status (S) - If set to one, the descriptor is being executed and running. Otherwise set to zero.
0	B2M descriptor completion (C) - If set to one, the descriptor was completed successfully.

If a descriptor's write-back bit in its control field is set to one, the descriptor's status field will be written back to memory after completion. The transfer uses the AMBA AHB Master interface of the core.

45.2.4 Conditional descriptors

A conditional descriptor is a special kind of descriptor which bonds to a data descriptor and provides additional conditional behavior to it. A conditional descriptor can be used to create a DMA channel that retrieves data from IO cores, therefore off loading the CPU from the task. Usually IO cores provide a status register or an interrupt line to notify the CPU of the availability of new data. A conditional descriptor can be set up to poll this status register or to be triggered by an interrupt, signaling for instance, the availability of new data. Once data is available, the bond data descriptor is executed, accumulating the data in the internal buffer of the DMA core, before bursting it to memory for the software to handle it.

There are, hence, two kinds of conditional descriptors: polling conditional descriptors or triggering conditional descriptors. The former kind will continuously poll an address for data, and once a termination condition on the retrieved data is met, will yield to the data descriptor. The latter kind will instead have the core entering a state where it waits for a monitored input signal line to trigger. When the monitored input line is sampled to a value of '1', the data descriptor will be executed.

To set up a triggering conditional descriptor, the IT bit field in the descriptor's control field needs to be set to '1'. Bits 5:0 of the conditional address/triggering line field will specify which of the 64 input lines of the IRQ_TRIG signal will be monitored. During the execution of the triggering conditional descriptor, the triggering line is monitored every clock cycle, and when the value of the line is '1', the conditional execution will terminate and the data descriptor will be yield, fetching COND_SIZE bytes before going back to executing the conditional triggering. The data descriptor will be considered completed when all the bytes from the data descriptor, specified in the SIZE field, have been transfered, in amounts of COND_SIZE at each triggering. If the *timer_en* VHDL configuration generic is set to '1',

GRIP

+46 31 7758650 | frontgrade.com/gaisler

an optional timeout counter can be enabled during the triggering conditional descriptor execution. By setting the TE bit field in the core's control register to '1' and by setting the Timer Reset Value Register to the required number of clock cycles, the descriptor execution is halted with a Timeout Error if an interrupt is not received before the timer expires. The error halts the channel execution after eventual descriptor write-back is performed.

To set up a polling conditional descriptor, the IT bit field in the descriptor's control field needs to be set to '0'. Bits 31:0 of the conditional address/triggering line field will point to the address that the DMA core will poll for data until the termination condition is TRUE. The condition is specified as the bitwise AND between the 32-bit word pointed by COND_ADDR and the COND_MASK. This value is compared to 0 according to the following formulas, according to the termination condition type selected in the conditional control field (CT).

Table 622. GRDMAC Conditional descriptor Termination condition type 0

$$(*COND\_ADDR \wedge COND\_MASK) = 0$$

Table 623. GRDMAC Conditional descriptor Termination condition type 1

$$*COND\_ADDR \wedge COND\_MASK \neq 0$$

When the condition is TRUE, the conditional descriptor will stop polling and will proceed with fetching COND_SIZE bytes from the data descriptor pointed by NEXT_PTR. The behavior of conditional descriptors is explained in depth in paragraph 45.3.2.

Also in paragraph 45.3.2 is an example configuration of a conditional DMA channel for UART reading.

Table 624. GRDMAC Conditional descriptor format

Address offset	Field
0x0	Conditional next_descriptor
0x4	Conditional address/triggering line
0x8	Conditional control
0xC	Conditional mask

Table 625. GRDMAC Conditional descriptor next_descriptor field (address offset 0x00)

31	4	3	1	0
NEXT_PTR		RESERVED		DT

31: 4	Conditional Next descriptor pointer address (NEXT_PTR) - Address of the data descriptor in the descriptor chain which the conditional descriptor is bond to. Cannot be NULL.
0	Conditional descriptor type (DT) - Descriptor type field, '0' for data descriptors, '1' for conditional descriptors. Must be set to '1' for this type of descriptor.

Table 626. GRDMAC Conditional descriptor address field (address offset 0x04)

31	6	5	0
COND_ADDR[31:6]		COND_ADDR[5:0] / IRQN	

31: 0	Conditional Address (COND_ADDR) - Address of the 32-bit word the core will read for the conditional termination expression matching.
5: 0	IRQ Trigger Line Number (IRQN) - Index of the IRQ_TRIG signal input vector which is used as the triggering line for triggered conditional descriptors, 0 to 63.

Table 627. GRDMAC Conditional descriptor control field (address offset 0x08)

31	16	15	4	3	2	1	0
COND_SIZE		COUNTER_RST		AN	CT	IT	EN

31: 16	Conditional descriptor total size (COND_SIZE) - Total size in Bytes of the data that will be fetched from the bond data descriptor each time the conditional termination expression matches to true.
15: 4	Conditional descriptor counter reset value (COUNTER_RST) - Reset value of the conditional counter timer that is executed before every polling or triggering. The unit is number of clock cycles and the purpose is to provide a timer between polling requests onto the AMBA AHB bus with enough clock cycles in order not to clog the bus.
3	Conditional descriptor AHB Master Interface Number (AN) - If set to '0', the descriptor's transfer will be performed by the main AHB Master Interface (AHBM0). If set to '1', the descriptor's transfer will be performed by the second AHB Master Interface (AHBM1). If this interface is not enabled by the configuration generic *en_ahbm1*, then the transfer will fall back to the main AHB Master Interface (AHBM0).
2	Conditional descriptor Termination Condition type (CT) - If the conditional descriptor is of type "polling", this bits specifies which type of termination condition is used. If '0', the termination condition is of type 0 as specified in this paragraph. If '1', the termination condition is of type 1.
1	Conditional Descriptor Irq Trigger (IT) - If set to '1', the conditional descriptor will wait for the input interrupt line to go high before executing the bond data descriptor. The selected interrupt line is the one indexed by IRQN in the IRQ_TRIG signal input vector. This bit enables triggering behavior of conditional descriptors. If this bit is set to '0', normal polling behavior with termination condition is enabled.
0	Conditional descriptor Enable (EN) - If set to one, the descriptor will be enabled, otherwise it will be skipped and the next descriptor fetched from memory.

Table 628. GRDMAC Conditional descriptor mask field (address offset 0x0C)

31	0
COND_MASK	

31: 0	Conditional Mask (COND_MASK) - Bit mask used in the conditional descriptor termination condition matching.

45.2.5 Register setup

Once the channel vector and the relative descriptor chains are setup in main memory, the GRDMAC register must be also setup. The 128-byte-aligned address, where the Channel Vector resides, must be written in the Channel Vector Pointer register. The control register must also be setup. Once the enable bit of the control register is set to one, the core will start running and will execute all the channels which are enabled.

45.3 Operation

45.3.1 Normal mode of operation

In normal mode of execution, GRDMAC will start executing all the enabled channels until they are complete or an error is generated.

When executing a DMA channel, the core will initially fetch the two descriptor pointers from the address provided in the CVP register which are relative to the channel. It will then fetch the first M2B and B2M descriptors from main memory. The M2B descriptor chain is then executed until either the internal buffer is full, or the M2B chain is completed. If one of this events happen, the core will switch to the B2M descriptor chain. The B2M chain will switch back to the M2B chain when the buffer is empty. The DMA channel is marked complete when the last descriptor in the B2M chain is executed, finally emptying the buffer.

During the execution of a chain, the core will fetch a new descriptor after the successful completion of the previous one, following the pointers in the linked list. When the core reaches a NULL pointer in the M2B chain, it will switch to the B2M chain. When it reaches a NULL pointer in the B2M chain, the core will update the DMA channel status and switch to the next enabled DMA channel, until all the channels are completed.

45.3.2 Operation with conditional descriptors

Conditional descriptors bond to the following data descriptor in the linked list and provide conditional behavior to the execution of the data descriptor. During the execution of a DMA channel, when the core fetches a conditional descriptor from memory, it will proceed and fetch the following descriptor in the chain as well, which must be a data descriptor.

After the descriptors' pair has been fetched, the conditional execution will follow these steps:

a) the core will execute the conditional counter, down counting for COUNTER_RST clock cycles

b) if the conditional descriptor is a polling descriptor, go to step **c1**, if it's a triggering descriptor, go to step **c2**.

c1) the core will fetch a 32-bit word at the COND_ADDR address.

d1) if the conditional termination condition of Table 623 is *false* then the core will go back to step **a,** if the conditional termination condition of Table 623 is *true*, the core will fetch a portion of the data from the data descriptor which is COND_SIZE bytes, then go back to step **a**.

c2) the core will monitor line IRQN of the IRQ_TRIG input signal, indefinitely or until the trigger counter expires.

d2) when the monitored line has a value of '1', the core will fetch a portion of the data from the data descriptor which is COND_SIZE bytes, then go back to step **a**.

The total SIZE of the bond data descriptor will be decremented by COND_SIZE bytes every time the bond data descriptor is executed, and the ADDRESS will be incremented by the same amount (unless the FA flag is set).

The FA (Fixed Address) bit field in the data descriptor control field is useful when accessing data to/ from a peripheral data register, i.e. UART data register, when you need to read/write always from/to the same address.

The execution of the descriptor pair (conditional and bond data descriptors) ends when the SIZE field of the data descriptor reaches 0. In other words, the execution ends when SIZE bytes have been fetched in total from the data descriptor, by fetching COND_SIZE byte amounts every time the conditional condition (polling or triggering) is true.

45.3.3 Simplified mode of operation

In Simplified Mode of Operation, the GRDMAC core configuration resides entirely in its configuration registers and the Channel Vector structure is not used. The core will not perform any memory access to fetch configuration data. This mode of operation makes use of only two data descriptors, respectively one descriptor for M2B transfers and one for B2M transfers. Conditional descriptors are not supported in this mode. The descriptors are written directly onto GRDMAC via APB at offsets 0x20 and 0x30. Their next_descriptor field is hardwired to zeroes. Their status is always written-back to their relative descriptor status register.

When the core is configured in Simplified mode of operation, the relative bit (SM) must be set to one in the control register. The core will execute the two internal descriptors on channel zero. Channel zero must therefore be enabled, and the core status can be read on channel zero's status bits in the status register.

45.4 AHB transfers

For every descriptor executed, GRDMAC will perform an AHB data transfer at the address and of the size specified. The AHB accesses that it can perform are up to 128-bit wide and can be at aligned or unaligned memory addresses. The maximum AHB access width depends on the AHB bus width and on the *busw* and *wbmask* generics, as described in paragraph 45.7.

The core will perform unaligned memory access if defined by the descriptors. It will perform byte (8 bit) accesses at byte-aligned addresses, half-word (16 bit) accesses at half-word aligned addresses, and so on. The core will perform burst transfers of the maximum supported width for as long as possible according to the total transfer size. For example, if the maximum supported bus width for one transfer is 64-bit, and a descriptor requests 18 bytes at address 0x40000006, the core will perform one 16-bit half-word access, and one two-beat burst of double words. In some cases, the total transfer size might require GRDMAC to perform additional word, half-word and/or byte accesses at the end of the transfer. The burst accesses performed by GRDMAC are of type incrementing burst of unspecified length. These bursts will never cross a 1KB memory boundary, or a smaller boundary that can be set with the generic *burstbound*. At the specified memory boundary set by *burstbound*, the burst will be interrupted, an idle cycle will be inserted and the incrementing burst of unspecified length will restart from the next address. This generic can be used to limit the maximum burst length performed by the core, making re-arbitration on the AHB bus more frequent.

When the core is configured with the VHDL generic *en_ahbm1* set to '1', a secondary AHB Master interface will be instantiated inside the GRDMAC core. This interface can be connected to a second AHB bus to provide bridging capabilities to the DMA controller. The core will fetch data from this interface when the AN flag in the descriptor's control field is set accordingly. This flag will be ignored in case the core is configured with the *en_ahbm1* VHDL generic set to '0'.

45.5 Data realignment buffer

The realignment buffer is the data buffer used internally by the GRDMAC core. The component allows the core to store the data in a tightly packed way, being optimized to store AMBA AHB transfer data of different size and at different address offsets.

The internal buffer uses RAM implemented using GRLIB parameterizable SYNCRAMBW memories, assuring portability to all supported technologies. Internally two SYNCRAMBW are used, one for even words and one for odd words. The total number of RAMs used depends on the *bufsize* generic, and its minimum size is two words, 8 bytes. To control the implementation technology of the internal RAMs, the technology mapping generic *memtech* may be used. Additionally, the generic *testen* will be propagated to the SYNCRAMBW and is used to enable scan test support.

Fault tolerance can be added to the RAM by setting the *ft* generic to a value different than 0. To obtain byte parity DMR memories, set the *ft* generic to 1. To use TMR set it to 2. Note that the *ft* generic

needs to be set to 0 unless the core is used together with the fault tolerant version of GRLIB, which is not available under the terms of the GPL.

45.6   Interrupts

GRDMAC provides fine-grained control of interrupt generation. At the highest level, the global Interrupt Enable bit (IE) in the control register can be set to zero to mask every interrupt setting in the core. If set to one, interrupt generation depends on the following settings.

The Interrupt on Error Enable bit (IEE) in the control register provides a way to generate interrupts in the event of errors. Error generation is discussed further in the next paragraph.

An interrupt can be also generated by the successful completion of a descriptor, if the Interrupt Enable (IE) bit is set to one in the descriptor's control field. The Interrupt Mask bit (Ix) in the Interrupt Mask register can be set to zero to mask all the descriptor completion interrupts. If descriptor write-back is enabled, the interrupt will be generated after writing back the descriptor's status in main memory.

For both interrupts on error and interrupts on descriptor completion events, a flag will be raised in the interrupt flag register at the bit corresponding to the channel where the interrupt event happened (IFx).

As an example of interrupt generation setup, one can enable interrupt on channel completion by performing the following steps. The Interrupt Enable (IE) bit in GRDMAC control register must be set to one, as must be the relevant channel's interrupt mask bit in the Interrupt mask register. Finally the Interrupt Enable (IE) bit in the control field of the last descriptor in the B2M chain of the channel must be set to one, while the same field must be set to zero in every other descriptor in the channel. This way, when the last descriptor in the buffer to memory chain is completed successfully, an interrupt will be generated.

45.7   Wide Data Bus support

The size of AMBA accesses supported through GRDMAC's AHB master interfaces depends on the maximum bus width and if the accessed memory area has been marked as being on the wide bus.

The generic *wbmask* is treated as a 16 bit mask where every bit represents a 256 MiB block of memory, with the least significant bit representing the range 0 - 0x10000000. If the corresponding bit is set to one, GRDMAC with perform wide accesses to that memory area. The size of the accesses is controlled with the *busw* generic. If the generic is set to 0, only 32 bit accesses will be performed.

Furthermore, the size of the AHB accesses can be limited with the Transfer Size Limit (TSL) field in the control register of GRDMAC. If the field is set to 1, the core will limit its maximum AHB transfer size to 32 bits. If it is set to 2, the limit will be 64 bits, and if it is set to 3, the limit will be 128 bits. The field must be interpreted as an upper limit on the transfer size and is subject to the *wbmask* and *busw* generic.

45.8   Errors

Four types of errors can be generated by GRDMAC. Transfer errors, descriptor errors, Channel Vector Pointer errors, conditional errors and timeout errors, as defined in the Error Register.

Transfer errors are generated when the core is accessing DMA data from and to memory and it encounters an AMBA AHB ERROR response. When a transfer error occurs on a descriptor which has the write-back flag enabled, the descriptor status will be written back to main memory with the error field set to one. An eventual interrupt will be generated only after the write back.

Descriptor errors are generated when an ERROR response is received while reading or writing back a descriptor in main memory.

Channel Vector Pointer errors are generated when the core receives an ERROR response when accessing the Channel Vector data structure in main memory.

Conditional errors are generated when a conditional polling descriptor encounters a problem during an AHB polling operation such as an ERROR response.

Finally timeout errors are caused by the timeout counter expiring before receiving an interrupt during triggered conditional descriptor execution. This requires the *timer_en* VHDL configuration generic to be set to '1' and the TE bit field in the control register to be configured to '1' during execution.

The core will enable the corresponding error type bit in the error register in addition to the error flag bit (E). The channel number where the error happened can be also read directly from the channel error field (CHERR) of the error register. Additionally an interrupt will be generated if the Interrupt on Error Enable bit (IEE) and the global Interrupt Enable (IE) bit in GRDMAC control register are set to one, and a flag will be raised in the interrupt flag register bit corresponding to the channel where the error event occurred (IFx).

45.9 Internal Buffer Readout Interface

In case of an error, the execution of the DMA channels will halt and the error will be reported as described in the previous session. It can happen that data that has been accumulated in the internal buffer during the M2B chain transactions, is not written out as part of the B2M chain, due to the channel halting. This internal data can still be read via the APB interface of the GRDMAC core, through the Internal Buffer Readout Interface memory area. The memory area is located at offset 0x800 to 0xFFF of the GRDMAC core memory address, totaling 2 KiB of accessible Internal Buffer space, as seen in Table 629. This area can only be read when the core is in an idle state and bit flag EN of the Control Register is set to '0'. The amount of valid data in the internal buffer can be inferred by reading the read pointer and write pointers to the buffer from the Internal Buffer Pointers Register (offset 0x40).

45.10 Endianness

The core is designed for big-endian systems.

*Register used only when the core is set to work in Simplified mode of operation.

45.12 Example DMA channel set-up

In this example a single DMA channel will be set-up, using conditional descriptors, to gather data from the UART core (APBUART) and write it into main memory.

The GRDMAC core is configured with its register address-space starting at address 0xCCC00200 and main memory starts at 0x40000000. The APBUART core's register is mapped at 0xCCC00100 and the UART receiver FIFO queue is configured as 4 bytes.

The DMA channel will need two descriptors in the M2B chain: a conditional descriptor bound to a data descriptor. The B2M chain will only need one data descriptor.

The conditional descriptor will poll the UART status register, mapped at 0xCCC00104, and will use the mask 0x00000100 for the termination condition. This mask will be ANDed with the status register, and the result of this operation will only show the value of the "Receiver FIFO half-full" field in the status register. This will enable the conditional register to stop polling when this bit becomes '1'. At this point the data descriptor will be executed for the amount of bytes specified in the conditional descriptor, which in this case is 1 bytes (half of the FIFO size). For the data transfer to read and accumulate correct data, the core must perform a single-byte access. The UART data register contains only one byte of relevant data. The size limit per transfer is therefore 1 byte and the address is marked as fixed, so the core will not increment it after every transfer.

The polling counter for the conditional descriptor is set according to the UART speed. If the UART baud rate is 38.4K and the system frequency is 100 MHz, one can assume that there is going to be 1 Byte available in the UART every 26k clock cycles. Setting the polling period to a value less than 26K will let the DMA get all the characters from the UART without missing any. The conditional counter reset value is set to its maximum, a period of 4095 clock cycles (0xFFF).

The polling will restart after the last read and the transfers will go on until the total size specified in the SIZE field of the data descriptor is reached. At this point the M2B chain is completed and the core will proceed with the B2M chain, emptying the contents of its buffer into memory, at the address specified.

0x40020044	0x40030000	B2M data descriptor 0 - address (DMA write address for UART data)
0x40020048	0x04000001	B2M data descriptor 0 - control (1024 Bytes)
0x4002004C	–	B2M data descriptor 0 - status (written by core)
...	...	
0x40030000	–	UART data written by the DMA core
...	...	
0xCCC00200	0x0001000C	GRDMAC Control register
0xCCC00204	–	GRDMAC Status register (updated by the DMA core)
0xCCC00208	0x00000001	GRDMAC interrupt mask register
0xCCC0020C	–	GRDMAC error register (updated by the DMA core)
0xCCC00200	0x40000080	GRDMAC channel vector pointer
0xCCC00204	–	Reserved
0xCCC00208	0x02000812	GRDMAC capability register
0xCCC0020C	–	GRDMAC interrupt flag register (updated by the DMA core)

as required by the core.

The core is configured with only one DMA channel (channel 0) and one master interface, as can be seen in the capability register. Additionally the internal core's buffer is 512 Bytes and the time-out timer is available.

The core's control register is pre-set to enable channel 0 and to enable interrupts and interrupts on errors. To start the execution of the channel the software will write a '1' to the enable bit in the control register, usually by reading the register, performing a logical OR with 0x00000001, and writing the value back to the register. In this case the value that needs to be written to address 0xCCC00200 to correctly start execution is 0x0001000D.

45.13 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x095. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

45.14 Implementation

45.14.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

GRIP
Apr 2024, Version 2024.1
591
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

45.14.2 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

45.15 Configuration options

Table 646 shows the configuration options of the GRDMAC core (VHDL generics). These options are specific to the generic entity *grdmac*. See the chapter Instantiation for more details on specialized versions of GRDMAC.

*Table 646.*Configuration options

Generic	Function	Allowed range	Default
hmindex	AHB master index (AHBM0)	0 - NAHBMST-1	0
hirq	IRQ line used by GRDMAC	0 - NAHBIRQ-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddress	Addr field of the APB bar.	0 - 16#FFF#	1
pmask	Mask field of the APB bar.	0 - 16#FFF#	16#FFF#
en_ahbm1	Enable second AHB master interface (AHBM1)	0 - NAHBMST-1	0
hmindex1	Second AHB master (AHBM1) index	0 - NAHBMST-1	1
ndmach	Number of available DMA channels.	1 - 16	1
bufsize	Internal buffer size. Must be a power of 2.	8 - 65536	256
burstbound	Boundary that the burst will never cross. Maximum is 1KB as per the AMBA AHB standard. Could be set to smaller values to ease re-arbitration. Must be a multiple of 2.	4 - 1024	512
timer_en	Enables the implementation of the timeout counter which can be set during triggered conditional descriptor execution.	0 - 1	0
memtech	Internal buffer's memory technology selection	0 - NTECH	0
testen	Enable bypass logic for scan testing	0 - 1	0
ft	This generic determines if fault tolerance should be added to the internal data realignment buffer. 0 = no fault tolerance, 1 = byte parity DMR, 2 = TMR. Note that this generic needs to be set to 0 if the core is used together with the GPL version of GRLIB, since that version does not include any fault tolerance capability.	0 - 2	0
wbmask	Wide-bus mask. Indicates which address ranges are 64/128 bit capable. Treated as a 16-bit vector with LSB bit (right-most) indicating address 0 - 0x10000000. See section 45.7 for more information.	0 - 16#FFFF#	0
busw	Bus width of the wide bus area (64 or 128). See section 45.7 for more information.	64, 128	64

45.16 Signal descriptions

Table 647 shows the interface signals of the core (VHDL ports).

*Table 647.*Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	AHB reset	Low
CLK	N/A	Input	AHB clock	-
AHBMI	*	Input	AHB master input	-
AHBMO	*	Output	AHB master output	-
AHBMI1	*	Input	AHB second master input	-
AHBMO1	*	Output	AHB second master output	-
APBI	*	Output	APB slave inputs	-
APBO	*	Input	APB slave outputs	-
IRQ_TRIG[63:0]		Input	Descriptor triggering input	

* see GRLIB IP Library User's Manual

45.17 Library dependencies

Table 648 shows the libraries used when instantiating the core (VHDL libraries).

*Table 648.*Library dependencies

Library	Package	Imported unit(s)	Description
GRLIB	AMBA	Signals	AMBA signal definitions
GAISLER	GRDMAC_PKG	Components, signals	GRDMAC internal components and signals.

45.18 Instantiation

In addition to the generic GRDMAC version, *grdmac*, a single-port version of the core is available, *grdmac_1p*, where the *en_ahbm1* generic is preset to '0', and the generics and ports related to the dual-port functionality are removed for convenience.

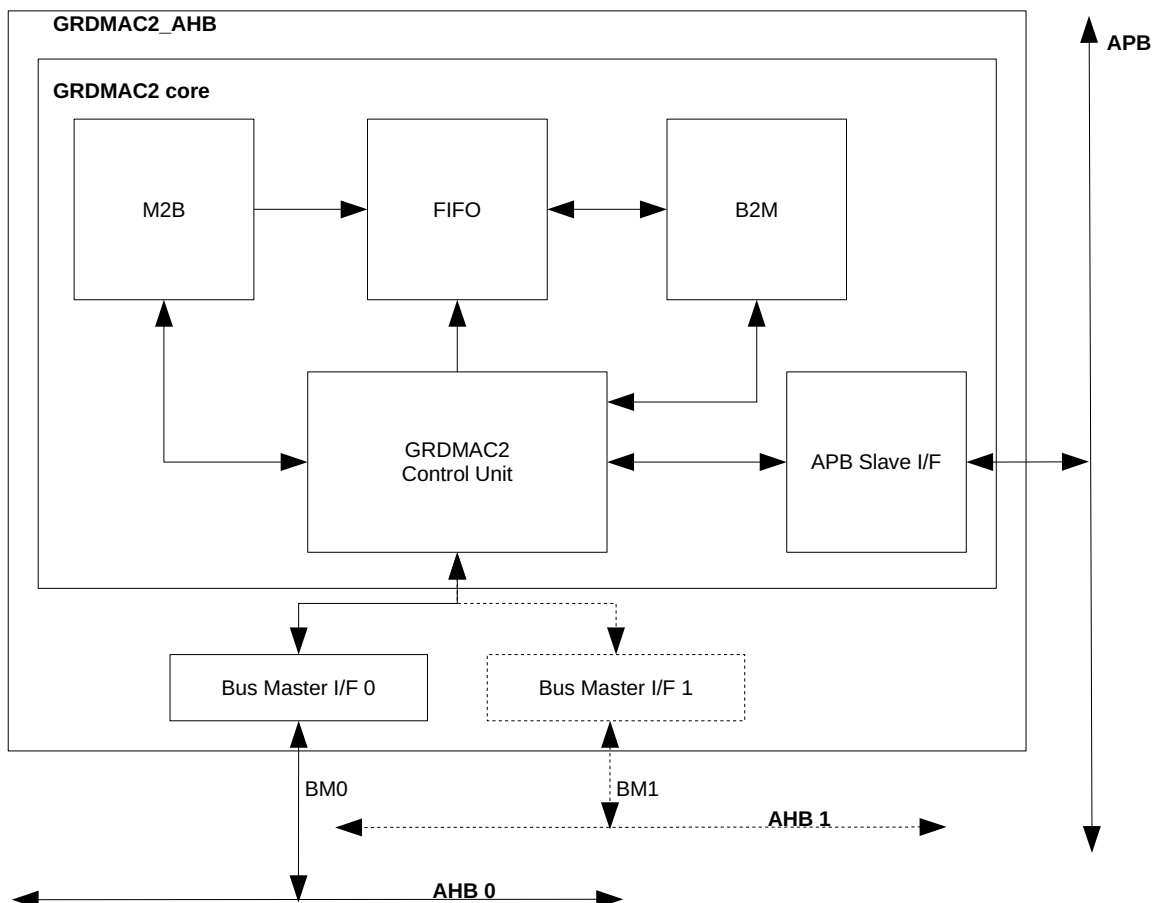
46 GRDMAC2 - DMA Controller

46.1 Overview

GRDMAC2 is a flexible direct memory access controller with Bus Master Interface. The basic building blocks of GRDMAC2 are a control module, internal buffer, memory to buffer operation module(M2B), buffer to memory operation module(B2M) and a wrapper layer which provides Bus Master Interface integration and APB register configuration interface. GRDMAC2 supports being attached to any AHB bus with a data width of 32-bit, 64-bit or 128-bit. Wrappers adapting Bus Master interface to both AMBA 2.0 AHB and AXI4 are available. GRDMAC2 can perform burst transfers of data between AHB and APB peripherals at aligned or unaligned memory addresses. GRDMAC2 can be instantiated with one or two Bus Master Interfaces to perform transfers among different AHB buses, therefore GRDMAC2 has a bridging capability.

GRDMAC2 works with self contained descriptors, with all information needed for the DMA transaction. Descriptor configuration allows specification of source and destination addresses which allows a scatter/gather behavior. GRDMAC2 allows multiple types of descriptors which can be broadly classified as data descriptor and conditional descriptor. This enables GRDMAC2 to perform regular data transfer as well as perform an action on occurrence of a specific condition. Conditional descriptors allows an if-else mode of execution based on the condition check outcome. Figure below depicts the basic block diagram of GRDMAC2. The diagram assumes that the AHB wrapper is used, but the functionality is equivalent if the bus master or the AXI wrapper are chosen instead.


With the flexible descriptor queue with conditional descriptors and data descriptors, GRDMAC2 can be used with peripherals like APBUART and other controllers like SPI controller. A typical use case example of GRDMAC2 is described in section 46.8.

GRIP

Apr 2024, Version 2024.1

595

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

GRDMAC2 is equipped with multiple error flags for different kinds of error events and eight individual APB registers solely for debug capability of the current descriptor that is being executed. GRDMAC2 always displays the current execution state in status register and freezes this display in case of an error to make debugging easy.

GRDMAC2 supports the use of an external accelerator core to modify the data in the FIFO between the M2B and the B2M operations. The support to use an accelerator is an extra feature and is not generally included in the core. Currently supported accelerators are:

• AES-256, compatible when using an internal buffer size of 128 bits or wider.

   For this accelerator two descriptor types are defined. These are described in section 46.9.

• SHA-256, compatible when using an internal buffer size of 512 bits or wider.

   For this accelerator, one descriptor type is defined. This is described in section 46.9.

46.2   Operation

46.2.1   Operation overview

When GRDMAC2 execution is enabled by the user by setting *'EN'* bit in the APB control register, descriptor execution starts from the first descriptor which is pointed by Descriptor Pointer APB Register. GRDMAC2 reads descriptor configurations from any AHB mapped address (typically main memory) through its main Bus Master Interface (BM0 if instantiated with support for two Bus Master Interfaces).
GRDMAC2 decodes the descriptor configuration, identifies the type of descriptor and continues with execution procedure specific to the current descriptor type. On completion of each of the descriptor, GRDMAC2 writes back the status to the descriptor status word, if '*wb*' bit is enabled in the descriptor. Execution continues with the next descriptor pointer by the current descriptor's next descriptor pointer field. In the case of a failed conditional descriptor, DMA controller selects address, pointed by '*fnext.addr*' field, to fetch next descriptor. Fetch-Decode-Execute procedure is performed on each enabled descriptor in the descriptor queue. Any disabled descriptor in the queue is simply skipped and the DMA controller continues execution with the next enabled descriptor in the queue. Descriptor queue should be set up such that the last descriptor in the queue should have '*next.last*' bit value as 1. GRDMAC2 continues execution until it encounters a last descriptor. After completing the last descriptor execution successfully, GRDMAC2 marks the execution status as 'Completed' in the status register and stays idle.
Bus master interface index to be selected for conditional descriptor execution is determined by '*bm*' field in descriptor control word. GRDMAC2 allows the selection of individual Bus Master Interface index for source and destination in data descriptors. The second Bus Master Interface is enabled by setting the VHDL generic *en_bm1* to 1. If the second interface is not enabled, all settings related to it will be ignored and the DMA controller will default to the main Bus Master Interface for all transfers. Descriptor fetches from the memory and write back to the descriptor status word in the memory is performed through default Bus Master Interface, irrespective of the type of descriptor.
The functionalities supported by GRDMAC2 for DMA operation is described in the following sections.

46.2.1.1   Pause and resume

When DMA controller has started processing the descriptors in the current descriptor queue, it is possible to pause the execution in between. Clearing the 'EN' bit in GRDMAC2 control register(CTRL) will pause the descriptor queue processing. However, execution will pause only after successfully completing the current descriptor execution. GRDMAC2 sets the '*PAU*' bit as 1, and clears the '*ONG*' bit in the status register. Once paused, GRDMAC2 stays idle until '*EN*' and '*KICK*' bit is set in the CTRL register. Once the paused GRDMAC2 is enabled again and kicked by the user, execution resumes from the next descriptor in the queue, if there are enabled descriptors in the remaining part of queue.

46.2.1.2   Restart

GRDMAC2 restarts current descriptor queue execution when '*RT*' bit is set in GRDMAC2 control register (CTRL). Restarting the descriptor queue execution will be performed only after completing the current descriptor execution. DMA controller restarts execution from the first descriptor pointed by Descriptor Pointer APB Register. When '*RT*' bit is set by the user when a descriptor processing is in progress, the request is acknowledged and '*RSP*' bit is set in GRDMAC2 status register. This self clearing bit is cleared by GRDMAC2 when the descriptor queue execution is restarted after the current descriptor is executed completely.

46.2.1.3   Descriptor queue management

GRDMAC2 allows the modification of descriptor queue even after the DMA has started processing the current descriptor queue. Only appending new descriptors are allowed. In order to append new descriptor at the end of descriptor queue, user need to clear '*next.last*' bit of the last descriptor in the current queue and point to the new descriptor as the next descriptor. Mark the new descriptor as the last one. Adding multiple new descriptors also have the same procedure apart from the fact that the last descriptor will be at the end of the newly added part of the queue. Once the descriptor queue is modified, it is mandatory to kick GRDMAC2 to indicate the presence of modified descriptor queue. DMA controller acknowledges kick by setting '*KP*' bit in GRDMAC2 status register. '*KP*' bit is cleared by GRDMAC2 when a new descriptor is taken up for execution. Any type of descriptor queue modification other than appending at the end of the current descriptor queue, is illegal.

46.2.1.4   Reset

Setting '*RST*' bit in GRDMAC2 control register(CTRL) resets the DMA controller, canceling any ongoing descriptor execution. The reset clears all the register fields to their default values.

46.2.2   Data descriptor execution

During a standard data descriptor execution, GRDMAC2 will perform two types of DMA transfers through one of the Bus Master Interfaces: from memory to the internal buffer (M2B) and from the internal buffer to memory (B2M). GRDMAC2 splits the total size of data to be transferred for a data descriptor, in to data chunks of size equal to minimum of the following factors: size of the internal buffer, maximum burst length or a maximum of 1024 bytes. Maximum burst length and size of internal buffer can be set through VHDL generics *max_burst_length, abits* and *dbits*.
After fixing the size of each burst, the DMA controller transfers data chunks from source to destination through M2B and B2M operations. A chunk of data is transferred from memory to the internal buffer as part of the M2B operation and M2B operation is paused. Execution control is switched to B2M operation, where the DMA controller transfers the data chunk from the internal buffer to the destination memory and pauses B2M operation. GRDMAC2 then switches back to the M2B operation which was paused earlier and repeats the same process for the next chunk of data. M2B-B2M cycles are repeated until the total size of data transfer is completed and descriptor is marked as completed. On descriptor completion, based on whether '*wb'* bit is enabled in the descriptor control word, status of the descriptor execution is written back to the descriptor status word.
Data is transferred between source address and destination address which are configured in the descriptor. The offset of source address from which data is fetched is determined by the bit field '*src_fixed_addr*' in the descriptor control word. Similarly the offset of destination address to which data is written is determined by the bit field 'dest_fixed_addr' in the descriptor control word. If src_fixed_addr field is set to 1, GRDMAC2 always fetches data from the same source address. Similarly if '*dest_fixed_addr'* field is set to 1, GRDMAC2 always writes to the same destination address. If any of these fields are not set to 1, GRDMAC2 automatically considers incrementing offsets for source/destination addresses for data read/write. In short, GRDMAC2 can perform burst transactions in the following ways based on the different configurations of '*src_fixed_addr'* and '*dest_fixed_addr'* fields:

1. Data fetched from incrementing source address offsets, written to incrementing destination address offsets.
2. Data fetched from incrementing source address offsets, written to fixed destination address.
3. Data fetched from fixed source address, written to incrementing destination address offsets.
4. Data fetched from fixed source address, written to fixed destination address.

M2B and B2M operation can be performed through the same or different Bus Master Interface index. This selection is performed by configuring *'srcbm'* and *'dstbm'* in descriptor control word provided that second Bus Master Interface is enabled while GRDMAC2 instantiation by VHDL generic *en_bm1*.

- **Data descriptor execution example**

Steps of a data descriptor execution example is given below.

a) GRDMAC2 starts M2B operation.
b) GRDMAC2 checks size of data to be transferred between source and destination for descriptor completion. GRDMAC2 compares the size of internal buffer, maximum burst length and maximum boundary of 1024 bytes and finds out the current burst size.
c) A read burst initiated on the selected Bus Master Interface transfers data from source memory address (incrementing offsets if *'src_fid_addr'* field is not set.) to GRDMAC2
internal buffer. If *'src_fid_addr'* field is set in the descriptor, data is always read from the same source address.
d) GRDMAC2 checks if there is data yet to be fetched from source to complete the descriptor execution. If yes goes to step **e**. Otherwise goes to step **f**.
e) GRDMAC2 pauses M2B operation and switches to B2M operation. Goes to step **g**.
f) GRDMAC2 completes M2B operation and Switches to B2M operation. Goes to step **g**.
g) GRDMAC2 checks size of data to be transferred between source and destination for descriptor completion. GRDMAC2 compares the size of internal buffer, maximum burst length and maximum boundary of 1024 bytes and finds out the current burst size.
h) A write burst is initiated on the selected Bus Master Interface transfers data from GRDMAC2 internal buffer to destination memory address(incrementing offsets if *'dest_fix_addr'* field is not set). If *'dest_fix_addr'* field is set in the descriptor, data is always written to the same destination address.
i) GRDMAC2 checks if there is data yet to be written to destination in order to complete the descriptor execution. If yes goes to step **j**. Otherwise goes to step **k**.
j) GRDMAC2 pauses B2M operation and switches to M2B operation. Goes to step **b**.
k) GRDMAC2 completes B2M operation. Mark descriptor as completed.
l) Writes back the execution status to descriptor status word, if *'wb'* bit is enabled in the descriptor control word.
m) Fetches the next descriptor (pointed by '*next.addr*') in the queue if there are any. On the other hand, if the current descriptor is the last, marks the execution completion in GRDMAC2 status register.

46.2.3 Conditional descriptor execution

A conditional descriptor is a special kind of descriptor which can be executed to perform a task with conditional behavior. A conditional descriptor can be used to create a DMA transfer that retrieves data from IO cores, therefore off loading the CPU from the task. Usually IO cores provide a status register or an interrupt line to notify the CPU of the availability of new data. A conditional descriptor can be set up to poll this status register or to be triggered by an interrupt, signaling for instance, the availability of new data. This is a typical use case of conditional descriptor execution.

GRDMAC2 identifies a conditional descriptor from the *'type'* field in the descriptor control word. Current version of GRDMAC2 supports 3 types of conditional descriptors. Polling type(*'type'* = 1), Triggering type(*'type'* = 2) and Poll-on-trigger type(*'type'* = 3). The field '*bm*' in descriptor control

GRIP

word, decides the Bus Master Interface index which performs memory accesses during conditional descriptor execution. This field is relevant only if VHDL generic *en_bm1* is set. Otherwise default Bus Master Interface is used for memory accesses.

Conditional descriptor *'next.addr'* field points to the next descriptor's control word address. Setting *'next.last'* bit marks the current descriptor as the last descriptor in the descriptor queue. Conditional descriptors allows an 'if-else' method of condition check by *'next'* and *'fnext'* fields. On successful execution of a conditional descriptor, GRDMAC2 execution control continues to *'next.addr'* as long as the *'next.last'* bit is not set. On the other hand, if the conditional descriptor execution was failed, execution continues with the next descriptor pointed by *'fnext'*. It is mandatory that *'fnext.last'* bit is never set. Setting this bit will result in a decode descriptor error and *'DE'* will be set in GRDMAC2 status register. This applies to all types of conditional descriptors. Conditional descriptor fields like *'poll.addr'*, *'expd.data'* and *'cond.mask'* are relevant only for polling or Poll-on-trigger type of descriptors.

46.2.3.1 Polling descriptor execution

A polling type descriptor should have *'ctrl.type'* field value 1 in descriptor control word. During a polling descriptor execution, GRDMAC2 polls the address configured in *'poll.addr'* field. Polling is performed in specific number of clock cycle intervals. Interval between polling accesses is decided by *'intrv'* field in descriptor control word. Setting interval between each poll access avoids holding the bus and makes the bus available for other cores in the system.
Polling result data is compared with expected data value configured in *'expd.data'* descriptor field and conditional mask for comparison configured in *'cond.mask'* descriptor field to evaluate the success of the conditional descriptor execution. Condition check is performed as follows.

Table 649. Condition for successful polling descriptor execution

(Content of 'poll.addr') AND 'cond.mask' = 'expd.data' AND 'cond.mask'

In other words, the polling result and expected data is compared only on the bit positions that are set in the conditional mask field. After each polling, condition is checked and this polling-condition check process id repeated for specific number of times based on the value configured in *'count'* field in descriptor control word. If the condition check is not successful even after repeating the polling-condition check process *'count'* times, polling descriptor execution will have a failed status. Otherwise if the condition check was successful before *'count'* times, the polling descriptor execution will be completed successfully.
Apart from the iteration limit on Polling and condition check process, polling descriptor execution is bound by a timeout mechanism if timeout check is enabled in GRDMAC2 control register(CTRL) and during IP instantiation. GRDMAC2 waits for number of clock cycles specified in APB register *'TRST'*(Timer reset value register) before generating a timeout status. Timeout is interpreted either as a failed execution or as an error, based on the field 'errto' in descriptor control word. Setting 'ctrl.errto', treats timeout as an error and a failed condition otherwise. On successful condition check, GRDMAC2 marks the descriptor as completed and moves on with the next descriptor execution if there are any present. If the polling descriptor execution is failed, GRDMAC2 fetches next descriptor from address pointed by *'fnext.addr'* descriptor field and continues execution.

- **Polling descriptor execution example**

Steps of a polling descriptor example is given below. A counter is decremented from reset value as soon as the polling descriptor execution has started (If timeout mechanism is enabled by VHDL generic *en_timer*). Reset value of this counter can be configured through GRDMAC2 *'TRST'* register.

a) GRDMAC2 checks if timeout counter value is zero. If yes, Goes to step **i**. Goes to step **c** otherwise

GRIP
Apr 2024, Version 2024.1
599
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

b) GRDMAC2 polls memory address configured in *'poll.addr'*. Starts incrementing counter(C0) which increments every clock cycle. Goes to step **d**.

c) Clears the counter C0. Goes to step **b**.

d) Increment a polling iteration count by 1. Goes to step **e**.

e) GRDMAC2 compares the read data with *'expd.data'* and *'cond.mask'* based on condition in table 649. If condition check is successful, Goes to step **h**. If the condition check is unsuccessful goes to step **f**.

f) GRDMAC2 checks if polling iteration count is equal to *'count'* configured in descriptor control word. If yes goes to step **k**, else goes to step **g**.

g) Checks if the counter (C0) value is equal to *'intrv'* configured in descriptor control word. If yes goes to step **a**, else goes to step **g**.

h) Marks descriptor as completed. Writes back the execution status to descriptor status word, if '*wb'* bit is enabled in the descriptor control word. Goes to step **j**.

i) Marks timeout. If *'errto'* field is set in the descriptor control word, marks error bit *'ERR'* and *'PE'* bit in GRDMAC2 status register and stop ongoing execution. If *'errto'* field is not set in the descriptor control word, goes to step **k**.

j) Fetches the next descriptor(pointed by *'next.addr'*) in the queue if there are any. On the other hand, if the current descriptor is the last, marks the execution completion in GRDMAC2 status register.

k) Writes back descriptor status if *'wb'* bit is enabled in the descriptor control word. Fetches the next descriptor pointed by *'fnext.addr'* and continue execution.

46.2.3.2   Triggering descriptor execution

A triggering type descriptor must have *'type'* field value 2 in descriptor control word. Triggering descriptor monitors the input trigger on the interrupt line specified in the field *'irqn'* in
the descriptor control word. If the timeout mechanism is enabled, the descriptor execution continues the process of monitoring for input trigger, either till the expected trigger is received or till timeout. Based on the *'errto'* bit field in the control word of a triggering descriptor, timeout is treated either as an error or as a failed descriptor execution status.
On successful execution of triggering descriptor, GRDMAC2 marks the descriptor as completed and moves
on with the next descriptor execution if there are any present. If triggering descriptor execution is failed, GRDMAC2 fetches next descriptor from address pointed by *'fnext.addr'* descriptor field and continues execution.
The expected trigger event type is configured by *'ctrl.trtp'* field and *'poll.trig_val'* field in the descriptor. Setting *'ctrl.trtp'* field to 1 in the descriptor will configure the expected event as level and clearing *'ctrl.trtp'* field will configure the expected event as edge. Setting *'poll.trig_val'* field to 1 in the descriptor will configure the expected event as a negative edge/
low level(based on the *'ctrl.trtp'* value). Clearing *'poll.trig_val'* field in the descriptor will configure the expected event as a positive edge/high level(based on the *'ctrl.trtp'* value).

•   **Triggering descriptor execution example**

Steps of a triggering descriptor example is given below. A counter is decremented from reset value as soon as the triggering descriptor execution has started(If timeout mechanism is enabled by VHDL generic *en_timer*). Reset value of this counter can be configured through GRDMAC2 *'TRST'* register.

a) GRDMAC2 checks if timeout counter value is zero. If yes, Goes to step **e**. Goes to step **b** otherwise.

b) GRDMAC2 monitors the interrupt line number *'irqn'* configured in descriptor control word for expected event.

c) If expected event occurs, goes to step **d**, else goes to step **a**.

d) Marks descriptor as completed. Writes back the execution status to descriptor status word, if *'wb'* bit is enabled in the descriptor control word. Goes to step **f**.

+46 31 7758650 | frontgrade.com/gaisler

e) Marks timeout. If *'errto'* field is set in the descriptor control word, Marks error bit *'ERR'* and *'PE'* bit in GRDMAC2 status register and stop ongoing execution. If *'errto'* field is not set in the descriptor control word, goes to step **k**.

f) Fetches the next descriptor (pointed by *next.addr*) in the queue if there are any. On the other hand, if the current descriptor is the last, marks the execution completion in GRDMAC2 status register.

g) Writes back descriptor status if '*wb*' bit is enabled in the descriptor control word. Fetches the next descriptor pointed by *fnext.addr* and continue execution.

46.2.3.3   Poll-on-trigger descriptor execution

A poll-on-trigger type descriptor must have '*ctrl.type*' field value 3 in descriptor control word. Poll-on-trigger type descriptor execution combines the functionality of a triggering descriptor and a polling descriptor. Poll-on-trigger type of descriptor execution monitors the input trigger on the interrupt line specified in the field '*irqn*' in the descriptor control word. On reception of the expected trigger on IRQ line of interest, GRDMAC2 polls the address configured in '*poll.addr*' field. Each polling access is separated by '*intrv*' number of clock cycle as configured in descriptor control word. After each polling the result(content of '*poll.addr*' address) is compared with expected data('*expd.data*') and mask('*cond.mask*') using the condition described in table 649. Polling and condition check process is repeated for '*count*' times as configured in the descriptor control word. Both trigger monitoring and polling are individually bound by timeout if timeout mechanism is enabled.

On successful execution of poll-on-trigger descriptor, GRDMAC2 marks the descriptor as completed and moves on with the next descriptor execution if there are any present. If poll-on-trigger descriptor execution is failed, GRDMAC2 fetches next descriptor from address pointed by '*fnext.addr*' descriptor field and continues execution.

46.3   Configuration

GRDMAC2 can be configured flexibly by means of different VHDL generics. VHDL generics support and their valid values are explained in section .

The DMA controller and descriptors should be configured properly for successful operation of the controller. The following sections describes the DMA controller and descriptor configuration in detail.

46.3.1   GRDMAC2 configuration

GRDMAC2 can be configured through APB register interface. The following APB registers should be used to configure DMA controller.

- **Control register (CTRL)**

Control register allows the configuration of interrupt generation on error and descriptor completion. Control register also allows the user to enable timeout mechanism for conditional descriptors. Timeout mechanism for conditional descriptors can be enabled by setting *'TE'* bit in control register provided that VHDL generic *en_timer* is set on IP instantiation. Conditional descriptor execution is bound by timeout if timeout mechanism is enabled. Conditional descriptor execution will continue for ever or until the successful condition check result if timeout is disabled.

There are designated bits which allows different functionalities like kicking, enabling, resetting, pausing and restarting GRDMAC2. These functionalities are explained in section 46.2.1, in detail.

- **Timer reset value register (TRST)**

Configuring TRST register has an impact only on the conditional descriptor execution, provided that timeout mechanism is enabled. During a conditional descriptor execution, GRDMAC2 will wait for, number of clock cycles configured in Timer reset value register, before generating a timeout status.

- **First descriptor pointer (FPTR)**

First descriptor pointer register should be configured to point to the first descriptor in a descriptor queue.

46.3.2 Descriptor configuration

Descriptor types supported by GRDMAC2 can be broadly classified as data and conditional descriptors. Conditional descriptors are further classified based on the type of condition check they are trying to satisfy. GRDMAC2 demands pre-defined descriptor configuration for each of these types, as described in sections 46.3.2.1 and 46.3.2.2. It is mandatory that descriptors are written to two byte aligned addresses in the memory. By default, Bus Master Interface index 0 is selected for all descriptor reading and execution status write back.

46.3.2.1 Data descriptor format

Data descriptor format and description of individual fields are displayed below.

Table 650. Data descriptor format

Address offset	Field
0x00	Control word

Table 663. 0x18 - cond - Conditional Mask

31	0
mask	

31 : 0	mask	Mask for polling type of descriptor execution. GRDMAC2 compares polling result with this mask during descriptor execution. Polling result data bits corresponding to mask bits which are set to one, is only considered for condition check comparison with expected data ('expd.data').

46.4   Bus Master Interface

While executing data descriptors, GRDMAC2 performs AHB data transfer at the address and of the size specified. The AHB accesses in GRDMAC2 is performed through a Bus Master Inter ace. GRD-MAC2 supports single or double Bus Master Interface implementation by VHDL generic *en_bm1* configuration. When GRDMAC2 is configured with the VHDL generic *en_bm1* set to '1', a secondary Bus Master Interface will be enabled in GRDMAC2 core. This interface can be connected to a second AHB bus to provide bridging capabilities to the DMA controller. GRDMAC2 will perform data accesses though this interface when the *'bm'* (*'srcbm'/'dstbm'* in case of data descriptors) field in the descriptor's control word is set to 1. This bit field will be ignored and default Bus Master Interface is used in case GRDMAC2 is configured with the VHDL generic *en_bm1* set to '0'. Bus master interface front end data width can be configured to 32, 64 or 128 based on VHDL generic *dbits*. Bus master interface brings in the flexibility of aligned or unaligned accessed in GRDMAC2. Burst accesses are always limited by 1KB boundary. However this can be further limited by setting VHDL generic *max_burst_length*. At the specified memory boundary the burst will be interrupted, an idle cycle will be inserted making re-arbitration on the AHB bus more frequent.

Additionally Frontgrade Gaisler provides Bus Master interface wrappers for both AMBA AHB 2.0 and AXI4. The wrapper for AXI4 features a bridge to convert the Bus Master into an AXI4 Bus Master Interface. For further information regarding the accesses contact Frontgrade Gaisler.

46.5   Internal buffer

For any data descriptor execution, data is fetched from the source memory and stored in an internal buffer in GRDMAC2. This data is later moved from the internal buffer and written to the destination memory. The internal buffer uses RAM implemented using GRLIB parameterizable SYNCRAMBW memory, assuring portability to all supported technologies. Depth of the RAM depends on the VHDL generic *abits*. Width of the internal buffer is configured identical to data width of Bus Master Interface. Fault tolerance can be added to the RAM by setting the VHDL generic *ft* to a valid value different than 0. Note that the VHDL generic *ft* needs to be set to 0 unless GRDMAC2 is used together with the fault tolerant version of GRLIB, which is not available under the terms of the GPL. Technology for SYNCRAM can be selected by VHDL generic *tech*.

46.6   Interrupts

GRDMAC2 provides fine-grained control of interrupt generation. At the highest level, the global Interrupt Enable bit (*'IE'*) in GRDMAC2 control register(CTRL) can be set to zero to mask every interrupt setting in GRDMAC2. If set to one, interrupt generation depends on the following settings. The Interrupt on Error Enable bit (*'IER'*) in CTRL register provides a way to generate interrupts in the event of errors. Error generation is discussed further in section 46.7. An interrupt can be also generated by the successful completion of a descriptor, if the Interrupt Enable (*'irqe'*) bit is set to one in the descriptor's control field. The Interrupt Mask bit (*'IM'*) in the CTRL register can be set to one to mask the descriptor completion interrupts. Descriptor completion interrupt will be generated as soon as the successful completion of the descriptor execution. Even before writing back the descriptor's status in main memory, if the write back is enabled. For both interrupts on error and interrupts on

descriptor completion events, a flag will be raised in the interrupt flag bit(*'IF'*) in GRDMAC2 status register. Interrupt generated on descriptor completion can be masked by configuring *'IM'* bit even though *'IE'* bit in CTRL register and '*irqe*' bit in descriptor control word is set to one. However it is not possible to mask the interrupt generated on error when *'IE'* bit in CTRL register is set to one. As an example of interrupt generation setup, one can perform the following steps. The Interrupt Enable (*'IE'*) bit in CTRL register must be set to one. The Interrupt Mask (*'IM'*) bit in CTRL register must be configured as zero. Set up a descriptor queue with a single data descriptor. Configure Interrupt Enable (*'irqe'*) bit in the control field of the descriptor as one and mark the descriptor as the last descriptor. When the descriptor queue is completed successfully, an interrupt will be generated.

46.7 Status and Errors

GRDMAC2 provides a very clear status display by an APB status register and 8 separate debug capability registers which displays details of the current descriptor that is being executed.

There is a general error flag *'ERR'* which will be set in any case of error and an individual flag which says the type of error that has occurred. A decode descriptor error(*'DE'*) can occur during the decoding of a descriptor if the type of descriptor is not a valid value(0 to 3 is only valid) for current version of GRDMAC2. Another situation which can generate this error is when a conditional descriptor has it's *'fnext.last'* bit set to one. A read descriptor error(*'RE'*) will be flagged in GRDMAC2 status register in case when the Bus Master Interface receives an error response during the descriptor read burst memory access. A polling error flag(*'PE'*) can be set in two cases. One case is when a Bus Master Interface receives an error response during the read access on the address being polled.

Another case is when timeout occurs during a polling descriptor execution and the descriptor is configured to treat timeout as an error. A triggering error(*'TRE'*) will be generated when a triggering type descriptor encounters a timeout and the descriptor is configured to treat timeout as an error. When the Bus Master Interface receives an error response during the write access on descriptor status word in the memory, a write back error(*'WBE'*) is flagged in GRDMAC2 status register. If the Bus Master Interface receives an error response during any part of the read accesses performed as part of M2B operation, M2B read data error flag(*'RDE'*) will be set status register. Similarly, in case the Bus Master Interface receives an error response during any part of the write accesses performed as part of B2M operation, B2M write data error

flag(*'WDE'*) will be set in status register. A FIFO error(*'FE'*) is flagged in GRDMAC2 status register only when an uncorrectable error status is reported from the internal FIFO when VHDL generic *ft* is enabled. In such a situation the *'FP'* field will be pointing to the offset in FIFO where the error has been detected. When GRDMAC2 receives a kick request, it reads the next descriptor pointer of the current descriptor again. If the Bus Master Interface receives an error response while this read access, a *'NPE'* flag will be set in APB status register. Timeout status flag *'TO'* will be set in case of a timeout during the conditional descriptor execution. All error flags are cleared on writing 1 to them. However the timeout flag *'TO'* is self clearing. In case of an error, GRDMAC2 pauses the execution and stays idle. Along with appropriate error flags, *'PAU'* flag will be set in GRDMAC2 status register. GRDMAC2 allows the user to clear the errors and kick GRDMAC2 to continue execution from the next descriptor in the queue.

GEDMAC2 has a 5 bit *'ST'* field which always displays the current state of descriptor execution. In case of any error, the *'ST'* field will freeze at the execution state where the error occurred. When GRDMAC2 is performing descriptor execution in a descriptor queue, the '*ONG'* bit in GRDMAC2 status register will be set to one. In case of an error or if GRDMAC2 has completed the execution of the entire queue, GRDMAC2 stays idle and clears the *'ONG'* bit, indicating that no operation is currently in progress. *'CMP'* flag is set to one, only when the descriptor queue is executed completely.

There are two self clearing flags *'KP'* and *'RSP'* which shows the existence of a pending kick request and a pending restart request. *'KP'* flag will be cleared whenever a new descriptor is taken up for execution. In other words, GRDMAC2 handles kick by reading the *'next'* field of the current descriptor again from the memory and processing it. *'RSP'* bit is cleared when the current descriptor execution is

completed and DMA operation restarted from the first descriptor. The debug capability registers displays all the fields of the current descriptor that is being executed.

The descriptor pointer debug capability register shows the base address where the current descriptor was read from.

46.8   GRDMAC2 Use case Example

A simple example showing how GRDMAC2 can be used with APBUART is explained below. In this example GRDMAC2 is used to read data, whenever a peripheral APBUART receives data from a host. GRDMAC2 transfers data from the APBUART receiver register to main memory. Assume that the system has SRAM memory at 0x30000000 and UART configuration registers are located at 0x80300000. Assume that IP is instantiated with VHDL generic *en_bm1* set to 1 and Bus Master Interface index 1 is connected to APB bus on which UART is also connected. SRAM is connected on the main bus to which default Bus Master Interface index 0 is connected.

1.   Set up a descriptor queue with 3 descriptors. A polling descriptor followed by a data descriptor and a disabled data descriptor. Descriptor queue should be written to a memory location (assuming 0x30000000). The descriptor configuration is listed below.

a) Polling descriptor:

Table 664. GRDMAC2 use case example- Conditional descriptor configuration

Field	Value	Comment
ctrl.en	1	Enabled descriptor
ctrl.type	1	Polling descriptor
ctrl.wb	1	Execution status write back is enabled
ctrl.irqn	-	Irrelevant for polling descriptors
ctrl.trtp	-	Irrelevant for polling descriptors
ctrl.intrv	0xFF	0xFF clock cycles between two polling accesses
ctrl.count	0xFF	Repeat polling condition check for 0xFF iterations before assuming failed execution status
ctrl.bm	1	Bus Master Interface 1 is to be used for UART status register polling
ctrl.errto	0	Timeout is not an error
ctrl.irqe	1	Interrupt enabled on descriptor completion
next.addr	0x3000001C	Pointer to next descriptor
nxt_des.last	0	Not last descriptor
f_nxt_des.addr	0x30000030	Pointer to next descriptor if the current descriptor execution failed.
f_nxt_des.last	0	Mandatory value
poll.trg_val	-	Irrelevant for polling descriptors
poll.addr	0x80300004	APBUART status register address.
expd.data	0x00000001	Expects data ready to be 1. Break, Framing error, Parity error and Overrun bits to be 0.
cond.mask	0x00000079	Consider bit 0, 3, 4, 5 and 6 for comparison using the condition check in table 649

b) Data descriptor 1

This descriptor is written at 0x3000001C

GRIP

Apr 2024, Version 2024.1   609   Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Table 665. GRDMAC2 use case example- Data descriptor configuration

Field	Value	Comment
ctrl.en	1	Enabled descriptor
ctrl.type	0	Data descriptor
ctrl.wb	1	Execution status write back is enabled
ctrl.dstbm	0	Bus master interface 0 is to be used for data write to SRAM area.
ctrl.srcbm	1	Bus master interface 1 is to be used for data fetch from UART RX register.
ctrl.destfix	0	Write data to incrementing destination address offsets
ctrl.srcfix	1	Fetch data always from the same source address
ctrl.irqe	1	Interrupt enabled on descriptor completion
ctrl.size	64	Transfer 64 bytes of data
next.addr	0x30000000	Pointer to next descriptor. This essentially creates a loop of polling- data transfer process
nxt_des.last	0	Not last descriptor
dest.addr	0x30000080	SRAM area where data read from UART is to be written
src.addr	0x80300000	APBUART data register from where data is to be read.

2. Write the same data descriptor described in step **b** at address 0x30000030 with *'ctrl.en'* bit as zero and *'nxt_des.last'* bit as 1. This disabled data descriptor is pointed as the descriptor to be executed on failure for the first polling descriptor.

3. Configure GRDMAC2 *'FPTR'* register as 0x30000000, control register bit field *'TE'* as zero.

4. After configuring descriptor queue and GRDMAC2 registers, start GRDMAC2 operation by setting GRDMAC2 control register(CTRL) *'EN'* bit field as one.

GRDMAC2 should transfer data from UART data register whenever the data ready bit in APBUART status register is set. Transferred data can be read from the destination SRAM area and verified.

46.9 Accelerator functionality

There is an option to include accelerator functionality to the core. Whether or not this functionality is added is decided in the configuration options (VHDL generics). This accelerator can be used to replace data in the FIFO between the M2B and B2M operations.

Currently the following accelerators are supported:

• AES-256 (when using an internal buffer size of 128 bits or wider)

• SHA-256 (when using an internal buffer size of 512 bits or wider)

Currently the following descriptor types are supported:

• 4 - Encryption descriptor for AES-256

• 5 - Accelerator update descriptor for AES-256

• 6 - Authentication descriptor for SHA-256

46.9.1 AES-256 Accelerator description

The Advanced Encryption Standard (AES) is a symmetric encryption algorithm. The accelerator implements the AES algorithm with 256-bit key length using CTR mode of operation. The AES algorithm is specified in the "Advanced Encryption Standard (AES)" document, Federal Information Processing Standards (FIPS) Publication 197. The document is established by the National Institute of

+46 31 7758650 | frontgrade.com/gaisler

Standards and Technology (NIST). Encryption and decryption are equal using this operation mode, meaning that if one encrypts already encrypted data using the same KEY and Initialization Vector (IV) the result will be the decrypted data.

To use the AES-256 accelerator the KEY is updated using an accelerator update descriptor with a length of 32 bytes and the IV is updated using and accelerator update descriptor with a length of 16 bytes. This descriptor specifies where the KEY and IV data is stored and the GRDMAC2 fetches the data and transfers it to the register in the AES-256 accelerator. The KEY can be reused by several encryption/decryption descriptors but the IV needs to be updated between every new descriptor. **It is very important that the IV always is a new unique value if it is ever used with the same key for a different descriptor.**

After updating the IV (and the KEY if needed) the encryption descriptor is used. The encryption works for lengths of any number of bytes, same as for regular data descriptors.

46.9.2 SHA-256 Accelerator description

The Secure Hash Algorithm (SHA) is a cryptographic hash function. The accelerator implements the SHA algorithm with a 256 bit hash output. The SHA algorithm is specified in the "Secure Hash Standard (SHS)" document, Federal Information Processing Standards (FIPS) Publication 180-4. The document is established by the National Institute of Standards and Technology (NIST).

To use the SHA-256 accelerator the authentication descriptor is used. The authentication works for lengths of any number of bytes, same as for regular data descriptors.

46.9.3 Encryption descriptor format

Encryption descriptor format and description of individual fields are displayed below.

Table 666. Encryption descriptor format

Address offset	Field
0x00	Control word
0x04	Next descriptor pointer
0x08	Destination base address
0x0C	Source base address
0x10	Status word

		1 - Completed

- **Encryption descriptor execution example**

Steps of an encryption descriptor execution example is given below.

a) GRDMAC2 starts M2B operation.

b) GRDMAC2 checks size of data to be transferred between source and destination for descriptor completion. GRDMAC2 compares the size of internal buffer, maximum burst length and maximum boundary of 1024 bytes and finds out the current burst size.

c) A read burst initiated on the selected Bus Master Interface transfers data from source memory address (incrementing offsets if 'src_fid_addr' field is not set.) to GRDMAC2 internal buffer. If 'src_fid_addr' field is set in the descriptor, data is always read from the same source address.

d) GRDMAC2 checks if there is data yet to be fetched from source to complete the descriptor execution. If yes goes to step e. Otherwise goes to step f.

e) GRDMAC2 pauses M2B operation and switches to ACC operation. Goes to step g.

f) GRDMAC2 completes M2B operation and Switches to ACC operation. Goes to step g.

g) GRDMAC2 executes encryption on the data currently in the internal buffer and replaces it with the encrypted data. GRDMAC2 checks if M2B is paused. If yes goes to step **h**. Otherwise goes to step **i**.

h) GRDMAC2 pauses ACC operation and switches to B2M operation. Goes to step j.

i) GRDMAC2 completes ACC operation and switches to B2M operation. Goes to step j.

j) GRDMAC2 checks size of data to be transferred between source and destination for descriptor completion. GRDMAC2 compares the size of internal buffer, maximum burst length and maximum boundary of 1024 bytes and finds out the current burst size.

k) A write burst is initiated on the selected Bus Master Interface transfers data from GRDMAC2 internal buffer to destination memory address(incrementing offsets if 'dest_fix_addr' field is not set). If 'dest_fix_addr' field is set in the descriptor, data is always written to the same destination address.

l) GRDMAC2 checks if there is data yet to be written to destination in order to complete the descriptor execution. If yes goes to step m. Otherwise goes to step n.

46.12   Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0C0 (GRD-MAC2). For description of vendor and device identifiers see GRLIB IP Library User's Manual.

46.13   Implementation

46.13.1 Reset

GRDMAC2 changes its reset behavior depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

GRDMAC2 will feature a synchronous reset if the parameter grlib_async_reset_enable is not set in the GRLIB configuration package. On the contrary, it will implement an asynchronous reset if grlib_async_reset_enable is set.

The reset is applied to all the registers in GRDMAC2.

46.14 Configuration options

Table 698 shows the configuration options of GRDMAC2 (VHDL generics).

Table 698. Configuration options

Generic name	Function	Allowed range	Default
tech	Technology for the internal FIFO	0 to NTECH	inferred
hindex0	AHB master index(BM0)	0 - NAHBMST-1	0
hindex1	AHB master index(BM1)	0 - NAHBMST-1	1
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar	0 - 16#FFF#	0
pmask	Mask field of the APB bar	0 - 16#FFF#	16#FF8#
pirq	Interrupt line used by GRDMAC2	0 - NAHBIRQ-1	1
ft	Enable fault-tolerance against SEU errors. GRDMAC2 can optionally be implemented with fault-tolerance against SEU errors in the FIFO memories by setting this generic to 1, 2,3,4 or 5. Possible options are byte parity protection (ft = 1), TMR registers (ft = 2), Parity, no DMR (ft = 3, detect only), SECDED BCH (ft = 4, max 57 data bits)) or technology specific protection (ft = 5, max 32 data bits). If set to 0, no protection is implemented.	0 - 5	0
abits	Address bits for the internal FIFO. FIFO depth is calculated as 2^abits	0 -10	4
dbits	Bus master front end data width and Internal FIFO data width	32 - 128	32
max_burst_length	Maximum burst length	2 - 256	256
en_bm1	Enable Bus Master Interface 1	0 - 1	0
en_timer	Enable timeout timer	0 - 1	0
en_acc	Enable accelerator. Possible options are no accelerator enabled (en_acc = 0), AES256 encryption accelerator enabled (en_acc = 1), SHA256 authentication accelerator enabled (en_acc = 2) or AES256+SHA256 encryption+authentication accelerators enabled (en_acc = 3).	0 - 4	0

47 GRECC - Elliptic Curve Cryptography

47.1 Overview

Elliptic Curve Cryptography (ECC) is used as a public key mechanism. The computational burden that is inhibited by ECC is less than the one of RSA. ECC provides the same level of security as RSA but with a significantly shorter key length. ECC is well suited for application in mobile communication.

The GRECC core implements encryption and decryption for an elliptic curve based on 233-bit key and point lengths. The implemented curve is denoted as *sect233r1* or *B-233*.

The *sect233r1* elliptic curve domain parameters are specified in the "Standards for Efficient Cryptography (SEC) - SEC2: Recommended Elliptic Curve Domain Parameters" document. The document is established by the Standards for Efficient Cryptography Group (SECG).

The *B-233* elliptic curve domain parameters are specified in the "Digital Signature Standard (DSS)" document, Federal Information Processing Standards (FIPS) Publication 186-2. The document is established by the National Institute of Standards and Technology (NIST).

The GRECC can be used with algorithms such as:

- Elliptic Curve Digital Signature Algorithm DSA (ECDSA), which appears in FIPS 186-2, IEEE 1363-2000 and ISO/IEC 15946-2

- Elliptic Curve El Gamal Method (key exchange protocol)

- Elliptic Curve Diffie-Hellman (ECDH) (key agreement protocol)

The core provides the following internal AMBA APB slave interface, with sideband signals as per [GRLIB] including:

- interrupt bus

- configuration information

- diagnostic information

The core can be partition in the following hierarchical elements:

- Elliptic Curve Cryptography (ECC) core

- AMBA APB slave

- GRLIB plug&play wrapper

Note that the core can also be used without the GRLIB plug&play information.

47.2 Operation

Elliptic Curve Cryptography (ECC) is an asymmetric cryptographic approach (also known as public key cryptography) that applies different keys for encryption and decryption. The most expensive operation during both encryption and decryption is the elliptic curve point multiplication. Hereby, a point on the elliptic curve is multiplied with a long integer ($k*P$ multiplication). The bit sizes of the coordinates of the point $P=(x, y)$ and the factor k have a length of hundreds of bits.

In this implementation the key and the point lengths are 233 bit, so that for every key there are 8 write cycles necessary and for every point (consisting of x and y) there are 16 write cycles necessary. After at least 16700 clock cycles the result can be read out.

GRIP

Apr 2024, Version 2024.1

627

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The key is input via eight registers. The input point $P_{in}=(x, y)$ is written via eight registers for x and eight registers for y. After the last y input register is written, the encryption or decryption is started. The progress can be observed via the status register. When the operation is completed, an interrupt is generated. The output point $P_{out}=(x, y)$ is then read out via eight registers for x and eight registers for y.

47.3   Advantages

The main operation in ECC is the k*P multiplication. One k*P multiplication requires about 1500 field multiplications in the base field, which is the most expensive base operation. The complexity of a field multiplication can be reduced by applying the Karatsuba method. Normally the Karatsuba approach is applied recursively. The GRECC core includes an iterative implementation of the Karatsuba method which allows to realize area efficient hardware accelerators for the *k*P* multiplication. Hardware accelerators which are realized applying an iterative approach need up to 60 per cent less area and about 30 per cent less energy per multiplication than the recursive variants.

47.4   Background

The Standards for Efficient Cryptography Group (SECG) was initiated by Certicom Corporation to address the difficulty vendors and users face when building and deploying interoperable security solutions. The SECG is a broad international coalition comprised of leading technology companies and key industry players in the information security industry. One of the goals is to enable the effective incorporation of Elliptic Curve Cryptographic (ECC) technology into these various cryptographic solutions.

The Standards for Efficient Cryptography Group (SECG) has develop two sets of documents. The first set, under the name SEC, specifies interoperable cryptographic technologies and solutions. The second set, Guidelines for Efficient Cryptography (GEC), provides background information on elliptic curve cryptography and recommendations for ECC parameter and curve selection.

The Federal Information Processing Standards Publication Series of the National Institute of Standards and Technology (NIST) is the official series of publications relating to standards and guidelines adopted under the provisions of the Information Technology Management Reform Act.

This Digital Signature Standard (DSS) specifies a suite of algorithms which can be used to generate a digital signature. Digital signatures are used to detect unauthorized modifications to data and to authenticate the identity of the signatory. In addition, the recipient of signed data can use a digital signature in proving to a third party that the signature was in fact generated by the signatory. This is known as nonrepudiation since the signatory cannot, at a later time, repudiate the signature.

47.5   233-bit elliptic curve domain parameters

The core implements the 233-bit elliptic curve domain parameters *sect233r1,* or the equivalent *B-233*, which are verifiably random parameters. The following specification is established in "Standards for Efficient Cryptography (SEC) - SEC 2: Recommended Elliptic Curve Domain Parameters". The verifiably random elliptic curve domain parameters over F_{2^m} are specified by the septuple $T = (m; f(x); a; b; G; n; h)$ where $m = 233$ and the representation of $F_{2^{233}}$ is defined by:

$f(x) = x^{233}+x^{74}+1$

The curve E: $y^2+xy = x^3+ax^2+b$ over F_{2^m} is defined by:

a = 0000 00000000 00000000 00000000 00000000 00000000 00000000 00000001

b = 0066 647EDE6C 332C7F8C 0923BB58 213B333B 20E9CE42 81FE115F 7D8F90AD

The base point G in compressed form is:

G = 0300FA C9DFCBAC 8313BB21 39F1BB75 5FEF65BC 391F8B36 F8F8EB73 71FD558B

and in uncompressed form is:

    36716F7E 01F81052

Finally the order *n* of *G* and the cofactor are:

n = 0100 00000000 00000000 00000000 0013E974 E72F8A69 22031D26 03CFE0D7

h = 02

47.6 Throughput

The data throughput for the GRECC core is around 233/16700 bits per clock cycle, i.e. approximately 13.9 kbits per MHz.

The underlaying EEC core has been implemented in a dual crypto chip on 250 nm technology as depicted in the figure below. The throughput at 33 MHz operating frequency was 850 kbit/s, the power consumption was 56,8 mW, and the size was 48,5 kgates.
Figure 132. Dual Crypto Chip

47.7 Characteristics

The GRECC core has been synthesized for a Xilinx Virtex-2 XC2V6000-4 devices with the following results:

- LUTs: 12850 (19%)
- Frequency:93 MHz

48   GRETH - Ethernet Media Access Controller (MAC) with EDCL support

48.1   Overview

Frontgrade Gaisler's Ethernet Media Access Controller (GRETH) provides an interface between an AMBA-AHB bus and an Ethernet network. It supports 10/100 Mbit speed in both full- and half-duplex. The AMBA interface consists of an APB interface for configuration and control and an AHB master interface which handles the dataflow. The dataflow is handled through DMA channels. There is one DMA engine for the transmitter and one for the receiver. Both share the same AHB master interface. The ethernet interface supports both the MII and RMII interfaces which should be connected to an external PHY. The GRETH also provides access to the MII Management interface which is used to configure the PHY.

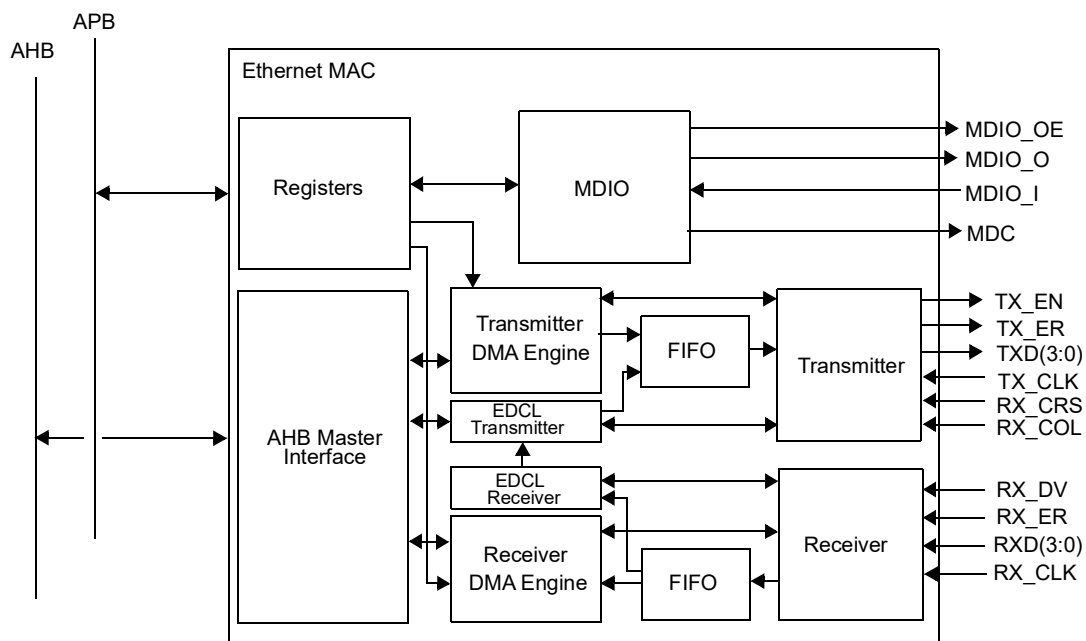
Optional hardware support for the Ethernet Debug Communication Link (EDCL) protocol is also provided. This is an UDP/IP based protocol used for remote debugging.


Figure 133. Block diagram of the internal structure of the GRETH.

48.2   Operation

48.2.1   System overview

The GRETH consists of 3 functional units: The DMA channels, MDIO interface and the optional Ethernet Debug Communication Link (EDCL).

The main functionality consists of the DMA channels which are used to transfer data between an AHB bus and an Ethernet network. There is one transmitter DMA channel and one Receiver DMA channel. The operation of the DMA channels is controlled through registers accessible through the APB interface.

The MDIO interface is used for accessing configuration and status registers in one or more PHYs connected to the MAC. The operation of this interface is also controlled through the APB interface.

The optional EDCL provides read and write access to an AHB bus through Ethernet. It uses the UDP, IP, ARP protocols together with a custom application layer protocol to accomplish this. The EDCL contains no user accessible registers and always runs in parallel with the DMA channels.

The Media Independent Interface (MII) is used for communicating with the PHY. There is an Ethernet transmitter which sends all data from the AHB domain on the Ethernet using the MII interface. Correspondingly, there is an Ethernet receiver which stores all data from the Ethernet on the AHB bus. Both of these interfaces use FIFOs when transferring the data streams. The GRETH also supports the RMII which uses a subset of the MII signals.

The EDCL and the DMA channels share the Ethernet receiver and transmitter.

48.2.2 Protocol support

The GRETH is implemented according to IEEE standard 802.3-2002 and IEEE standard 802.3Q-2003. There is no support for the optional control sublayer. This means that packets with type 0x8808 (the only currently defined ctrl packets) are discarded. The support for 802.3Q is optional and need to be enabled via generics.

48.2.3 Clocking

GRETH has three clock domains: The AHB clock, Ethernet receiver clock and the Ethernet transmitter clock. The ethernet transmitter and receiver clocks are generated by the external ethernet PHY, and are inputs to the core through the MII interface. The three clock domains are unrelated to each other and all signals crossing the clock regions are fully synchronized inside the core.

Both full-duplex and half-duplex operating modes are supported and both can be run in either 10 or 100 Mbit. The minimum AHB clock for 10 Mbit operation is 2.5 MHz, while 18 MHz is needed for 100 Mbit. Using a lower AHB clock than specified will lead to excessive packet loss.

48.2.4 RAM debug support

Support for debug accesses the core's internal RAM blocks can be optionally enabled using the ramdebug VHDL generic. Setting it to 1 enables accesses to the transmitter and receiver RAM buffers and setting it to 2 enables accesses to the EDCL buffer in addition to the previous two buffers.

The transmitter RAM buffer is accessed starting from APB address offset 0x10000 which corresponds to location 0 in the RAM. There are 512 32-bit wide locations in the RAM which results in the last address being 0x107FC corresponding to RAM location 511 (byte addressing used on the APB bus).

Correspondingly the receiver RAM buffer is accessed starting from APB address offset 0x20000. The addresses, width and depth is the same.

The EDCL buffers are accessed starting from address 0x30000. The number of locations depend on the configuration and can be from 256 to 16384. Each location is 32-bits wide so the maximum address is 0x3FC and 0xFFFC correspondingly.

Before any debug accesses can be made the ramdebugen bit in the control register has to be set. During this time the debug interface controls the RAM blocks and normal operations is stopped. EDCL packets are not received. The MAC transmitter and receiver could still operate if enabled but the RAM buffers would be corrupt if debug accces are made simultaneously. Thus they MUST be disabled before the RAM debug mode is enabled.

48.2.5 Multibus version

There is a version of the core which has an additional master interface that can be used for the EDCL. Otherwise this version is identical to the basic version. The additional master interface is enabled with the edclsepahb VHDL generic. Then the ethi.edclsepahb signal control whether EDCL accesses are done on the standard master interface or the additional interface. Setting the signal to '0' makes the EDCL use the standard master interface while '1' selects the additional master. This signal is only sampled at reset and changes to this signal have no effect until the next reset.

48.2.6 Endianness

The core is designed for big-endian systems.

48.3 Tx DMA interface

The transmitter DMA interface is used for transmitting data on an Ethernet network. The transmission is done using descriptors located in memory.

48.3.1 Setting up a descriptor.

A single descriptor is shown in table 746 and 747. The number of bytes to be sent should be set in the length field and the address field should point to the data. The address must be word-aligned. If the interrupt enable (IE) bit is set, an interrupt will be generated when the packet has been sent (this requires that the transmitter interrupt bit in the control register is also set). The interrupt will be generated regardless of whether the packet was transmitted successfully or not. The Wrap (WR) bit is also a control bit that should be set before transmission and it will be explained later in this section.

*Table 746.*GRETH transmit descriptor word 0 (address offset 0x0)

31 16	15	14	13	12	11	10 0
RESERVED	AL	UE	IE	WR	EN	LENGTH

31: 16	RESERVED
15	Attempt Limit Error (AL) - The packet was not transmitted because the maximum number of attempts was reached.
14	Underrun Error (UE) - The packet was incorrectly transmitted due to a FIFO underrun error.
13	Interrupt Enable (IE) - Enable Interrupts. An interrupt will be generated when the packet from this descriptor has been sent provided that the transmitter interrupt enable bit in the control register is set. The interrupt is generated regardless if the packet was transmitted successfully or if it terminated with an error.
12	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 8. The pointer automatically wraps to zero when the 1 kB boundary of the descriptor table is reached.
11	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.
10: 0	LENGTH - The number of bytes to be transmitted.

*Table 747.*GRETH transmit descriptor word 1 (address offset 0x4)

31 2	1 0
ADDRESS	RES

31: 2	Address (ADDRESS) - Pointer to the buffer area from where the packet data will be loaded.
1: 0	RESERVED

To enable a descriptor the enable (EN) bit should be set and after this is done, the descriptor should not be touched until the enable bit has been cleared by the GRETH.

48.3.2 Starting transmissions

Enabling a descriptor is not enough to start reception. A pointer to the memory area holding the descriptors must first be set in the GRETH. This is done in the receiver descriptor pointer register. The the beginning of the area and must start on an address that is aligned to the size of the descriptor table. The size of the descriptor table can be determined from the formula: STS.NRD*8. The STS.NRD field shows the number of entries in the descriptor table, and each descriptor size is 8 bytes.

GRIP

Apr 2024, Version 2024.1

644

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

Bits 31 to STS.NRD+10 hold the base address of descriptor area while bits STS.NRD+9 to 3 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the GRETH the pointer field is incremented by 8 to point at the next descriptor. The pointer will automatically wrap back to zero when the upper boundary has been reached. The WR bit in the descriptors can be set to make the pointer wrap back to zero before the upper boundary.The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when a transmission is active.

The final step to activate the transmission is to set the transmit enable bit in the control register. This tells the GRETH that there are more active descriptors in the descriptor table. This bit should always be set when new descriptors are enabled, even if transmissions are already active. The descriptors must always be enabled before the transmit enable bit is set.

48.3.3   Descriptor handling after transmission

When a transmission of a packet has finished, status is written to the first word in the corresponding descriptor. The Underrun Error bit is set if the FIFO became empty before the packet was completely transmitted while the Attempt Limit Error bit is set if more collisions occurred than allowed. The packet was successfully transmitted only if both of these bits are zero. The other bits in the first descriptor word are set to zero after transmission while the second word is left untouched.

The enable bit should be used as the indicator when a descriptor can be used again, which is when it has been cleared by the GRETH. There are three bits in the GRETH status register that hold transmission status. The Transmitter Error (TE) bit is set each time an transmission ended with an error (when at least one of the two status bits in the transmit descriptor has been set). The Transmitter Interrupt (TI) is set each time a transmission ended successfully.

The transmitter AHB error (TA) bit is set when an AHB error was encountered either when reading a descriptor or when reading packet data. Any active transmissions were aborted and the transmitter was disabled. The transmitter can be activated again by setting the transmit enable register.

48.3.4   Setting up the data for transmission

The data to be transmitted should be placed beginning at the address pointed by the descriptor address field. The GRETH does not add the Ethernet address and type fields so they must also be stored in the data buffer. The 4 B Ethernet CRC is automatically appended at the end of each packet. Each descriptor will be sent as a single Ethernet packet. If the size field in a descriptor is greater than defined by maxsize generic + header size bytes, the packet will not be sent.

48.4   Rx DMA interface

The receiver DMA interface is used for receiving data from an Ethernet network. The reception is done using descriptors located in memory.

48.4.1   Setting up descriptors

A single descriptor is shown in table 748 and 749. The address field should point to a word-aligned buffer where the received data should be stored. The GRETH will never store more than defined by the maxisize generic + header size bytes to the buffer. If the interrupt enable (IE) bit is set, an interrupt will be generated when a packet has been received to this buffer (this requires that the receiver interrupt bit in the control register is also set). The interrupt will be generated regardless of whether the packet was received successfully or not. The Wrap (WR) bit is also a control bit that should be set before the descriptor is enabled and it will be explained later in this section.

*Table 748.*GRETH receive descriptor word 0 (address offset 0x0)

31	27	26	25	19	18	17	16	15	14	13	12	11	10	0
RESERVED		MC	RESERVED		LE	OE	CE	FT	AE	IE	WR	EN	LENGTH	

*Table 748.*GRETH receive descriptor word 0 (address offset 0x0)

31: 27	RESERVED
26	Multicast address (MC) - The destination address of the packet was a multicast address (not broadcast).
25: 19	RESERVED
18	Length error (LE) - The length/type field of the packet did not match the actual number of received bytes.
17	Overrun error (OE) - The frame was incorrectly received due to a FIFO overrun.
16	CRC error (CE) - A CRC error was detected in this frame.
15	Frame too long (FT) - A frame larger than the maximum size was received. The excessive part was truncated.
14	Alignment error (AE) - An odd number of nibbles were received.
13	Interrupt Enable (IE) - Enable Interrupts. An interrupt will be generated when a packet has been received to this descriptor provided that the receiver interrupt enable bit in the control register is set. The interrupt is generated regardless if the packet was received successfully or if it terminated with an error.
12	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 8. The pointer automatically wraps to zero when the 1 kB boundary of the descriptor table is reached.
11	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.
10: 0	LENGTH - The number of bytes received to this descriptor.

*Table 749.*GRETH receive descriptor word 1 (address offset 0x4)

31	2	1	0
ADDRESS			RES

31: 2	Address (ADDRESS) - Pointer to the buffer area from where the packet data will be loaded.
1: 0	RESERVED

48.4.2 Starting reception

Enabling a descriptor is not enough to start reception. A pointer to the memory area holding the descriptors must first be set in the GRETH. This is done in the receiver descriptor pointer register. The the beginning of the area and must start on an address that is aligned to the size of the descriptor table. The size of the descriptor table can be determined from the formula: STS.NRD*8. The STS.NRD field shows the number of entries in the descriptor table, and each descriptor size is 8 bytes.

Bits 31 to STS.NRD+10 hold the base address of descriptor area while bits STS.NRD+9 to 3 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the GRETH the pointer field is incremented by 8 to point at the next descriptor. The pointer will automatically wrap back to zero when the upper boundary has been reached. The WR bit in the descriptors can be set to make the pointer wrap back to zero before the upper boundary.

The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when reception is active.

The final step to activate reception is to set the receiver enable bit in the control register. This will make the GRETH read the first descriptor and wait for an incoming packet.

48.4.3 Descriptor handling after reception

The GRETH indicates a completed reception by clearing the descriptor enable bit. The other control bits (WR, IE) are also cleared. The number of received bytes is shown in the length field. The parts of the Ethernet frame stored are the destination address, source address, type and data fields. Bits 17-14 in the first descriptor word are status bits indicating different receive errors. All four bits are zero after a reception without errors. The status bits are described in table 748.

GRIP
Apr 2024, Version 2024.1

646

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Packets arriving that are smaller than the minimum Ethernet size of 64 B are not considered as a reception and are discarded. The current receive descriptor will be left untouched an used for the first packet arriving with an accepted size. The TS bit in the status register is set each time this event occurs.

If a packet is received with an address not accepted by the MAC, the IA status register bit will be set.

Packets larger than maximum size cause the FT bit in the receive descriptor to be set. The length field is not guaranteed to hold the correct value of received bytes. The counting stops after the word containing the last byte up to the maximum size limit has been written to memory.

The address word of the descriptor is never touched by the GRETH.

48.4.4   Reception with AHB errors

If an AHB error occurs during a descriptor read or data store, the Receiver AHB Error (RA) bit in the status register will be set and the receiver is disabled. The current reception is aborted. The receiver can be enabled again by setting the Receive Enable bit in the control register.

48.4.5   Accepted MAC addresses

In the default configuration the core receives packets with either the unicast address set in the MAC address register or the broadcast address. Multicast support can also be enabled and in that case a hash function is used to filter received multicast packets. A 64-bit register, which is accessible through the APB interface, determines which addresses should be received. Each address is mapped to one of the 64 bits using the hash function and if the bit is set to one the packet will be received. The address is mapped to the table by taking the 6 least significant bits of the 32-bit Ethernet crc calculated over the destination address of the MAC frame. A bit in the receive descriptor is set if a packet with a multicast address has been received to it.

48.5   MDIO Interface

The MDIO interface provides access to PHY configuration and status registers through a two-wire interface which is included in the MII interface. The GRETH provided full support for the MDIO interface. If it is not needed in a design it can be removed with a VHDL generic.

The MDIO interface can be used to access from 1 to 32 PHY containing 1 to 32 16-bit registers. A read transfer i set up by writing the PHY and register addresses to the MDIO Control register and setting the read bit. This caused the Busy bit to be set and the operation is finished when the Busy bit is cleared. If the operation was successful the Linkfail bit is zero and the data field contains the read data. An unsuccessful operation is indicated by the Linkfail bit being set. The data field is undefined in this case.

A write operation is started by writing the 16-bit data, PHY address and register address to the MDIO Control register and setting the write bit. The operation is finished when the busy bit is cleared and it was successful if the Linkfail bit is zero.

48.5.1   PHY interrupts

The core also supports status change interrupts from the PHY. A level sensitive interrupt signal can be connected on the mdint input. The mdint_pol vhdl generic can be used to select the polarity. The PHY status change bit in the status register is set each time an event is detected in this signal. If the PHY status interrupt enable bit is set at the time of the event the core will also generate an interrupt on the AHB bus.

48.6   Ethernet Debug Communication Link (EDCL)

The EDCL provides access to an on-chip AHB bus through Ethernet. It uses the UDP, IP and ARP protocols together with a custom application layer protocol. The application layer protocol uses an

GRIP

Apr 2024, Version 2024.1

647

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

ARQ algorithm to provide reliable AHB instruction transfers. Through this link, a read or write transfer can be generated to any address on the AHB bus. The EDCL is optional and must be enabled with a generic.

48.6.1 Operation

The EDCL receives packets in parallel with the MAC receive DMA channel. It uses a separate MAC address which is used for distinguishing EDCL packets from packets destined to the MAC DMA channel. The EDCL also has an IP address which is set through generics. Since ARP packets use the Ethernet broadcast address, the IP-address must be used in this case to distinguish between EDCL ARP packets and those that should go to the DMA-channel. Packets that are determined to be EDCL packets are not processed by the receive DMA channel.

When the packets are checked to be correct, the AHB operation is performed. The operation is performed with the same AHB master interface that the DMA-engines use. The replies are automatically sent by the EDCL transmitter when the operation is finished. It shares the Ethernet transmitter with the transmitter DMA-engine but has higher priority.

48.6.2 EDCL protocols

The EDCL accepts Ethernet frames containing IP or ARP data. ARP is handled according to the protocol specification with no exceptions.

IP packets carry the actual AHB commands. The EDCL expects an Ethernet frame containing IP, UDP and the EDCL specific application layer parts. Table 750 shows the IP packet required by the EDCL. The contents of the different protocol headers can be found in TCP/IP literature.

Table 750. The IP packet expected by the EDCL.

Ethernet Header	IP Header	UDP Header	2 B Offset	4 B Control word	4 B Address	Data 0 - 242 4B Words	Ethernet CRC

The following is required for successful communication with the EDCL: A correct destination MAC address as set by the generics, an Ethernet type field containing 0x0806 (ARP) or 0x0800 (IP). The IP-address is then compared with the value determined by the generics for a match. The IP-header checksum and identification fields are not checked. There are a few restrictions on the IP-header fields. The version must be four and the header size must be 5 B (no options). The protocol field must always be 0x11 indicating a UDP packet. The length and checksum are the only IP fields changed for the reply.

The EDCL only provides one service at the moment and it is therefore not required to check the UDP port number. The reply will have the original source port number in both the source and destination fields. UDP checksum are not used and the checksum field is set to zero in the replies.

The UDP data field contains the EDCL application protocol fields. Table 751 shows the application protocol fields (data field excluded) in packets received by the EDCL. The 16-bit offset is used to align the rest of the application layer data to word boundaries in memory and can thus be set to any value. The R/W field determines whether a read (0) or a write(1) should be performed. The length

Table 751. The EDCL application layer fields in received frames.

16-bit Offset	14-bit Sequence number	1-bit R/W	10-bit Length	7-bit Unused

field contains the number of bytes to be read or written. If R/W is one the data field shown in table 750 contains the data to be written. If R/W is zero the data field is empty in the received packets. Table 752 shows the application layer fields of the replies from the EDCL. The length field is always zero for replies to write requests. For read requests it contains the number of bytes of data contained in the data field.

*Table 752.*The EDCL application layer fields in transmitted frames.

16-bit Offset	14-bit sequence number	1-bit ACK/NAK	10-bit Length	7-bit Unused

The EDCL implements a Go-Back-N algorithm providing reliable transfers. The 14-bit sequence number in received packets are checked against an internal counter for a match. If they do not match, no operation is performed and the ACK/NAK field is set to 1 in the reply frame. The reply frame contains the internal counter value in the sequence number field. If the sequence number matches, the operation is performed, the internal counter value is stored in the sequence number field, the ACK/NAK field is set to 0 in the reply and the internal counter is incremented, . The length field is always set to 0 for ACK/NAK=1 frames. The unused field is not checked and is copied to the reply. It can thus be set to hold for example some extra identifier bits if needed.

48.6.3 EDCL IP and Ethernet address settings

The default value of the EDCL IP and MAC addresses are set by `ipaddrh, ipaddrl, macaddrh and macaddrl` generics. The IP address and MAC address can later be changed by software. To allow several EDCL enabled GRETH controllers on the same sub-net, the 4 LSB bits of the IP and MAC address can optionally be set by an input signal. This is enabled by setting the `edcl` generic = 2, and driving the 4-bit LSB value on ethi.edcladdr.

48.6.4 EDCL buffer size

The EDCL has a dedicated internal buffer memory which stores the received packets during processing. The size of this buffer is configurable with a VHDL generic to be able to obtain a suitable compromise between throughput and resource utilization in the hardware. Table 753 lists the different buffer configurations. For each size the table shows how many concurrent packets the EDCL can handle, the maximum size of each packet including headers and the maximum size of the data payload. Sending more packets before receiving a reply than specified for the selected buffer size will lead to dropped packets. The behavior is unspecified if sending larger packets than the maximum allowed.

*Table 753.*EDCL buffer sizes

Total buffer size (kB)	Number of packet buffers	Packet buffer size (B)	Maximum data payload (B)
1	4	256	200
2	4	512	456
4	8	512	456
8	8	1024	968
16	16	1024	968
32	32	1024	968
64	64	1024	968

48.7 Media Independent Interfaces

There are several interfaces defined between the MAC sublayer and the Physical layer. The GRETH supports two of them: The Media Independent Interface (MII) and the Reduced Media Independent Interface (RMII).

The MII was defined in the 802.3 standard and is most commonly supported. The ethernet interface have been implemented according to this specification. It uses 16 signals.

GRIP
Apr 2024, Version 2024.1

+46 31 7758650 | frontgrade.com/gaisler

To support lower speed where the operation and clock frequency of the core and phy remains unchanged i.e. running at 10Mb/s when the IP is configured for 100Mb/s speed enable signals should be created to mimic the desired bit rate.

When operating at 10Mb/s, every byte of the MAC frame is repeated 10 clock periods to achieve the correct bit rate. The GRETH_GBIT core does not take care of this operation and enable signals with toggling frequency of the correct bit rate needs to be created.

The RMII was developed to meet the need for an interface allowing Ethernet controllers with smaller pin counts. It uses 6 (7) signals which are a subset of the MII signals. Table 754 shows the mapping between the RMII signals and the GRLIB MII interface.

*Table 754.*Signal mappings between RMII and the GRLIB MII interface.

RMII	MII
txd[1:0]	txd[1:0]
tx_en	tx_en
crs_dv	rx_crs
rxd[1:0]	rxd[1:0]
ref_clk	rmii_clk
rx_er	not used

48.8   AXI support

The core is designed for an AMBA system but can be adapted for AXI using the AHBM2AXI adapter.

48.9   Registers

The core is programmed through registers mapped into APB address space.

*Table 755.*GRETH registers

APB address offset	Register
0x0	Control register
0x4	Status/Interrupt-source register
0x8	MAC Address MSB
0xC	MAC Address LSB
0x10	MDIO Control/Status
0x14	Transmit descriptor pointer
0x18	Receiver descriptor pointer
0x1C	EDCL IP
0x20	Hash table msb
0x24	Hash table lsb
0x28	EDCL MAC address MSB
0x2C	EDCL MAC address LSB
0x10000 - 0x107FC	Transmit RAM buffer debug access
0x20000 - 0x207FC	Receiver RAM buffer debug access
0x30000 - 0x3FFFC	EDCL buffer debug access

48.9.1 Control Register

*Table 756.*0x00 - CTRL - GRETH control register

31	30	28	27	26	25	24		15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
EA	BS			MA	MC	RESERVED			ED	RD	DD	ME	PI	RES		SP	RS	PM	FD	RI	TI	RE	TE
*	*		*	*	*	0			*	*	0	0	0	0		1	0	0	0	0	0	0	0
r	r		r	r	r	r			rw	rw	rw	rw	rw	r		rw	wc	rw	rw	rw	rw	rw	rw

31	EDCL available (EA) - Set to one if the EDCL is available.
30: 28	EDCL buffer size (BS) - Shows the amount of memory used for EDCL buffers. 0 = 1 kB, 1 = 2 kB, ..., 6 = 64 kB.
27	RESERVED
26	MDIO interrupts available (MA) - Set to one when the core supports mdio interrupts. Read only.
25	Multicast available (MC) - Set to one when the core supports multicast address reception. Read only.
24: 15	RESERVED
14	EDCL Disable (ED) - Set to one to disable the EDCL and zero to enable it. Reset value taken from the ethi.edcldisable signal. Only available if the EDCL hardware is present in the core.
13	RAM debug enable (RD) - Set to one to enable the RAM debug mode. Reset value: '0'. Only available if the VHDL generic ramdebug is nonzero.
12	Disable duplex detection (DD) - Disable the EDCL speed/duplex detection FSM. If the FSM cannot complete the detection the MDIO interface will be locked in busy mode. If software needs to access the MDIO the FSM can be disabled here and as soon as the MDIO busy bit is 0 the interface is available. Note that the FSM cannot be reenabled again.
11	Multicast enable (ME) - Enable reception of multicast addresses. Reset value: '0'.
10	PHY status change interrupt enable (PI) - Enables interrupts for detected PHY status changes.
9: 8	RESERVED
7	Speed (SP) - Sets the current speed mode. 0 = 10 Mbit, 1 = 100 Mbit. Only used in RMII mode (rmii = 1). A default value is automatically read from the PHY after reset. Reset value: '1'.
6	Reset (RS) - A one written to this bit resets the GRETH core. Self clearing. No other accesses should be done .to the slave interface other than polling this bit until it is cleared.
5	Promiscuous mode (PM) - If set, the GRETH operates in promiscuous mode which means it will receive all packets regardless of the destination address. Reset value: '0'.
4	Full duplex (FD) - If set, the GRETH operates in full-duplex mode otherwise it operates in half-duplex. Reset value: '0'.
3	Receiver interrupt (RI) - Enable Receiver Interrupts. An interrupt will be generated each time a packet is received when this bit is set. The interrupt is generated regardless if the packet was received successfully or if it terminated with an error. Reset value: '0'.
2	Transmitter interrupt (TI) - Enable Transmitter Interrupts. An interrupt will be generated each time a packet is transmitted when this bit is set. The interrupt is generated regardless if the packet was transmitted successfully or if it terminated with an error. Reset value: '0'.
1	Receive enable (RE) - Should be written with a one each time new descriptors are enabled. As long as this bit is one the GRETH will read new descriptors and as soon as it encounters a disabled descriptor it will stop until RE is set again. This bit should be written with a one after the new descriptors have been enabled. Reset value: '0'.
0	Transmit enable (TE) - Should be written with a one each time new descriptors are enabled. As long as this bit is one the GRETH will read new descriptors and as soon as it encounters a disabled descriptor it will stop until TE is set again. This bit should be written with a one after the new descriptors have been enabled. Reset value: '0'.

48.9.2 Status Register

48.10   Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x1D. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

48.11   Implementation

48.11.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

48.11.2 Endianness

The core changes endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). Changing *grlib_little_endian* controls TBD

48.12 Configuration options

Table 768 shows the configuration options of the core (VHDL generics).

*Table 768.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB master index.	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar.	0 - 16#FFF#	0
pmask	Mask field of the APB bar.	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by the GRETH.	0 - NAHBIRQ-1	0
memtech	Memory technology used for the FIFOs.	0 - NTECH	inferred
ifg_gap	Number of ethernet clock cycles used for one interframe gap. Default value as required by the standard. Do not change unless you know what you are doing.	1 - 255	24
attempt_limit	Maximum number of transmission attempts for one packet. Default value as required by the standard.	1 - 255	16
backoff_limit	Limit on the backoff size of the backoff time. Default value as required by the standard. Sets the number of bits used for the random value. Do not change unless you know what your doing.	1 - 10	10
slot_time	Number of ethernet clock cycles used for one slot- time. Default value as required by the ethernet standard. Do not change unless you know what you are doing.	1 - 255	128
mdcscaler	Sets the divisor value use to generate the mdio clock (mdc). The mdc frequency will be clk/(2*(mdcscaler+1)).	0 - 255	25
enable_mdio	Enable the Management interface,	0 - 1	0
fifosize	Sets the size in 32-bit words of the receiver and transmitter FIFOs.	4 - 32	8
nsync	Number of synchronization registers used.	1 - 2	2
edcl	Enable EDCL. 0 = disabled. 1 = enabled. 2 = enabled and 4-bit LSB of IP and ethernet MAC address programmed by ethi.edcladdr, 3=in addition to features for value 2 the reset value for the EDCL disable bit is taken from the ethi.edcldisable signal instead of being hardcoded to 0. 4=in addition to features for value 2 and 3 the an option is given to disable the EDCL via external input signal.	0 - 4	0
edclbufsz	Select the size of the EDCL buffer in kB.	1 - 64	1
macaddrh	Sets the upper 24 bits of the EDCL MAC address. Not all addresses are allowed and most NICs and protocol implementations will discard frames with illegal addresses silently. Consult network literature if unsure about the addresses.	0 - 16#FFFFFF#	16#00005E#
macaddrl	Sets the lower 24 bits of the EDCL MAC address. Not all addresses are allowed and most NICs and protocol implementations will discard frames with illegal addresses silently. Consult network literature if unsure about the addresses.	0 - 16#FFFFFF#	16#000000#
ipaddrh	Sets the upper 16 bits of the EDCL IP address reset value.	0 - 16#FFFF#	16#C0A8#
ipaddrl	Sets the lower 16 bits of the EDCL IP address reset value.	0 - 16#FFFF#	16#0035#

*Table 768.*Configuration options

Generic	Function	Allowed range	Default
phyrstadr	Sets the reset value of the PHY address field in the MDIO register. When set to 32, the address is taken from the ethi.phyrstaddr signal.	0 - 32	0
rmii	Selects the desired PHY interface. 0 = MII, 1 = RMII.	0 - 1	0
oepol	Selects polarity on output enable (ETHO.MDIO_OE). 0 = active low, 1 = active high	0 - 1	0
mdint_pol	Selects polarity for level sensitive PHY interrupt line. 0 = active low, 1 = active high	0 - 1	0
enable_mdint	Enable mdio interrupts	0 - 1	0
multicast	Enable multicast support	0 - 1	0
ramdebug	Enables debug access to the core's RAM blocks through the APB interface. 1=enables access to the receiver and transmitter RAM buffers, 2=enables access to the EDCL buffers in addition to the functionality of value 1. Setting this generic to 2 will have no effect if the edcl generic is 0.	0 - 2	0
ehindex	AHB master index for the separate EDCL master interface. Only used if edclsepahb is 1.	0 - NAHBMST-1	0
edclsepahb	Enables separate EDCL AHB master interface. A signal determines if the separate interface or the common interface is used. Only available in the GRETH_GBIT_MB version of the core.	0 - 1	0
mdiohold	Set output hold time for MDIO in number of AHB cycles. Should be 10 ns or more.	1 - 30	1
maxsize	Set maximum length of the data field of Ethernet 802.3 frame. Values of 'maxsize' and below for this field indicate that the ethernet type field is used as the size of the payload of the Ethernet Frame while values of above 'maxsize' indicate that the field is used to represent EtherType. For 802.3q support set the length of the payload to 1504	64 - 2047	1500
gmiimode	Enable the use of receive and transmit valid signals to enter data to/from the PHY at the correct rate.	0-1	0
ft	Enable fault tolerance for receive and transmit buffers. 0 - no fault tolerance, 1 - Parity DMR, 2 - TMR.	0-2	0
edclft	Enable fault tolerance for EDCL buffers. 0 - no fault tolerance, 1 - Parity DMR, 2 - TMR. This generic only has effect if generic edcl is non-zero.	0-2	0
num_desc	Specifies the number of entries in the descriptor table	128, 256, 512, 1024, 2048, 4096, 8192, 16384, 32728, 65536	128

49 GRETH_GBIT - Gigabit Ethernet Media Access Controller (MAC) w. EDCL

49.1 Overview

Frontgrade Gaisler's Gigabit Ethernet Media Access Controller (GRETH_GBIT) provides an interface between an AMBA-AHB bus and an Ethernet network. It supports 10/100/1000 Mbit speed in both full- and half-duplex. The AMBA interface consists of an APB interface for configuration and control and an AHB master interface which handles the dataflow. The dataflow is handled through DMA channels. There is one DMA engine for the transmitter and one for the receiver. Both share the same AHB master interface.

The ethernet interface supports the MII and GMII interfaces which should be connected to an external PHY. The GRETH also provides access to the MII Management interface which is used to configure the PHY. Optional hardware support for the Ethernet Debug Communication Link (EDCL) protocol is also provided. This is an UDP/IP based protocol used for remote debugging.

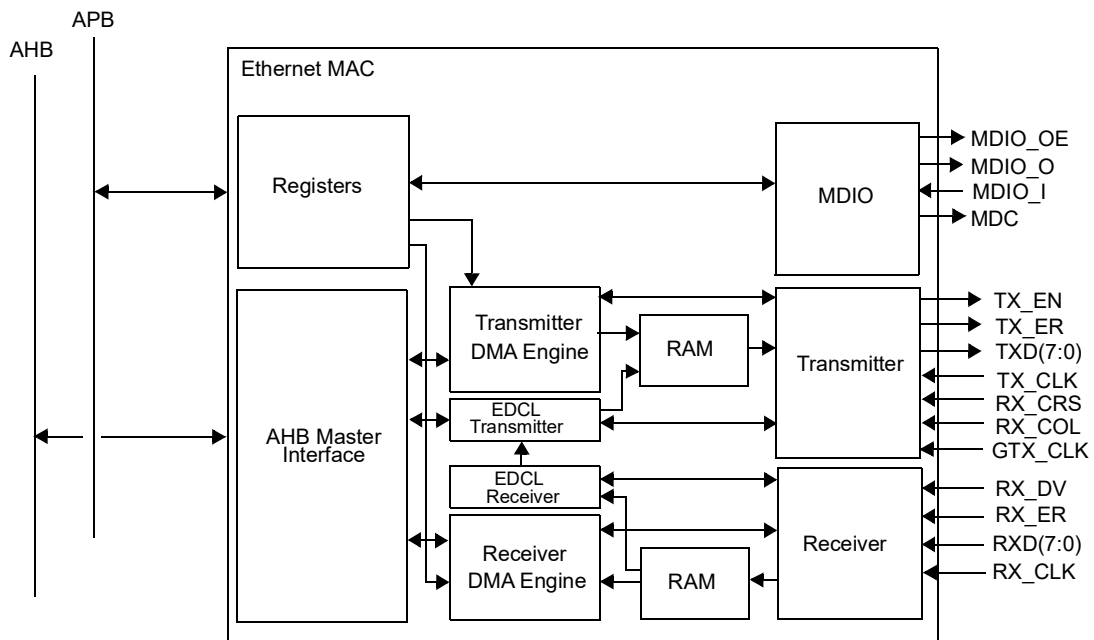
Supported features for the DMA channels are Scatter Gather I/O and TCP/UDP over IPv4 checksum offloading for both receiver and transmitter.


Figure 134. Block diagram of the internal structure of the GRETH_GBIT.

49.2 Operation

49.2.1 System overview

The GRETH_GBIT consists of 3 functional units: The DMA channels, MDIO interface and the optional Ethernet Debug Communication Link (EDCL).

The main functionality consists of the DMA channels which are used for transferring data between an AHB bus and an Ethernet network. There is one transmitter DMA channel and one Receiver DMA channel. The operation of the DMA channels is controlled through registers accessible through the APB interface.

GRIP
Apr 2024, Version 2024.1
662
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The MDIO interface is used for accessing configuration and status registers in one or more PHYs connected to the MAC. The operation of this interface is also controlled through the APB interface.

The optional EDCL provides read and write access to an AHB bus through Ethernet. It uses the UDP, IP and ARP protocols together with a custom application layer protocol to accomplish this. The EDCL contains no user accessible registers and always runs in parallel with the DMA channels.

The Media Independent Interface (MII) and Gigabit Media Independent Interface (GMII) are used for communicating with the PHY. More information can be found in section 49.7.

The EDCL and the DMA channels share the Ethernet receiver and transmitter. More information on these functional units is provided in sections 49.3 - 49.6.

49.2.2 Protocol support

The GRETH_GBIT is implemented according to IEEE standard 802.3-2002. There is no support for the optional control sublayer. This means that packets with type 0x8808 (the only currently defined ctrl packets) are discarded.

49.2.3 Hardware requirements

The GRETH_GBIT is synthesisable with most Synthesis tools. There are three or four clock domains depending on if the gigabit mode is used. The three domains always present are the AHB clock, Ethernet Receiver clock (RX_CLK) and the 10/100 Ethernet transmitter clock (TX_CLK). If the gigabit mode is also used the fourth clock domain is the gigabit transmitter clock (GTX_CLK). Both full-duplex and half-duplex operating modes are supported and both can be run in either 10/100 or 1000 Mbit. The system frequency requirement (AHB clock) for 10 Mbit operation is 2.5 MHz, 18 MHz for 100 Mbit and 40 MHz for 1000 Mbit mode. The 18 MHz limit was tested on a Xilinx board with a DCM that did not support lower frequencies so it might be possible to run it on lower frequencies. It might also be possible to run the 10 Mbit mode on lower frequencies.

RX_CLK and TX_CLK are sourced by the PHY while GTX_CLK is sourced by the MAC according to the 802.3-2002 standard. The GRETH_GBIT does not contain an internal clock generator so GTX_CLK should either be generated in the FPGA (with a PLL/DLL) or with an external oscillator.

49.2.4 RAM debug support

Support for debug accesses the core's internal RAM blocks can be optionally enabled using the ramdebug VHDL generic. Setting it to 1 enables accesses to the transmitter and receiver RAM buffers and setting it to 2 enables accesses to the EDCL buffer in addition to the previous two buffers.

The transmitter RAM buffer is accessed starting from APB address offset 0x10000 which corresponds to location 0 in the RAM. There are 512 32-bit wide locations in the RAM which results in the last address being 0x107FC corresponding to RAM location 511 (byte addressing used on the APB bus).

Correspondingly the receiver RAM buffer is accessed starting from APB address offset 0x20000. The addresses, width and depth is the same.

The EDCL buffers are accessed starting from address 0x30000. The number of locations depend on the configuration and can be from 256 to 16384. Each location is 32-bits wide so the maximum address is 0x3FC and 0xFFFC correspondingly.

Before any debug accesses can be made the ramdebugen bit in the control register has to be set. During this time the debug interface controls the RAM blocks and normal operations is stopped. EDCL packets are not received. The MAC transmitter and receiver could still operate if enabled but the RAM buffers would be corrupt if debug accces are made simultaneously. Thus they MUST be disabled before the RAM debug mode is enabled.

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

49.2.5 Multibus version

There is a version of the core which has an additional master interface that can be used for the EDCL. Otherwise this version is identical to the basic version. The additional master interface is enabled with the edclsepahb VHDL generic. Then the ethi.edclsepahb signal control whether EDCL accesses are done on the standard master interface or the additional interface. Setting the signal to '0' makes the EDCL use the standard master interface while '1' selects the additional master. This signal is only sampled at reset and changes to this signal have no effect until the next reset.

49.2.6 Endianness

The core is designed for big-endian systems.

49.3 Tx DMA interface

The transmitter DMA interface is used for transmitting data on an Ethernet network. The transmission is done using descriptors located in memory.

49.3.1 Setting up a descriptor.

A single descriptor is shown in table 771 and 772. The number of bytes to be sent should be set in the length field and the address field should point to the data. There are no alignment restrictions on the address field. If the interrupt enable (IE) bit is set, an interrupt will be generated when the packet has been sent (this requires that the transmitter interrupt bit in the control register is also set). The interrupt will be generated regardless of whether the packet was transmitted successfully or not.

*Table 771.*GRETH_GBIT transmit descriptor word 0 (address offset 0x0)

31	21	20	19	18	17	16	15	14	13	12	11	10	0
RESERVED		UC	TC	IC	MO	LC	AL	UE	IE	WR	EN	LENGTH	

31: 21	RESERVED	
20	UDP checksum (UC) - Calculate and insert the UDP checksum for this packet. The checksum is only inserted if an UDP packet is detected.	
19	TCP checksum (TC) - Calculate and insert the TCP checksum for this packet. The checksum is only inserted if an TCP packet is detected.	
18	IP checksum (IC) - Calculate and insert the IP header checksum for this packet. The checksum is only inserted if an IP packet is detected.	
17	More (MO) - More descriptors should be fetched for this packet (Scatter Gather I/O).	
16	Late collision (LC) - A late collision occurred during the transmission (1000 Mbit mode only).	
15	Attempt limit error (AL) - The packet was not transmitted because the maximum number of attempts was reached.	
14	Underrun error (UE) - The packet was incorrectly transmitted due to a FIFO underrun error.	
13	Interrupt enable (IE) - Enable Interrupts. An interrupt will be generated when the packet from this descriptor has been sent provided that the transmitter interrupt enable bit in the control register is set. The interrupt is generated regardless if the packet was transmitted successfully or if it terminated with an error.	
12	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 8. The pointer automatically wraps to zero when the 1 kB boundary of the descriptor table is reached.	
11	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.	
10: 0	LENGTH - The number of bytes to be transmitted.	

*Table 772.*GRETH_GBIT transmit descriptor word 1 (address offset 0x4)

31	0
ADDRESS	

Table 772.GRETH_GBIT transmit descriptor word 1 (address offset 0x4)

31: 0	Address (ADDRESS) - Pointer to the buffer area from where the packet data will be loaded.

To enable a descriptor the enable (EN) bit should be set and after this is done, the descriptor should not be touched until the enable bit has been cleared by the GRETH_GBIT. The rest of the fields in the descriptor are explained later in this section.

49.3.2 Starting transmissions

Enabling a descriptor is not enough to start a transmission. A pointer to the memory area holding the descriptors must first be set in the GRETH_GBIT. This is done in the transmitter descriptor pointer register. The address must be aligned to a 1 kB boundary. Bits 31 to 10 hold the base address of descriptor area while bits 9 to 3 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the GRETH_GBIT the pointer field is incremented by 8 to point at the next descriptor. The pointer will automatically wrap back to zero when the next 1 kB boundary has been reached (the descriptor at address offset 0x3F8 has been used). The WR bit in the descriptors can be set to make the pointer wrap back to zero before the 1 kB boundary.

The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when a transmission is active.

The final step to activate the transmission is to set the transmit enable bit in the control register. This tells the GRETH_GBIT that there are more active descriptors in the descriptor table. This bit should always be set when new descriptors are enabled, even if transmissions are already active. The descriptors must always be enabled before the transmit enable bit is set.

49.3.3 Descriptor handling after transmission

When a transmission of a packet has finished, status is written to the first word in the corresponding descriptor. The Underrun Error bit is set if the transmitter RAM was not able to provide data at a sufficient rate. This indicates a synchronization problem most probably caused by a low clock rate on the AHB clock. The whole packet is buffered in the transmitter RAM before transmission so underruns cannot be caused by bus congestion. The Attempt Limit Error bit is set if more collisions occurred than allowed. When running in 1000 Mbit mode the Late Collision bit indicates that a collision occurred after the slottime boundary was passed.

The packet was successfully transmitted only if these three bits are zero. The other bits in the first descriptor word are set to zero after transmission while the second word is left untouched.

The enable bit should be used as the indicator when a descriptor can be used again, which is when it has been cleared by the GRETH_GBIT. There are three bits in the GRETH_GBIT status register that hold transmission status. The Transmit Error (TE) bit is set each time an transmission ended with an error (when at least one of the three status bits in the transmit descriptor has been set). The Transmit Successful (TI) is set each time a transmission ended successfully.

The Transmit AHB Error (TA) bit is set when an AHB error was encountered either when reading a descriptor, reading packet data or writing status to the descriptor. Any active transmissions are aborted and the transmitter is disabled. The transmitter can be activated again by setting the transmit enable register.

49.3.4 Setting up the data for transmission

The data to be transmitted should be placed beginning at the address pointed by the descriptor address field. The GRETH_GBIT does not add the Ethernet address and type fields so they must also be stored in the data buffer. The 4 B Ethernet CRC is automatically appended at the end of each packet.

GRIP

Apr 2024, Version 2024.1   665   Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Each descriptor will be sent as a single Ethernet packet. If the size field in a descriptor is greater than 1514 B, the packet will not be sent.

49.3.5 Scatter Gather I/O

A packet can be generated from data fetched from several descriptors. This is called Scatter Gather I/O. The More (MO) bit should be set to 1 to indicate that more descriptors should be used to generate the current packet. When data from the current descriptor has been read to the RAM the next descriptor is fetched and the new data is appended to the previous data. This continues until a descriptor with the MO bit set to 0 is encountered. The packet will then be transmitted.

Status is written immediately when data has been read to RAM for descriptors with MO set to 1. The status bits are always set to 0 since no transmission has occurred. The status bits will be written to the last descriptor for the packet (which had MO set to 0) when the transmission has finished.

No interrupts are generated for descriptors with MO set to 1 so the IE bit is don't care in this case.

The checksum offload control bits (explained in section 49.3.6) must be set to the same values for all descriptors used for a single packet.

49.3.6 Checksum offloading

Support is provided for correct checksum calculations in hardware for TCP and UDP over IPv4 for non-fragmented packets with data length less or equal to maximum transmission unit. The checksum calculations are enabled in each descriptor and applies only to that packet (when the MO bit is set all descriptors used for a single packet must have the checksum control bits set in the same way).

The IP Checksum bit (IC) enables IP header checksum calculations. If an IPv4 packet is detected when transmitting the packet associated with the descriptor the header checksum is calculated and inserted. If TCP Checksum (TC) is set the TCP checksum is calculated and inserted if an TCP/IPv4 packet is detected. Finally, if the UDP Checksum bit is set the UDP checksum is calculated and inserted if a UDP/IPv4 packet is detected. In the case of fragmented IP packets, incorrect checksums for TCP and UDP are inserted for the first fragment (which contains the TCP or UDP header).

49.4 Rx DMA interface

The receiver DMA interface is used for receiving data from an Ethernet network. The reception is done using descriptors located in memory.

49.4.1 Setting up descriptors

A single descriptor is shown in table 773 and 774. The address field points at the location where the received data should be stored. There are no restrictions on alignment. The GRETH_GBIT will never store more than 1518 B to the buffer (the tagged maximum frame size excluding CRC). The CRC field (4 B) is never stored to memory so it is not included in this number. If the interrupt enable (IE) bit is set, an interrupt will be generated when a packet has been received to this buffer (this requires that the receiver interrupt bit in the control register is also set). The interrupt will be generated regardless of whether the packet was received successfully or not.

The enable bit is set to indicate that the descriptor is valid which means it can be used by the to store a packet. After it is set the descriptor should not be touched until the EN bit has been cleared by the GRETH_GBIT.

+46 31 7758650 | frontgrade.com/gaisler

The rest of the fields in the descriptor are explained later in this section..

*Table 773.*GRETH_GBIT receive descriptor word 0 (address offset 0x0)

31 27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10 0
RESERVED	MC	IF	TR	TD	UR	UD	IR	ID	LE	OE	CE	FT	AE	IE	WR	EN	LENGTH

31: 27	RESERVED
26	Multicast address (MC) - The destination address of the packet was a multicast address (not broadcast).
25	IP fragment (IF) - Fragmented IP packet detected.
24	TCP error (TR) - TCP checksum error detected.
23	TCP detected (TD) - TCP packet detected.
22	UDP error (UR) - UDP checksum error detected.
21	UDP detected (UD) - UDP packet detected.
20	IP error (IR) - IP checksum error detected.
19	IP detected (ID) - IP packet detected.
18	Length error (LE) - The length/type field of the packet did not match the actual number of received bytes.
17	Overrun error (OE) - The frame was incorrectly received due to a FIFO overrun.
16	CRC error (CE) - A CRC error was detected in this frame.
15	Frame too long (FT) - A frame larger than the maximum size was received. The excessive part was truncated.
14	Alignment error (AE) - An odd number of nibbles were received.
13	Interrupt Enable (IE) - Enable Interrupts. An interrupt will be generated when a packet has been received to this descriptor provided that the receiver interrupt enable bit in the control register is set. The interrupt is generated regardless if the packet was received successfully or if it terminated with an error.
12	Wrap (WR) - Set to one to make the descriptor pointer wrap to zero after this descriptor has been used. If this bit is not set the pointer will increment by 8. The pointer automatically wraps to zero when the 1 kB boundary of the descriptor table is reached.
11	Enable (EN) - Set to one to enable the descriptor. Should always be set last of all the descriptor fields.
10: 0	LENGTH - The number of bytes received to this descriptor.

*Table 774.*GRETH_GBIT receive descriptor word 1 (address offset 0x4)

31 0
ADDRESS

31: 0	Address (ADDRESS) - Pointer to the buffer area from where the packet data will be loaded.

49.4.2 Starting reception

Enabling a descriptor is not enough to start reception. A pointer to the memory area holding the descriptors must first be set in the GRETH_GBIT. This is done in the receiver descriptor pointer register. The address must be aligned to a 1 kB boundary. Bits 31 to 10 hold the base address of descriptor area while bits 9 to 3 form a pointer to an individual descriptor. The first descriptor should be located at the base address and when it has been used by the GRETH_GBIT the pointer field is incremented by 8 to point at the next descriptor. The pointer will automatically wrap back to zero when the next 1 kB boundary has been reached (the descriptor at address offset 0x3F8 has been used). The WR bit in the descriptors can be set to make the pointer wrap back to zero before the 1 kB boundary.

The pointer field has also been made writable for maximum flexibility but care should be taken when writing to the descriptor pointer register. It should never be touched when reception is active.

The final step to activate reception is to set the receiver enable bit in the control register. This will make the GRETH_GBIT read the first descriptor and wait for an incoming packet.

GRIP
Apr 2024, Version 2024.1
667
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

49.4.3 Descriptor handling after reception

The GRETH indicates a completed reception by clearing the descriptor enable bit. The other control bits (WR, IE) are also cleared. The number of received bytes is shown in the length field. The parts of the Ethernet frame stored are the destination address, source address, type and data fields. Bits 24-14 in the first descriptor word are status bits indicating different receive errors. Bits 18 - 14 are zero after a reception without link layer errors. The status bits are described in table 773 (except the checksum offload bits which are also described in section 49.4.6).

Packets arriving that are smaller than the minimum Ethernet size of 64 B are not considered as a reception and are discarded. The current receive descriptor will be left untouched an used for the first packet arriving with an accepted size. The TS bit in the status register is set each time this event occurs.

If a packet is received with an address not accepted by the MAC, the IA status register bit will be set.

Packets larger than maximum size cause the FT bit in the receive descriptor to be set. The length field is not guaranteed to hold the correct value of received bytes. The counting stops after the word containing the last byte up to the maximum size limit has been written to memory.

The address word of the descriptor is never touched by the GRETH.

49.4.4 Reception with AHB errors

If an AHB error occurs during a descriptor read or data store, the Receiver AHB Error (RA) bit in the status register will be set and the receiver is disabled. The current reception is aborted. The receiver can be enabled again by setting the Receive Enable bit in the control register.

49.4.5 Accepted MAC addresses

In the default configuration the core receives packets with either the unicast address set in the MAC address register or the broadcast address. Multicast support can also be enabled and in that case a hash function is used to filter received multicast packets. A 64-bit register, which is accessible through the APB interface, determines which addresses should be received. Each address is mapped to one of the 64 bits using the hash function and if the bit is set to one the packet will be received. The address is mapped to the table by taking the 6 least significant bits of the 32-bit Ethernet crc calculated over the destination address of the MAC frame. A bit in the receive descriptor is set if a packet with a multicast address has been received to it.

49.4.6 Checksum offload

Support is provided for checksum calculations in hardware for TCP/UDP over IPv4. The checksum logic is always active and detects IPv4 packets with TCP or UDP payloads. If IPv4 is detected the ID bit is set, UD is set if an UDP payload is detected in the IP packet and TD is set if a TCP payload is detected in the IP packet (TD and UD are never set if an IPv4 packet is not detected). When one or more of these packet types is detected its corresponding checksum is calculated and if an error is detected the checksum error bit for that packet type is set. The error bits are never set if the corresponding packet type is not detected. The core does not support checksum calculations for TCP and UDP when the IP packet has been fragmented. This condition is indicated by the IF bit in the receiver descriptor and when set neither the TCP nor the UDP checksum error indications are valid.

49.5 MDIO Interface

The MDIO interface provides access to PHY configuration and status registers through a two-wire interface which is included in the MII interface. The GRETH_GBIT provides full support for the MDIO interface.

The MDIO interface can be used to access from 1 to 32 PHY containing 1 to 32 16-bit registers. A read transfer i set up by writing the PHY and register addresses to the MDIO Control register and set-

GRIP

Apr 2024, Version 2024.1

668

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

ting the read bit. This caused the Busy bit to be set and the operation is finished when the Busy bit is cleared. If the operation was successful the Linkfail bit is zero and the data field contains the read data. An unsuccessful operation is indicated by the Linkfail bit being set. The data field is undefined in this case.

A write operation is started by writing the 16-bit data, PHY address and register address to the MDIO Control register and setting the write bit. The operation is finished when the busy bit is cleared and it was successful if the Linkfail bit is zero.

49.5.1 PHY interrupts

The core also supports status change interrupts from the PHY. A level sensitive interrupt signal can be connected on the mdint input. The mdint_pol vhdl generic can be used to select the polarity. The PHY status change bit in the status register is set each time an event is detected in this signal. If the PHY status interrupt enable bit is set at the time of the event the core will also generate an interrupt on the AHB bus.

49.6 Ethernet Debug Communication Link (EDCL)

The EDCL provides access to an on-chip AHB bus through Ethernet. It uses the UDP, IP and ARP protocols together with a custom application layer protocol. The application layer protocol uses an ARQ algorithm to provide reliable AHB instruction transfers. Through this link, a read or write transfer can be generated to any address on the AHB bus. The EDCL is optional and must be enabled with a generic.

49.6.1 Operation

The EDCL receives packets in parallel with the MAC receive DMA channel. It uses a separate MAC address which is used for distinguishing EDCL packets from packets destined to the MAC DMA channel. The EDCL also has an IP address which is set through generics. Since ARP packets use the Ethernet broadcast address, the IP-address must be used in this case to distinguish between EDCL ARP packets and those that should go to the DMA-channel. Packets that are determined to be EDCL packets are not processed by the receive DMA channel.

When the packets are checked to be correct, the AHB operation is performed. The operation is performed with the same AHB master interface that the DMA-engines use. The replies are automatically sent by the EDCL transmitter when the operation is finished. It shares the Ethernet transmitter with the transmitter DMA-engine but has higher priority.

49.6.2 EDCL protocols

The EDCL accepts Ethernet frames containing IP or ARP data. ARP is handled according to the protocol specification with no exceptions.

IP packets carry the actual AHB commands. The EDCL expects an Ethernet frame containing IP, UDP and the EDCL specific application layer parts. Table 775 shows the IP packet required by the EDCL. The contents of the different protocol headers can be found in TCP/IP literature.

*Table 775.*The IP packet expected by the EDCL.

Ethernet Header	IP Header	UDP Header	2 B Offset	4 B Control word	4 B Address	Data 0 - 242 4B Words	Ethernet CRC

The following is required for successful communication with the EDCL: A correct destination MAC address as set by the generics, an Ethernet type field containing 0x0806 (ARP) or 0x0800 (IP). The IP-address is then compared with the value determined by the generics for a match. The IP-header checksum and identification fields are not checked. There are a few restrictions on the IP-header fields. The version must be four and the header size must be 5 B (no options). The protocol field must

GRIP

+46 31 7758650 | frontgrade.com/gaisler

always be 0x11 indicating a UDP packet. The length and checksum are the only IP fields changed for the reply.

The EDCL only provides one service at the moment and it is therefore not required to check the UDP port number. The reply will have the original source port number in both the source and destination fields. UDP checksum are not used and the checksum field is set to zero in the replies.

The UDP data field contains the EDCL application protocol fields. Table 776 shows the application protocol fields (data field excluded) in packets received by the EDCL. The 16-bit offset is used to align the rest of the application layer data to word boundaries in memory and can thus be set to any value. The R/W field determines whether a read (0) or a write(1) should be performed. The length

Table 776. The EDCL application layer fields in received frames.

16-bit Offset	14-bit Sequence number	1-bit R/W	10-bit Length	7-bit Unused

field contains the number of bytes to be read or written. If R/W is one the data field shown in Table 775 contains the data to be written. If R/W is zero the data field is empty in the received packets. Table 777 shows the application layer fields of the replies from the EDCL. The length field is always zero for replies to write requests. For read requests it contains the number of bytes of data contained in the data field.

Table 777. The EDCL application layer fields in transmitted frames.

16-bit Offset	14-bit sequence number	1-bit ACK/NAK	10-bit Length	7-bit Unused

The EDCL implements a Go-Back-N algorithm providing reliable transfers. The 14-bit sequence number in received packets are checked against an internal counter for a match. If they do not match, no operation is performed and the ACK/NAK field is set to 1 in the reply frame. The reply frame contains the internal counter value in the sequence number field. If the sequence number matches, the operation is performed, the internal counter is incremented, the internal counter value is stored in the sequence number field and the ACK/NAK field is set to 0 in the reply. The length field is always set to 0 for ACK/NAK=1 frames. The unused field is not checked and is copied to the reply. It can thus be set to hold for example some extra id bits if needed.

49.6.3 EDCL IP and Ethernet address settings

The default value of the EDCL IP and MAC addresses are set by `ipaddrh, ipaddrl, macaddrh and macaddrl` generics. The IP address and MAC address can later be changed by software. To allow several EDCL enabled GRETH controllers on the same sub-net, the 4 LSB bits of the IP and MAC address can optionally be set by an input signal. This is enabled by setting the `edcl` generic = 2, and driving the 4-bit LSB value on ethi.edcladdr.

49.6.4 EDCL buffer size

The EDCL has a dedicated internal buffer memory which stores the received packets during processing. The size of this buffer is configurable with a VHDL generic to be able to obtain a suitable compromise between throughput and resource utilization in the hardware. Table 778 lists the different buffer configurations. For each size the table shows how many concurrent packets the EDCL can handle, the maximum size of each packet including headers and the maximum size of the data payload.

Sending more packets before receiving a reply than specified for the selected buffer size will lead to dropped packets. The behavior is unspecified if sending larger packets than the maximum allowed.

Table 778. EDCL buffer sizes

Total buffer size (kB)	Number of packet buffers	Packet buffer size (B)	Maximum data payload (B)
1	4	256	200
2	4	512	456
4	8	512	456
8	8	1024	968
16	16	1024	968
32	32	1024	968
64	64	1024	968

49.7 Media Independent Interfaces

There are several interfaces defined between the MAC sublayer and the Physical layer. The GRETH_GBIT supports the Media Independent Interface (MII) and the Gigabit Media Independent Interface (GMII).

The GMII is used in 1000 Mbit mode and the MII in 10 and 100 Mbit. These interfaces are defined separately in the 802.3-2002 standard but in practice they share most of the signals. The GMII has 9 additional signals compared to the MII. Four data signals are added to the receiver and transmitter data interfaces respectively and a new transmit clock for the gigabit mode is also introduced.

To support lower speed where the operation and clock frequency of the core and phy remains unchanged i.e. running at 100Mb/s when the IP is configured for 1000Mb/s speed enable signals should be created to mimic the desired bit rate.

When operating at 100Mb/s, every byte of the MAC frame is repeated 10 clock periods to achieve the correct bit rate. The GRETH_GBIT core does not take care of this operation and enable signals with toggling frequency of the correct bit rate needs to be created.

When operating at 10Mb/s, every byte of the MAC frame is repeated 100 clock periods to achieve the correct bit rate. The GRETH_GBIT core does not take care of this operation and enable signals with toggling frequency of the correct bit rate needs to be created.

49.8   AXI support

The core is designed for an AMBA system but can be adapted for AXI using the AHBM2AXI adapter.

49.9   Registers

The core is programmed through registers mapped into APB address space.

*Table 780.*GRETH_GBIT registers

APB address offset	Register
0x00	Control register
0x04	Status/Interrupt-source register
0x08	MAC Address MSB
0x0C	MAC Address LSB
0x10	MDIO Control/Status
0x14	Transmit descriptor pointer
0x18	Receiver descriptor pointer
0x1C	EDCL IP
0x20	Hash table msb
0x24	Hash table lsb
0x28	EDCL MAC address MSB
0x2C	EDCL MAC address LSB
0x10000 - 0x107FC	Transmit RAM buffer debug access
0x20000 - 0x207FC	Receiver RAM buffer debug access
0x30000 - 0x3FFFC	EDCL buffer debug access

49.9.1 Control register

*Table 781.*0x00 - CTRL - GRETH control register

31	30	28	27	26	25	24	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
EA	BS		GA	MA	MC		RESERVED	ED	RD	DD	ME	PI	BM	GB	SP	RS	PM	FD	RI	TI	RE	TE
*	*		*	*	*		0	*	0	0	0	0	0	0	0	0	0	0	0	0	0	0
r	r		r	r	r		r	rw	rw	rw	rw	rw	rw	rw	rw	wc	rw	rw	rw	rw	rw	rw

31	EDCL available (EA) - Set to one if the EDCL is available.
30: 28	EDCL buffer size (BS) - Shows the amount of memory used for EDCL buffers. 0 = 1 kB, 1 = 2 kB, ..., 6 = 64 kB.
27	Gigabit MAC available (GA) - This bit always reads as a 1 and indicates that the MAC has 1000 Mbit capability.
26	Mdio interrupts enabled (ME) - Set to one when the core supports mdio interrupts. Read only.
25	Multicast available (MC) - Set to one when the core supports multicast address reception. Read only.
24: 15	RESERVED
14	EDCL Disable(ED) - Set to one to disablethe EDCL and zero to enable it. Reset value taken from the ethi.edcldisable signal. Only available if the EDCL hardware is present in the core.
13	RAM debug enable (RD) - Set to one to enable the RAM debug mode. Reset value: '0'. Only available if the VHDL generic ramdebug is nonzero.
12	Disable duplex detection (DD) - Disable the EDCL speed/duplex detection FSM. If the FSM cannot complete the detection the MDIO interface will be locked in busy mode. If software needs to access the MDIO the FSM can be disabled here and as soon as the MDIO busy bit is 0 the interface is available. Note that the FSM cannot be reenabled again.
11	Multicast enable (ME) - Enable reception of multicast addresses. Reset value: '0'.
10	PHY status change interrupt enable (PI) - Enables interrupts for detected PHY status changes.
9	Burstmode (BM) - When set to 1, transmissions use burstmode in 1000 Mbit Half-duplex mode (GB=1, FD = 0). When 0 in this speed mode normal transmissions are always used with extension inserted. Operation is undefined when set to 1 in other speed modes. Reset value: '0'.
8	Gigabit (GB) - 1 sets the current speed mode to 1000 Mbit and when set to 0, the speed mode is selected with bit 7 (SP). Reset value: '0'.
7	Speed (SP) - Sets the current speed mode. 0 = 10 Mbit, 1 = 100 Mbit. Must not be set to 1 at the same time as bit 8 (GB). Reset valuie: '0'.
6	Reset (RS) - A one written to this bit resets the GRETH_GBIT core. Self clearing. No other accesses should be done .to the slave interface other than polling this bit until it is cleared.
5	Promiscuous mode (PM) - If set, the GRETH_GBIT operates in promiscuous mode which means it will receive all packets regardless of the destination address. Reset value: '0'.
4	Full duplex (FD) - If set, the GRETH_GBIT operates in full-duplex mode otherwise it operates in half-duplex. Reset value: '0'.
3	Receiver interrupt (RI) - Enable Receiver Interrupts. An interrupt will be generated each time a packet is received when this bit is set. The interrupt is generated regardless if the packet was received successfully or if it terminated with an error. Reset value: '0'.
2	Transmitter interrupt (TI) - Enable Transmitter Interrupts. An interrupt will be generated each time a packet is transmitted when this bit is set. The interrupt is generated regardless if the packet was transmitted successfully or if it terminated with an error. Reset value: '0'.
1	Receive enable (RE) - Should be written with a one each time new descriptors are enabled. As long as this bit is one the GRETH_GBIT will read new descriptors and as soon as it encounters a disabled descriptor it will stop until RE is set again. This bit should be written with a one after the new descriptors have been enabled. Reset value: '0'.
0	Transmit enable (TE) - Should be written with a one each time new descriptors are enabled. As long as this bit is one the GRETH_GBIT will read new descriptors and as soon as it encounters a disabled descriptor it will stop until TE is set again. This bit should be written with a one after the new descriptors have been enabled. Reset value: '0'.

49.10 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x01D. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

49.11 Implementation

49.11.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers if the GRLIB config package setting *grlib_async_reset_enable* is set.

49.11.2 Internal reset and reset via EDCL link

It is recommended to only use the internal reset bit in the control register for GRLIB releases 2018.2 and later. For earlier releases of GRLIB it is recommend to always use the input signal RST.

49.11.3 Endianness

The core changes endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). Changing *grlib_little_endian* controls TBD

49.12 Configuration options

Table 793 shows the configuration options of the core (VHDL generics).*) Not all addresses are allowed and most NICs and protocol implementations will discard frames with illegal addresses silently. Consult network literature if unsure about the addresses.

*Table 793.*Configuration options

Generic	Function	Allowed range	Default
hindex	AHB master index.	0 - NAHBMST-1	0
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	Addr field of the APB bar.	0 - 16#FFF#	0
pmask	Mask field of the APB bar.	0 - 16#FFF#	16#FFF#
pirq	Interrupt line used by the GRETH.	0 - NAHBIRQ-1	0
memtech	Memory technology used for the FIFOs.	0 - NTECH	inferred
ifg_gap	Number of ethernet clock cycles used for one interframe gap. Default value as required by the standard. Do not change unless you know what your doing.	1 - 255	24
attempt_limit	Maximum number of transmission attempts for one packet. Default value as required by the standard.	1 - 255	16
backoff_limit	Limit on the backoff size of the backoff time. Default value as required by the standard. Sets the number of bits used for the random value. Do not change unless you know what your doing.	1 - 10	10
slot_time	Number of ethernet clock cycles used for one slot- time. Default value as required by the ethernet standard. Do not change unless you know what you are doing.	1 - 255	128
mdcscaler	Sets the divisor value use to generate the mdio clock (mdc). The mdc frequency will be clk/(2*(mdcscaler+1)).	0 - 255	25

*Table 793.*Configuration options

Generic	Function	Allowed range	Default
nsync	Number of synchronization registers used.	1 - 2	2
edcl	Enable EDCL. 0 = disabled. 1 = enabled. 2 = enabled and 4-bit LSB of IP and ethernet MAC address programmed by ethi.edcladdr, 3=in addition to features for value 2 the reset value for the EDCL disable bit is taken from the ethi.edcldisable signal instead of being hardcoded to 0. 4=in addition to features for value 2 and 3 the an option is given to disable the EDCL via external input signal.	0 - 4	0
edclbufsz	Select the size of the EDCL buffer in kB.	1 - 64	1
burstlength	Sets the maximum burstlength used during DMA	4 - 128	32
macaddrh	Sets the upper 24 bits of the EDCL MAC address. Not all addresses are allowed and most NICs and protocol implementations will discard frames with illegal addresses silently. Consult network literature if unsure about the addresses.	0 - 16#FFFFFF#	16#00005E#
macaddrl	Sets the lower 24 bits of the EDCL MAC address. Not all addresses are allowed and most NICs and protocol implementations will discard frames with illegal addresses silently. Consult network literature if unsure about the addresses.	0 - 16#FFFFFF#	16#000000#
ipaddrh	Sets the upper 16 bits of the EDCL IP address reset value.	0 - 16#FFFF#	16#C0A8#
ipaddrl	Sets the lower 16 bits of the EDCL IP address reset value.	0 - 16#FFFF#	16#0035#
phyrstadr	Sets the reset value of the PHY address field in the MDIO register. When set to 32, the address is taken from the ethi.phyrstaddr signal.	0 - 32	0
sim	Set to 1 for simulations and 0 for synthesis. 1 selects a faster mdc clock to speed up simulations.	0 - 1	0
mdint_pol	Selects polarity for level sensitive PHY interrupt line. 0 = active low, 1 = active high	0 - 1	0
enable_mdint	Enables mdio interrupts.	0 - 1	0
multicast	Enables multicast support.	0 - 1	0
ramdebug	Enables debug access to the core's RAM blocks through the APB interface. 1=enables access to the receiver and transmitter RAM buffers, 2=enables access to the EDCL buffers in addition to the functionality of value 1. Setting this generic to 2 will have no effect if the edcl generic is 0.	0 - 2	0
ehindex	AHB master index for the separate EDCL master interface. Only used if edclsepahb is 1.	0 - NAHBMST-1	0
edclsepahb	Enables separate EDCL AHB master interface. A signal determines if the separate interface or the common interface is used. Only available in the GRETH_GBIT_MB version of the core.	0 - 1	0
mdiohold	Set output hold time for MDIO in number of AHB cycles. Should be 10 ns or more.	1 - 30	1
gmiimode	Enable the use of receive and transmit valid signals to enter data to/from the PHY at the correct rate.	0-1	0
ft	Enable fault tolerance for receive and transmit buffers. 0 - no fault tolerance, 1 - Parity DMR, 2 - TMR.	0-2	0
edclft	Enable fault tolerance for EDCL buffers. 0 - no fault tolerance, 1 - Parity DMR, 2 - TMR. This generic only has effect if generic edcl is non-zero.	0-2	0

50   GRFIFO - FIFO Interface

50.1   Overview

The FIFO interface is assumed to operate in an AMBA bus system where both the AMBA AHB bus and the APB bus are present. The AMBA APB bus is used for configuration, control and status handling. The AMBA AHB bus is used for retrieving and storing FIFO data in memory external to the FIFO interface. This memory can be located on-chip or external to the chip.

The FIFO interface supports transmission and reception of blocks of data by use of circular buffers located in memory external to the core. Separate transmit and receive buffers are assumed. Reception and transmission of data can be ongoing simultaneously.

After a data transfer has been set up via the AMBA APB interface, the DMA controller initiates a burst of read accesses on the AMBA AHB bus to fetch data from memory that are performed by the AHB master. The data are then written to the external FIFO. When a programmable amount of data has been transmitted, the DMA controller issues an interrupt.

After reception has been set up via the AMBA APB interface, data are read from the external FIFO. To store data to memory, the DMA controller initiates a burst of write accesses on the AMBA AHB bus that are performed by the AHB master. When a programmable amount of data has been received, the DMA controller issues an interrupt.

50.1.1 Function

The core implements the following functions:

- data transmission to external FIFO
- circular transmit buffer
- direct memory access for transmitter
- data reception from external FIFO
- circular receive buffer for receiver
- direct memory access
- automatic 8- and 16-bit data width conversion
- general purpose input output

50.1.2 Transmission

Data to be transferred via the FIFO interface are fetched via the AMBA AHB master interface from on-chip or off-chip memory. This is performed by means of direct memory access (DMA), implementing a circular transmit buffer in the memory. The transmit channel is programmable via the AMBA APB slave interface, which is also used for the monitoring of the FIFO and DMA status.

The transmit channel is programmed in terms of a base address and size of the circular transmit buffer. The outgoing data are stored in the circular transmit buffer by the system. A write address pointer register is then set by the system to indicate the last byte written to the circular transmit buffer. An interrupt address pointer register is used by the system to specify a location in the circular transmit buffer from which a data read should cause an interrupt to be generated.

The FIFO interface automatically indicates with a read address pointer register the location of the last fetched byte from the circular transmit buffer. Read accesses are performed as incremental bursts, except when close to the location specified by the interrupt pointer register at which point the last bytes might be fetched by means of single accesses.

Data transferred via the FIFO interface can be either 8- or 16-bit wide. The handling of the transmit channel is however the same. All transfers performed by the AMBA AHB master are 32-bit word based. No byte or half-word transfers are performed.

To handle the 8- and 16-bit FIFO data width, a 32-bit read access might carry less than four valid bytes. In such a case, the remaining bytes are ignored. When additional data are available in the circular transmit buffer, the previously fetched bytes will be re-read together with the newly written bytes to form the 32-bit data. Only the new bytes will be transmitted to the FIFO, not to transmit the same byte more than once. The aforementioned write address pointer indicates what bytes are valid.

An interrupt is generated when the circular transmit buffer is empty. The status of the external FIFO is observed via the AMBA APB slave interface, indicating Full Flag and Half-Full Flag.

50.1.3 Reception

Data received via the FIFO interface are stored via the AMBA AHB master interface to on-chip or off-chip memory. This is performed by means of direct memory access (DMA), implementing a circular receive buffer in the memory. The receive channel is programmable via the AMBA APB slave interface, which is also used for the monitoring of the FIFO and DMA status.

The receive channel is programmed in terms of a base address and size of the circular receive buffer. The incoming data are stored in the circular receive buffer. The interface automatically indicates with a write address pointer register the location of the last stored byte. A read address pointer register is used by the system to indicate the last byte read from the circular receive buffer. An interrupt address pointer register is used by the system to specify a location in the circular receive buffer to which a data write should cause an interrupt to be generated.

GRIP

Apr 2024, Version 2024.1

685

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

Write accesses are performed as incremental bursts, except when close to the location specified by the interrupt pointer register at which point the last bytes might be stored by means of single accesses.

Data transferred via the FIFO interface can be either 8- or 16-bit wide. The handling of the receive channel is however the same. All transfers performed by the AMBA AHB master are 32-bit word based. No byte or half-word transfers are performed.

To handle the 8- and 16-bit FIFO data width, a 32-bit write access might carry less than four valid bytes. In such a case, the remaining bytes will all be zero. When additional data are received from the FIFO interface, the previously stored bytes will be re-written together with the newly received bytes to form the 32-bit data. In this way, the previously written bytes are never overwritten. The aforementioned write address pointer indicates what bytes are valid.

An interrupt is generated when the circular receive buffer is full. If more FIFO data are available, they will not be moved to the circular receive buffer. The status of the external FIFO is observed via the AMBA APB slave interface, indicating Empty Flag and Half-Full Flag.

50.1.4 General purpose input output

Data input and output signals unused by the FIFO interface can be used as general purpose input output, providing 0, 8 or 16 individually programmable channels.

50.1.5 Interfaces

The core provides the following external and internal interfaces:

- FIFO interface
- AMBA AHB master interface, with sideband signals as per [GLRIB] including:
- cachability information
- interrupt bus
- configuration information
- diagnostic information
- AMBA APB slave interface, with sideband signals as per [GLRIB] including:
- interrupt bus
- configuration information
- diagnostic information

The interface is intended to be used with the following FIFO devices from ATMEL:

Name:Type:

M67204H4K x 9 FIFOESA/SCC 9301/049, SMD/5962-89568

M67206H16K x 9 FIFOESA/SCC 9301/048, SMD/5962-93177

M672061H16K x 9 FIFO ESA/SCC 9301/048, SMD/5962-93177

50.2   Interface

The external interface supports one or more FIFO devices for data output (transmission) and/or one or more FIFO devices for data input (reception). The external interface supports FIFO devices with 8- and 16-bit data width. Note that one device is used when 8-bit and two devices are used when 16-bit data width is needed. The data width is programmable. Note that this is performed commonly for both directions.

GRIP

Apr 2024, Version 2024.1

686

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The external interface supports one parity bit over every 8 data bits. Note that there can be up to two parity bits in either direction. The parity is programmable in terms of odd or even parity. Note that odd parity is defined as an odd number of logical ones in the data bits and parity bit. Note that even parity is defined as an even number of logical ones in the data bits and parity bit. Parity is generated for write accesses to the external FIFO devices. Parity is checked for read accesses from the external FIFO devices and a parity failure results in an internal interrupt.

The external interface provides a Write Enable output signal. The external interface provides a Read Enable output signal. The timing of the access towards the FIFO devices is programmable in terms of wait states based on system clock periods.

The external interface provides an Empty Flag input signal, which is used for flow-control during the reading of data from the external FIFO, not reading any data while the external FIFO is empty. Note that the Empty Flag is sampled at the end of the read access to determine if the FIFO is empty. To determine when the FIFO is not empty, the Empty Flag is re-synchronized with Clk.

The external interface provides a Full Flag input signal, which is used for flow-control during the writing of data to the external FIFO, not writing any data while the external FIFO is full. Note that the Full Flag is sampled at the end of the write access to determine if the FIFO is full. To determine when the FIFO is not full, the Full Flag is re-synchronized with Clk.

The external interface provides a Half-Full Flag input signal, which is used as status information only.

The data input and output signals are possible to use as general purpose input output channels. This need is only realized when the data signals are not used by the FIFO interface. Each general purpose input output channel is individually programmed as input or output. The default reset configuration for each general purpose input output channel is as input. The default reset value each general purpose input output channel is logical zero. Note that protection toward spurious pulse commands during power up shall be mitigated as far as possible by means of I/O cell selection from the target technology.

50.3   Waveforms

The following figures show read and write accesses to the FIFO with 0 and 4 wait states, respectively.

50.4 Transmission

The transmit channel is defined by the following parameters:

- base address
- buffer size
- write pointer
- read pointer

The transmit channel can be enabled or disabled.

50.4.1 Circular buffer

The transmit channel operates on a circular buffer located in memory external to the FIFO controller. The circular buffer can also be used as a straight buffer. The buffer memory is accessed via the AMBA AHB master interface.

The size of the buffer is defined by the FifoTxSIZE.SIZE field, specifying the number of 64 byte blocks that fit in the buffer.

E.g. FifoTxSIZE.SIZE = 1 means 64 bytes fit in the buffer.

Note however that it is not possible to fill the buffer completely, leaving at least one word in the buffer empty. This is to simplify wrap-around condition checking.

E.g. FifoTxSIZE.SIZE = 1 means that 60 bytes fit in the buffer at any given time.

50.4.2 Write and read pointers

The write pointer (FifoTxWR.WRITE) indicates the position+1 of the last byte written to the buffer. The write pointer operates on number of bytes, not on absolute or relative addresses.

The read pointer (FifoTxRD.READ) indicates the position+1 of the last byte read from the buffer. The read pointer operates on number of bytes, not on absolute or relative addresses.

The difference between the write and the read pointers is the number of bytes available in the buffer for transmission. The difference is calculated using the buffer size, specified by the FifoTxSIZE.SIZE field, taking wrap around effects of the circular buffer into account.

Examples:

- There are 2 bytes available for transmit when FifoTxSIZE.SIZE=1, FifoTxWR.WRITE=2 and FifoTxRD.READ=0.
- There are 2 bytes available for transmit when FifoTxSIZE.SIZE=1, FifoTxWR.WRITE =0 and FifoTxRD.READ =62.
- There are 2 bytes available for transmit when FifoTxSIZE.SIZE=1, FifoTxWR.WRITE =1 and FifoTxRD.READ =63.
- There are 2 bytes available for transmit when FifoTxSIZE.SIZE=1, FifoTxWR.WRITE =5 and FifoTxRD.READ =3.

When a byte has been successfully written to the FIFO, the read pointer (FifoTxRD.READ) is automatically incremented, taking wrap around effects of the circular buffer into account. Whenever the write pointer FifoTxWR.WRITE and read pointer FifoTxRD.READ are equal, there are no bytes available for transmission.

50.4.3 Location

The location of the circular buffer is defined by a base address (FifoTxADDR.ADDR), which is an absolute address. The location of a circular buffer is aligned on a 1kbyte address boundary.

GRIP
Apr 2024, Version 2024.1

690

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

50.4.4 Transmission procedure

When the channel is enabled (FifoTxCTRL.ENABLE=1), as soon as there is a difference between the write and read pointer, a transmission will be started. Note that the channel should not be enabled if a potential difference between the write and read pointers could be created, to avoid the data transmission to start prematurely.

A data transmission will begin with a fetch of the data from the circular buffer to a local buffer in the FIFO controller. After a successful fetch, a write access will be performed to the FIFO.

The read pointer (FifoTxRD.READ) is automatically incremented after a successful transmission, taking wrap around effects of the circular buffer into account. If there is at least one byte available in the circular buffer, a new fetch will be performed.

If the write and read pointers are equal, no more prefetches and fetches will be performed, and transmission will stop.

Interrupts are provided to aid the user during transmission, as described in detail later in this section. The main interrupts are the TxError, TxEmpty and TxIrq which are issued on the unsuccessful transmission of a byte due to an error condition on the AMBA bus, when all bytes have been transmitted successfully and when a predefined number of bytes have been transmitted successfully.

Note that 32-bit wide read accesses past the address of the last byte or halfword available for transmission can be performed as part of a burst operation, although no read accesses are made beyond the circular buffer size.

All accesses to the AMBA AHB bus are performed as two consecutive 32-bit accesses in a burst, or as a single 32-bit access in case of an AMBA AHB bus error.

50.4.5 Straight buffer

It is possible to use the circular buffer as a straight buffer, with a higher granularity than the 1kbyte address boundary limited by the base address (FifoTxADDR.ADDR) field.

While the channel is disabled, the read pointer (FifoTxRD.READ) can be changed to an arbitrary value pointing to the first byte to be transmitted, and the write pointer (FifoTxWR.WRITE) can be changed to an arbitrary value.

When the channel is enabled, the transmission will start from the read pointer and continue to the write pointer.

50.4.6 AMBA AHB error

An AHB error response occurring on the AMBA AHB bus while data is being fetched will result in a TxError interrupt.

If the FifoCONF.ABORT bit is set to 0b, the channel causing the AHB error will re-try to read the data being fetched from memory till successful.

If the FifoCONF.ABORT bit is set to 1b, the channel causing the AHB error will be disabled (FifoTxCTRL.ENABLE is cleared automatically to 0 b). The read pointer can be used to determine which data caused the AHB error. The interface will not start any new write accesses to the FIFO. Any ongoing FIFO access will be completed and the FifoTxSTAT.TxOnGoing bit will be cleared. When the channel is re-enabled, the fetch and transmission of data will resume at the position where it was disabled, without losing any data.

50.4.7 Enable and disable

When an enabled transmit channel is disabled (FifoTxCTRL.ENABLE=0b), the interface will not start any new read accesses to the circular buffer by means of DMA over the AMBA AHB bus. No new write accesses to the FIFO will be started. Any ongoing FIFO access will be completed. If the

GRIP
Apr 2024, Version 2024.1
691
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

data is written successfully, the read pointer (FifoTxRD.READ) is automatically incremented and the FifoTxSTAT.TxOnGoing bit will be cleared. Any associated interrupts will be generated.

Any other fetched or pre-fetched data from the circular buffer which is temporarily stored in the local buffer will be discarded, and will be fetched again when the transmit channel is re-enabled.

The progress of the any ongoing access can be observed via the FifoTxSTAT.TxOnGoing bit. The FifoTxSTAT.TxOnGoing must be 0b before the channel can be re-configured safely (i.e. changing address, size or read/write pointers). It is also possible to wait for the TxEmpty interrupt described hereafter.

The channel can be re-enabled again without the need to re-configure the address, size and pointers. No data transmission is started while the channel is not enabled.

50.4.8 Interrupts

During transmission several interrupts can be generated:

- TxEmpty: Successful transmission of all data in buffer
- TxIrq: Successful transmission of a predefined number of data
- TxError: AHB access error during transmission

The TxEmpty and TxIrq interrupts are only generated as the result of a successful data transmission, after the FifoTxRD.READ pointer has been incremented.

50.5 Reception

The receive channel is defined by the following parameters:

- base address
- buffer size
- write pointer
- read pointer

The receive channel can be enabled or disabled.

50.5.1 Circular buffer

The receive channel operates on a circular buffer located in memory external to the FIFO controller. The circular buffer can also be used as a straight buffer. The buffer memory is accessed via the AMBA AHB master interface.

The size of the buffer is defined by the FifoRxSIZE.SIZE field, specifying the number 64 byte blocks that fit in the buffer.

E.g. FifoRxSIZE.SIZE=1 means 64 bytes fit in the buffer.

Note however that it is not possible for the hardware to fill the buffer completely, leaving at least two words in the buffer empty. This is to simplify wrap-around condition checking.

E.g. FifoRxSIZE.SIZE=1 means that 56 bytes fit in the buffer at any given time.

50.5.2 Write and read pointers

The write pointer (FifoRxWR.WRITE) indicates the position+1 of the last byte written to the buffer. The write pointer operates on number of bytes, not on absolute or relative addresses.

The read pointer (FifoRxRD.READ) indicates the position+1 of the last byte read from the buffer. The read pointer operates on number of bytes, not on absolute or relative addresses.

GRIP
Apr 2024, Version 2024.1

692

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The difference between the write and the read pointers is the number of bytes available in the buffer for reception. The difference is calculated using the buffer size, specified by the FifoRxSIZE.SIZE field, taking wrap around effects of the circular buffer into account.

Examples:

- There are 2 bytes available for read-out when FifoRxSIZE.SIZE=1, FifoRxWR.WRITE =2 and FifoRxRD.READ=0.

- There are 2 bytes available for read-out when FifoRxSIZE.SIZE=1, FifoRxWR.WRITE =0 and FifoRxRD.READ=62.

- There are 2 bytes available for read-out when FifoRxSIZE.SIZE=1, FifoRxWR.WRITE =1 and FifoRxRD.READ=63.

- There are 2 bytes available for read-out when FifoRxSIZE.SIZE=1, FifoRxWR.WRITE =5 and FifoRxRD.READ=3.

When a byte has been successfully received and stored, the write pointer (FifoRxWR.WRITE) is automatically incremented, taking wrap around effects of the circular buffer into account.

50.5.3 Location

The location of the circular buffer is defined by a base address (FifoRxADDR.ADDR), which is an absolute address. The location of a circular buffer is aligned on a 1kbyte address boundary.

50.5.4 Reception procedure

When the channel is enabled (FifoRxCTRL.ENABLE=1), and there is space available for data in the circular buffer (as defined by the write and read pointer), a read access will be started towards the FIFO, and then an AMBA AHB store access will be started. The received data will be temporarily stored in a local store-buffer in the FIFO controller. Note that the channel should not be enabled until the write and read pointers are configured, to avoid the data reception to start prematurely

After a datum has been successfully stored the FIFO controller is ready to receive new data. The write pointer (FifoRxWR.WRITE) is automatically incremented, taking wrap around effects of the circular buffer into account.

Interrupts are provided to aid the user during reception, as described in detail later in this section. The main interrupts are the RxError, RxParity, RxFull and RxIrq which are issued on the unsuccessful reception of data due to an AMBA AHB error or parity error, when the buffer has been successfully filled and when a predefined number of data have been received successfully.

All accesses to the AMBA AHB bus are performed as two consecutive 32-bit accesses in a burst, or as a single 32-bit access in case of an AMBA AHB bus error.

50.5.5 Straight buffer

It is possible to use the circular buffer as a straight buffer, with a higher granularity than the 1kbyte address boundary limited by the base address (FifoRxADDR.ADDR) field.

While the channel is disabled, the write pointer (FifoRxWR.WRITE) can be changed to an arbitrary value pointing to the first data to be received, and the read pointer (FifoRxRD.READ) can be changed to an arbitrary value.

When the channel is enabled, the reception will start from the write pointer and continue to the read pointer.

+46 31 7758650 | frontgrade.com/gaisler

50.5.6   AMBA AHB error

An AHB error response occurring on the AMBA AHB bus while data is being stored will result in an RxError interrupt.

If the FifoCONF.ABORT bit is set to 0b, the channel causing the AHB error will retry to store the received data till successful

If the FifoCONF.ABORT bit is set to 1b, the channel causing the AHB error will be disabled (FifoRxCTRL.ENABLE is cleared automatically to 0b). The write pointer can be used to determine which address caused the AHB error. The interface will not start any new read accesses to the FIFO. Any ongoing FIFO access will be completed and the data will be stored in the local receive buffer. The FifoRxSTAT.ONGOING bit will be cleared. When the receive channel is re-enabled, the reception and storage of data will resume at the position where it was disabled, without losing any data.

50.5.7   Enable and disable

When an enabled receive channel is disabled (FifoRxCTRL.ENABLE=0b), any ongoing data storage on the AHB bus will not be aborted, and no new storage will be started. If the data is stored successfully, the write pointer (FifoRxWR.WRITE) is automatically incremented. Any associated interrupts will be generated. The interface will not start any new read accesses to the FIFO. Any ongoing FIFO access will be completed.

The channel can be re-enabled again without the need to re-configure the address, size and pointers. No data reception is performed while the channel is not enabled.

The progress of the any ongoing access can be observed via the FifoRxSTAT.ONGOING bit. Note that the there might be data left in the local store-buffer in the FIFO controller. This can be observed via the FifoRxSTAT.RxByteCntr field. The data will not be lost if the channel is not reconfigured before re-enabled.

To empty this data from the local store-buffer to the external memory, the channel needs to be ren-abled. By setting the FifoRxIRQ.IRQ field to match the value of the FifoRxWR.WRITE field plus the value of the FifoRxSTAT.RxByteCntr field, an emptying to the external memory is forced of any data temporarily stored in the local store-buffer. Note however that additional data could be received in the local store-buffer when the channel is re-enabled.

The FifoRxSTAT.ONGOING must be 0b before the channel can be re-configured safely (i.e. changing address, size or read/write pointers).

50.5.8   Interrupts

During reception several interrupts can be generated:

- RxFull: Successful reception of all data possible to store in buffer
- RxIrq: Successful reception of a predefined number of data
- RxError: AHB access error during reception
- RxParity: Parity error during reception

The RxFull and RxIrq interrupts are only generated as the result of a successful data reception, after the FifoRxWR.WRITE pointer has been incremented.

50.6   Operation

50.6.1   Global reset and enable

When the FifoCTRL.RESET bit is set to 1b, a reset of the core is performed. The reset clears all the register fields to their default values. Any ongoing data transfers will be aborted.

50.6.2 Interrupt

Seven interrupts are implemented by the FIFO interface:

Index:	Name:Description:
0	TxIrq Successful transmission of block of data
1	TxEmptyCircular transmission buffer empty
2	TxErrorAMBA AHB access error during transmission
3	RxIrq Successful reception of block of data
4	RxFullCircular reception buffer full
5	RxErrorAMBA AHB access error during reception
6	RxParityParity error during reception

The interrupts are configured by means of the *pirq* VHDL generic. The setting of the *singleirq* VHDL generic results in a single interrupt output, instead of multiple, configured by the means of the *pirq* VHDL generic, and enables the read and write of the interrupt registers. When multiple interrupts are implemented, each interrupt is generated as a one system clock period long active high output pulse. When a single interrupt is implemented, it is generated as an active high level output.

50.6.3 Reset

After a reset the values of the output signals are as follows:

Signal:	Value after reset:
FIFOO.WEn	de-asserted
FIFOO.REn	de-asserted

50.6.4 Asynchronous interfaces

The following input signals are synchronized to Clk:

- FIFOI.EFn
- FIFOI.FFn
- FIFOI.HFn

		11b = spare/none
3:	PARITY	Parity type:
		0b = even
		1b = odd
2-0:	WS	Number of wait states, 0 to 7

Note that the transmit or receive channel active during the AMBA AHB error is disabled if the ABORT bit is set to 1b. Note that all accesses on the affected channel will be disabled after an AMBA AHB error occurs while the ABORT bit is set to 1b. The accesses will be disabled until the affected channel is re-enabled setting the FifoTxCTRL.ENABLE or FifoRxCTRL.ENABLE bit, respectively.

Note that a wait states corresponds to an additional clock cycle added to the period when the read or write strobe is asserted. The default asserted width is one clock period for the read or write strobe when WS=0. Note that an idle gap of one clock cycle is always inserted between read and write accesses, with neither the read nor the write strobe being asserted.

Note that an additional gap of one clock cycle with the read or write strobe de-asserted is inserted between two accesses when WS is equal to or larger than 100b.

50.7.2 Status Register [FifoSTAT]

Note that in the case of an AHB bus error during an access while fetching transmit data, and the Fifo-Conf.ABORT bit is 1b, then the ENABLE bit will be reset automatically.

At the time the ENABLE is cleared to 0b, any ongoing data writes to the FIFO are not aborted.

50.7.5 Transmit Channel Status Register [FifoTxSTAT]

Table 801. Transmit Channel Status Register

32		7	6	5	4	3	2	1	0
			TxOnGoing	R	TxIrq	TxEmpty	TxError	FF	HF

6: TxOnGoing   Access ongoing
4: TxIrq   Successful transmission of block of data. cleared on read
3: TxEmpty   Transmission buffer has been emptied. cleared on read
2: TxError   AMB AHB access error during transmission. cleared on read
1: FF   FIFO Full Flag
0: HF   FIFO Half-Full Flag

50.7.6 Transmit Channel Address Register [FifoTxADDR]

Table 802. Transmit Channel Address Register

31	10	9	0
ADDR			
0			
rw			

31-10: ADDR   Base address for circular buffer

50.7.7 Transmit Channel Size Register [FifoTxSIZE]

Table 803. Transmit Channel Size Register

31	17	16	6	5	0
		SIZE			
		0			
		rw			

16-6: SIZE   Size of circular buffer, in number of 64 bytes block

Valid SIZE values are 0, and between 1 and 1024. Note that the resulting behavior of invalid SIZE values is undefined.

Note that only SIZE*64-4 bytes can be stored simultaneously in the buffer. This is to simplify wrap-around condition checking.

The width of the SIZE field is configurable indirectly by means of the VHDL generic (ptrwidth) which sets the width of the read and write data pointers. In the above example VHDL generic ptrwidth=16, making the SIZE field 11 bits wide.

50.7.8 Transmit Channel Write Register [FifoTxWR]

*Table 804.*Transmit Channel Write Register

31	16	15	0
		WRITE	
		0	
		rw	

15-0:   WRITE   Pointer to last written byte + 1

The WRITE field is written to in order to initiate a transfer, indicating the position +1 of the last byte to transmit.

Note that it is not possible to fill the buffer. There is always one word position in buffer unused. Software is responsible for not over-writing the buffer on wrap around (i.e. setting WRITE=READ).

Note that the LSB may be ignored for 16-bit wide FIFO devices.

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

50.7.9 Transmit Channel Read Register [FifoTxRD]

*Table 805.*Transmit Channel Read Register

31	16	15	0
		READ	
		0	
		rw	

15-0:   READ   Pointer to last read byte + 1

The READ field is written to automatically when a transfer has been completed successfully, indicating the position +1 of the last byte transmitted.

Note that the READ field can be used to read out the progress of a transfer.

Note that the READ field can be written to in order to set up the starting point of a transfer. This should only be done while the transmit channel is not enabled.

Note that the READ field can be automatically incremented even if the transmit channel has been disabled, since the last requested transfer is not aborted until completed.

Note that the LSB may be ignored for 16-bit wide FIFO devices.

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

50.7.10 Transmit Channel Interrupt Register [FifoTxIRQ]

*Table 806.*Transmit Channel Interrupt Register

31	16	15	0
		IRQ	
		0	
		rw	

15-0:   IRQ   Pointer+1 to a byte address from which the read of transmitted data shall result in an interrupt

Note that this indicates that a programmed amount of data has been sent. Note that the LSB may be ignored for 16-bit wide FIFO devices.

The field is implemented as relative to the buffer base address (scaled with the SIZE field).

                                     0b = input = high impedance,
                                     1b = output = driven

Note that only the part of FIFOO.Dout[15:0] not used by the FIFO can be used as general purpose input output, see FifoCONF.DW.

Note that only bits dwidth-1 to 0 are implemented.

50.7.21 Interrupt registers

The interrupt registers give complete freedom to the software, by providing means to mask interrupts, clear interrupts, force interrupts and read interrupt status.

When an interrupt occurs the corresponding bit in the Pending Interrupt Register is set. The normal sequence to initialize and handle a module interrupt is:

- Set up the software interrupt-handler to accept an interrupt from the module.

- Read the Pending Interrupt Register to clear any spurious interrupts.

- Initialize the Interrupt Mask Register, unmasking each bit that should generate the module interrupt.

- When an interrupt occurs, read the Pending Interrupt Status Register in the software interrupt-handler to determine the causes of the interrupt.

- Handle the interrupt, taking into account all causes of the interrupt.

- Clear the handled interrupt using Pending Interrupt Clear Register.

Masking interrupts: After reset, all interrupt bits are masked, since the Interrupt Mask Register is zero. To enable generation of a module interrupt for an interrupt bit, set the corresponding bit in the Interrupt Mask Register.

Clearing interrupts: All bits of the Pending Interrupt Register are cleared when it is read or when the Pending Interrupt Masked Register is read. Reading the Pending Interrupt Masked Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register. Selected bits can be cleared by writing ones to the bits that shall be cleared to the Pending Interrupt Clear Register.

Forcing interrupts: When the Pending Interrupt Register is written, the resulting value is the original contents of the register logically OR-ed with the write data. This means that writing the register can force (set) an interrupt bit, but never clear it.

Reading interrupt status: Reading the Pending Interrupt Status Register yields the same data as a read of the Pending Interrupt Register, but without clearing the contents.

Reading interrupt status of unmasked bits: Reading the Pending Interrupt Masked Status Register yields the contents of the Pending Interrupt Register masked with the contents of the Interrupt Mask Register, but without clearing the contents.

The interrupt registers comprise the following:

Table 817. Interrupt registers

Description	Name	Mode
Pending Interrupt Masked Status Register	FifoPIMSR	r
Pending Interrupt Masked Register	FifoPIMR	r
Pending Interrupt Status Register	FifoPISR	r
Pending Interrupt Register	FifoPIR	rw

3:    RxIrq   Successful reception of block of data*
2:    TxError   AMBA AHB access error during transmission*
1:    TxEmpty   Circular transmission buffer empty*
0:    TxIrq   Successful transmission of block of data*

*See table 817.

50.8   Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x035. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

50.9   Implementation

50.9.1   Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

50.9.2   Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core only performs 32-bit accesses and supports both big-endian and little-endian systems as long as the system can handle the 32-bit accesses.

51 GRFPU - High-performance IEEE-754 Floating-point unit

51.1 Overview

GRFPU is a high-performance FPU implementing floating-point operations as defined in the IEEE Standard for Binary Floating-Point Arithmetic (IEEE-754) and the SPARC V8 standard (IEEE-1754). Supported formats are single and double precision floating-point numbers. The advanced design combines two execution units, a fully pipelined unit for execution of the most common FP operations and a non-blocking unit for execution of divide and square-root operations.

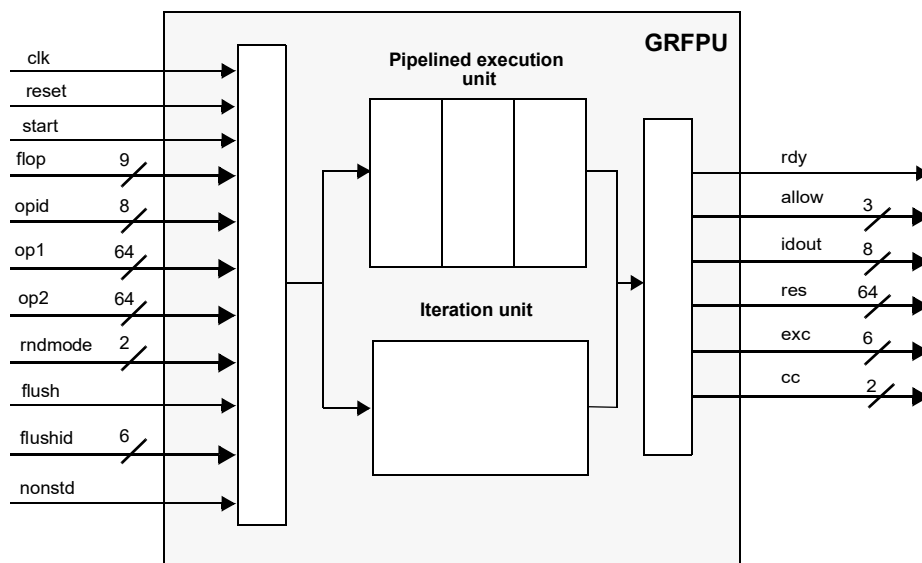
The logical view of the GRFPU is shown in figure 140.


Figure 140. GRFPU Logical View

This document describes GRFPU from functional point of view. Chapter "Functional description" gives details about GRFPU's implementation of the IEEE-754 standard including FP formats, operations, opcodes, operation timing, rounding and exceptions. "Signals and timing" describes the GRFPU interface and its signals. "GRFPU Control Unit" describes the software aspects of the GRFPU integration into a LEON processor through the GRFPU Control Unit - GRFPC. For implementation details refer to the white paper, "GRFPU - High Performance IEEE-754 Floating-Point Unit" (available at *www.gaisler.com*).

51.2 Functional description

51.2.1 Floating-point number formats

GRFPU handles floating-point numbers in single or double precision format as defined in the IEEE-754 standard with exception for denormalized numbers. See section 51.2.5 for more information on denormalized numbers.

51.2.2 FP operations

GRFPU supports four types of floating-point operations: arithmetic, compare, convert and move. The operations implement all FP instructions specified by SPARC V8 instruction set, and most of the operations defined in IEEE-754. All operations are summarized in table 824, with their opcodes, operands, results and exception codes. Throughputs and latencies and are shown in table 824.

FITOS FITOD	011000100 011001000	- 	INT 	SP DP	NX -	Integer to floating-point conversion
FSTOI FDTOI	011010001 011010010	- 	SP DP	INT 	UNF, NV, NX	Floating-point to integer conversion. The result is rounded in round-to-zero mode.
FSTOI_RND FDTOI_RND	111010001 111010010	- 	SP DP	INT 	UNF, NV, NX	Floating-point to integer conversion. Rounding according to RND input.
FSTOD FDTOS	011001001 011000110	- 	SP DP	DP SP	UNF, NV UNF, NV, OF, UF, NX	Conversion between floating-point formats
Comparison operations						
FCMPS FCMPD	001010001 001010010	SP DP	SP DP	CC 	NV	Floating-point compare. Invalid exception is generated if either operand is a signaling NaN.
FCMPES FCMPED	001010101 001010110	SP DP	SP DP	CC 	NV	Floating point compare. Invalid exception is generated if either operand is a NaN (quiet or signaling).
Negate, Absolute value and Move						
FABSS	000001001	-	SP	SP	-	Absolute value.
FNEGS	000000101	-	SP	SP	-	Negate.
FMOVS	000000001		SP	SP	-	Move. Copies operand to result output.

SP - single precision floating-point number   CC - condition codes, see table 827

DP - double precision floating-point number   UNF, NV, OF, UF, NX - floating-point exceptions, see section 51.2.3

INT - 32 bit integer

Arithmetic operations include addition, subtraction, multiplication, division and square-root. Each arithmetic operation can be performed in single or double precision formats. Arithmetic operations have one clock cycle throughput and a latency of four clock cycles, except for divide and square-root operations, which have a throughput of 16 - 25 clock cycles and latency of 16 - 25 clock cycles (see

GRIP

Apr 2024, Version 2024.1

709

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

table 825). Add, sub and multiply can be started on every clock cycle, providing high throughput for these common operations. Divide and square-root operations have lower throughput and higher latency due to complexity of the algorithms, but are executed in parallel with all other FP operations in a non-blocking iteration unit. Out-of-order execution of operations with different latencies is easily handled through the GRFPU interface by assigning an id to every operation which appears with the result on the output once the operation is completed (see section 51.4).

Table 825.: Throughput and latency

Operation	Throughput	Latency
FADDS, FADDD, FSUBS, FSUBD, FMULS, FMULD, FSMULD	1	4
FITOS, FITOD, FSTOI, FSTOI_RND, FDTOI, FDTOI_RND, FSTOD, FDTOS	1	4
FCMPS, FCMPD, FCMPES, FCMPED	1	4
FDIVS	16	16
FDIVD	16.5 (15/18)*	16.5 (15/18)*
FSQRTS	24	24
FSQRTD	24.5 (23/26)*	24.5 (23/26)*

* Throughput and latency are data dependant with two possible cases with equal statistical possibility.

Conversion operations execute in a pipelined execution unit and have throughput of one clock cycle and latency of four clock cycles. Conversion operations provide conversion between different floating-point numbers and between floating-point numbers and integers.

Comparison functions offering two different types of quiet Not-a-Numbers (QNaNs) handling are provided. Move, negate and absolute value are also provided. These operations do not ever generate unfinished exception (unfinished exception is never signaled since compare, negate, absolute value and move handle denormalized numbers).

51.2.3 Exceptions

GRFPU detects all exceptions defined by the IEEE-754 standard. This includes detection of Invalid Operation (NV), Overflow (OF), Underflow (UF), Division-by-Zero (DZ) and Inexact (NX) exception conditions. Generation of special results such as NaNs and infinity is also implemented. Overflow (OF) and underflow (UF) are detected before rounding. If an operation underflows the result is flushed to zero (GRFPU does not support denormalized numbers or gradual underflow). A special Unfinished exception (UNF) is signaled when one of the operands is a denormalized number which is not handled by the arithmetic and conversion operations.

51.2.4 Rounding

All four rounding modes defined in the IEEE-754 standard are supported: round-to-nearest, round-to-+inf, round-to--inf and round-to-zero.

51.2.5 Denormalized numbers

Denormalized numbers are not handled by the GRFPU arithmetic and conversion operations. A system (microprocessor) with the GRFPU could emulate rare cases of operations on denormals in software using non-FPU operations. A special Unfinished exception (UNF) is used to signal an arithmetic or conversion operation on the denormalized numbers. Compare, move, negate and absolute value operations can handle denormalized numbers and do not raise the unfinished exception. GRFPU does not generate any denormalized numbers during arithmetic and conversion operations on normalized numbers. If the infinitely precise result of an operation is a tiny number (smaller than minimum value representable in normal format) the result is flushed to zero (with underflow and inexact flags set).

GRIP

Apr 2024, Version 2024.1

710

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

51.2.6 Non-standard Mode

GRFPU can operate in a non-standard mode where all denormalized operands to arithmetic and conversion operations are treated as (correctly signed) zeroes. Calculations are performed on zero operands instead of the denormalized numbers obeying all rules of the floating-point arithmetics including rounding of the results and detecting exceptions.

51.2.7 NaNs

GRFPU supports handling of Not-a-Numbers (NaNs) as defined in the IEEE-754 standard. Operations on signaling NaNs (SNaNs) and invalid operations (e.g. inf/inf) generate the Invalid exception and deliver QNaN_GEN as result. Operations on Quiet NaNs (QNaNs), except for FCMPES and FCMPED, do not raise any exceptions and propagate QNaNs through the FP operations by delivering NaN-results according to table 826. QNaN_GEN is 0x7fffe00000000000 for double precision results and 0x7fff0000 for single precision results.

Table 826.: Operations on NaNs

		Operand 2		
Operand 1		FP	QNaN2	SNaN2
	none	FP	QNaN2	QNaN_GEN
	FP	FP	QNaN2	QNaN_GEN
	QNaN1	QNaN1	QNaN2	QNaN_GEN
	SNaN1	QNaN_GEN	QNaN_GEN	QNaN_GEN

51.3 Signal descriptions

Table 827 shows the interface signals of the core (VHDL ports). All signals are active high except for RST which is active low.

Table 827.: Signal descriptions

Signal	I/O	Description
CLK	I	Clock
RESET	I	Reset
START	I	Start an FP operation on the next rising clock edge
NONSTD	I	Nonstandard mode. Denormalized operands are converted to zero.
FLOP[8:0]	I	FP operation. For codes see table 824.
OP1[63:0] OP2[63:0]	I	FP operation operands are provided on these one or both of these inputs. All 64 bits are used for IEEE-754 double precision floating-point numbers, bits [63:32] are used for IEEE-754 single precision floating-point numbers and 32-bit integers.
OPID[7:0]	I	FP operation id. Every operation is associated with an id which will appear on the RESID output when the FP operation is completed. This value shall be incremented by 1 (with wrap-around) for every started FP operation. If flushing is used, FP operation id is 6 -bits wide (OPID[5:0] are used for id, OPID[7:6] are tied to "00"). If flushing is not used (input signal FLUSH is tied to '0'), all 8-bits (OPID[7:0]) are used.
FLUSH	I	Flush FP operation with FLUSHID.
FLUSHID[5:0]	I	Id of the FP operation to be flushed.
RNDMODE[1:0]	I	Rounding mode. 00 - rounding-to-nearest, 01 - round-to-zero, 10 - round-to-+inf, 11 - round-to--inf.
RES[63:0]	O	Result of an FP operation. If the result is double precision floating-point number all 64 bits are used, otherwise single precision or integer result appears on RESULT[63:32].
EXC[5:0]	O	Floating-point exceptions generated by an FP operation. EXC[5] - Unfinished FP operation. Generated by an arithmetic or conversion operation with denormalized input(s). EXC[4] - Invalid exception. EXC[3] - Overflow. EXC[2] - Underflow. EXC[1] - Division by zero. EXC[0] - Inexact.
ALLOW[2:0]	O	Indicates allowed FP operations during the next clock cycle. ALLOW[0] - FDIVS, FDIVD, FSQRTS and FSQRTD allowed ALLOW[1] - FMULS, FMULD, FSMULD allowed ALLOW[2] - all other FP operations allowed
RDY	O	The result of a FP operation will be available at the end of the next clock cycle.
CC[1:0]	O	Result (condition code) of an FP compare operation. 00 - equal 01 - operand1 < operand2 10 - operand1 > operand2 11 - unordered
IDOUT[7:0]	O	Id of the FP operation whose result appears at the end of the next clock cycle.
TESTEN	I	Test enable. When GRLIB has been configured to use asynchronous reset then TESTEN selects if the internal reset signal should come from RESET or TESTRST.
TESTRST	I	Reset signal in test mode (TESTEN = High). Only used when GRLIB has been configured to use asynchronous reset,

+46 31 7758650 | frontgrade.com/gaisler

51.4 Timing

An FP operation is started by providing the operands, opcode, rounding mode and id before rising edge. The operands need to be provided a small set-up time before a rising edge while all other signals are latched on rising edge.

The FPU is fully pipelined and a new operation can be started every clock cycle. The only exceptions are divide and square-root operations which require 16 to 26 clock cycles to complete, and which are not pipelined. Division and square-root are implemented through iterative series expansion algorithm. Since the algorithms basic step is multiplication the floating-point multiplier is shared between multiplication, division and square-root. Division and square-root do not occupy the multiplier during the whole operation and allow multiplication to be interleaved and executed parallelly with division or square-root.

One clock cycle before an operation is completed, the output signal RDY is asserted to indicate that the result of an FPU operation will appear on the output signals at the end of the next cycle. The id of the operation to be completed and allowed operations are reported on signals RESID and ALLOW. During the next clock cycle the result appears on RES, EXCEPT and CC outputs.

Figure 141 shows signal timing during four arithmetic operations on GRFPU.
Figure 141. Signal timing

51.5 Shared FPU

51.5.1 Overview

In multi-processor systems, a single GRFPU can be shared between multiple CPU cores providing an area efficient solution. In this configuration, the GRFPU is extended with a wrapper. Each CPU core issues a request to execute a specific FP operation to the wrapper, which performs fair arbitration using the round-robin algorithm. When a CPU core has started a divide or square-root operation, the FPU is not able to accept a new division or square-root until the current operation has finished. Also, during the execution of a division or square-root, other operations cannot be accepted during certain cycles. This can lead to the, currently, highest prioritized CPU core being prevented from issuing an operation to the FPU. If this happens, the next CPU core that has a operation that can be started will be allowed to access the FPU and the current arbitration order will be saved. The arbitration order will be restored when the operation type that was prevented can be started. This allows the FPU resource

the be fairly shared between several CPU cores while at the same time allowing maximum utilization of the FPU.

In shared FPU configuration, GRFPU uses an 8 bit wide id for each operation. The three high-order bits are used to identify the CPU core which issued the FP operation, while the five low-order bits are used to enumerate FP operations issued by one core. FP operation flushing is not possible in shared FPU configuration.

51.5.2 Shared FPU and clock gating

Clock gating of LEON processors is typically implemented so that the clock for a processor core is gated off when the processor is idle. The clock for a shared FPU is typically gated off when the connected processors are all idle or have floating-point disabled.

This means that, in a shared FPU configuration, a processor may be clock gated off while the connected FPU continues to be clocked. The power-down instruction may overtake a previously issued floating-point instruction and cause the processor to be gated off before the floating-point operation has completed. This can in turn lead to the processor not reacting to the completion of the floating-point operation and to a subsequent processor freeze after the processor wakes up and continues to wait for the completion of the floating-point operation.

In order to avoid this, software must make sure that all floating-point operations have completed before the processor enters power-down. This is generally not a problem in real-world applications as the power-down instruction is typically used in a idle loop and floating-point results have been stored to memory before entering the idle loop. To make sure that there are no floating-point operations pending, software should perform a store of the %fsr register before the power-down instruction.

51.6 Implementation

51.6.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set.

52 GRFPC - GRFPU Control Unit

The GRFPU Control Unit (GRFPC) is used to attach the GRFPU to the LEON integer unit (IU). GRFPC performs scheduling, decoding and dispatching of the FP operations to the GRFPU as well as managing the floating-point register file, the floating-point state register (FSR) and the floating-point deferred-trap queue (FQ). Floating-point operations are executed in parallel with other integer instructions, the LEON integer pipeline is only stalled in case of operand or resource conflicts.

In the FT-version, all registers are protected with TMR and the floating-point register file is protected using parity coding.

52.1 Floating-Point register file

The GRFPU floating-point register file contains 32 32-bit floating-point registers (%f0-%f31). The register file is accessed by floating-point load and store instructions (LDF, LDDF, STD, STDF) and floating-point operate instructions (FPop).

52.2 Floating-Point State Register (FSR)

The GRFPC manages the floating-point state register (FSR) containing FPU mode and status information. All fields of the FSR register as defined in SPARC V8 specification are implemented and managed by the GRFPU conforming to the SPARC V8 specification and the IEEE-754 standard. Implementation-specific parts of the FSR managing are the NS (non-standard) bit and *ftt* field.

If the NS (non-standard) bit of the FSR register is set, all floating-point operations will be performed in non-standard mode as described in section 51.2.6. When the NS bit is cleared all operations are performed in standard IEEE-compliant mode.

Following floating-point trap types never occur and are therefore never set in the ftt field:
- unimplemented_FPop: all FPop operations are implemented
- hardware_error: non-resumable hardware error
- invalid_fp_register: no check that double-precision register is 0 mod 2 is performed

GRFPU implements the *qne* bit of the FSR register which reads 0 if the floating-point deferred-queue (FQ) is empty and 1 otherwise.

The FSR is accessed using LDFSR and STFSR instructions.

52.3 Floating-Point Exceptions and Floating-Point Deferred-Queue

GRFPU implements the SPARC deferred trap model for floating-point exceptions (fp_exception). A floating-point exception is caused by a floating-point instruction performing an operation resulting in one of following conditions:

- an operation raises IEEE floating-point exception (ftt = IEEE_754_exception) e.g. executing invalid operation such as 0/0 while the NVM bit of the TEM field id set (invalid exception enabled).

- an operation on denormalized floating-point numbers (in standard IEEE-mode) raises unfinished_FPop floating-point exception

- sequence error: abnormal error condition in the FPU due to the erroneous use of the floating-point instructions in the supervisor software.

The trap is deferred to one of the floating-point instructions (FPop, FP load/store, FP branch) following the trap-inducing instruction (note that this may not be next floating-point instruction in the program order due to exception-detecting mechanism and out-of-order instruction execution in the GRFPC). When the trap is taken the floating-point deferred-queue (FQ) contains the trap-inducing instruction and up to seven FPop instructions that were dispatched in the GRFPC but did not complete.

GRIP
Apr 2024, Version 2024.1

715

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

After the trap is taken the *qne* bit of the FSR is set and remains set until the FQ is emptied. The STDFQ instruction reads a double-word from the floating-point deferred queue, the first word is the address of the instruction and the second word is the instruction code. All instructions in the FQ are FPop type instructions. The first access to the FQ gives a double-word with the trap-inducing instruction, following double-words contain pending floating-point instructions. Supervisor software should emulate FPops from the FQ in the same order as they were read from the FQ.

Note that instructions in the FQ may not appear in the same order as the program order since GRFPU executes floating-point instructions out-of-order. A floating-point trap is never deferred past an instruction specifying source registers, destination registers or condition codes that could be modified by the trap-inducing instruction. Execution or emulation of instructions in the FQ by the supervisor software gives therefore the same FPU state as if the instructions were executed in the program order.

52.4   Implementation

52.4.1   Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

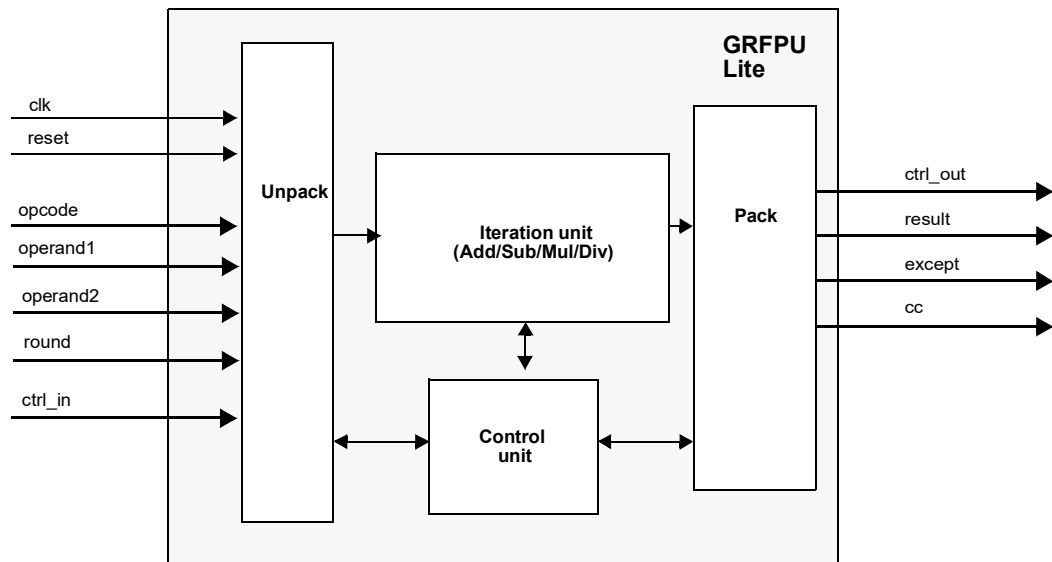
The core will add reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The GRFPC4 core will use asynchronous reset for all registers, except synchronization registers, if the GRLIB config package setting *grlib_async_reset_enable* is set. The GRFPC core does not support *grlib_async_reset_enable*.

53 GRFPU Lite - IEEE-754 Floating-Point Unit

53.1 Overview

The GRFPU Lite floating-point unit implements floating-point operations as defined in IEEE Standard for Binary Floating-Point Arithmetic (IEEE-754) and SPARC V8 standard (IEEE-1754).

Supported formats are single and double precision floating-point numbers. The floating-point unit is not pipelined and executes one floating-point operation at a time.


53.2 Functional Description

53.2.1 Floating-point number formats

The floating-point unit handles floating-point numbers in single or double precision format as defined in IEEE-754 standard.

53.2.2 FP operations

The floating-point unit supports four types of floating-point operations: arithmetic, compare, convert and move. The operations, summarised in the table below, implement all FP instructions specified by the SPARC V8 instruction set except FSMULD and instructions with quadruple precision.

Table 828.: Floating-point operations

Operation	Op1	Op2	Result	Exceptions	Description
Arithmetic operations					
FADDS FADDD	SP DP	SP DP	SP DP	NV, OF, UF, NX	Addition
FSUBS FSUBD	SP DP	SP DP	SP DP	NV, OF, UF, NX	Subtraction
FMULS FMULD	SP DP	SP DP	SP DP	NV, OF, UF, NX NV, OF, UF, NX	Multiplication
FDIVS FDIVD	SP DP	SP DP	SP DP	NV, OF, UF, NX, DZ	Division
FSQRTS FSQRTD	- -	SP DP	SP DP	NV, NX	Square-root
Conversion operations					
FITOS FITOD	- 	INT 	SP DP	NX -	Integer to floating-point conversion
FSTOI FDTOI	- 	SP DP	INT 	NV, NX	Floating-point to integer conversion. The result is rounded in round-to-zero mode.
FSTOD FDTOS	- 	SP DP	DP SP	NV NV, OF, UF, NX	Conversion between floating-point formats
Comparison operations					
FCMPS FCMPD	SP DP	SP DP	CC 	NV	Floating-point compare. Invalid exception is generated if either operand is a signaling NaN.
FCMPES FCMPED	SP DP	SP DP	CC 	NV	Floating point compare. Invalid exception is generated if either operand is a NaN (quiet or signaling).
Negate, Absolute value and Move					
FABSS	-	SP	SP	-	Absolute value.
FNEGS	-	SP	SP	-	Negate.
FMOVS		SP	SP	-	Move. Copies operand to result output.

SP - single precision floating-point number

DP - double precision floating-point number

INT - 32 bit integer

CC - condition codes

NV, OF, UF, NX - floating-point exceptions, see section 53.2.3

Below is a table of worst-case throughput of the floating point unit.

Table 829. Worst-case instruction timing

Instruction	Throughput	Latency

53.2.3 Exceptions

The floating-point unit detects all exceptions defined by the IEEE-754 standard. This includes detection of Invalid Operation (NV), Overflow (OF), Underflow (UF), Division-by-Zero (DZ) and Inexact (NX) exception conditions. Generation of special results such as NaNs and infinity is also implemented.

53.2.4 Rounding

All four rounding modes defined in the IEEE-754 standard are supported: round-to-nearest, round-to-+inf, round-to--inf and round-to-zero.

53.3 Implementation

53.3.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

54 GRLFPC - GRFPU Lite Floating-point unit Controller

54.1 Overview

The GRFPU Lite Floating-Point Unit Controller (GRLFPC) is used to attach the GRFPU Lite floating-point unit (FPU) to the LEON integer unit (IU). It performs decoding and dispatching of the floating-point (FP) operations to the floating-point unit as well as managing the floating-point register file, the floating-point state register (FSR) and the floating-point deferred-trap queue (FQ).

The GRFPU Lite floating-point unit is not pipelined and executes only one instruction at a time. To improve performance, the controller (GRLFPC) allows the GRFPU Lite floating-point unit to execute in parallel with the processor pipeline as long as no new floating-point instructions are pending.

54.2 Floating-Point register file

The floating-point register file contains 32 32-bit floating-point registers (%f0-%f31). The register file is accessed by floating-point load and store instructions (LDF, LDDF, STD, STDF) and floating-point operate instructions (FPop).

In the FT-version, the floating-point register file is protected using 4-bit parity per 32-bit word. The controller is capable of detecting and correcting one bit error per byte. Errors are corrected using the instruction restart function in the IU.

54.3 Floating-Point State Register (FSR)

The controller manages the floating-point state register (FSR) containing FPU mode and status information. All fields of the FSR register as defined in SPARC V8 specification are implemented and managed by the controller conform to the SPARC V8 specification and IEEE-754 standard.

The non-standard bit of the FSR register is not used, all floating-point operations are performed in standard IEEE-compliant mode.

Following floating-point trap types never occur and are therefore never set in the ftt field:
- unimplemented_FPop: all FPop operations are implemented
- unfinished_FPop: all FPop operation complete with valid result
- invalid_fp_register: no check that double-precision register is 0 mod 2 is performed

The controller implements the *qne* bit of the FSR register which reads 0 if the floating-point deferred-queue (FQ) is empty and 1 otherwise. The FSR is accessed using LDFSR and STFSR instructions.

54.4 Floating-Point Exceptions and Floating-Point Deferred-Queue

The floating-point unit implements the SPARC deferred trap model for floating-point exceptions (fp_exception). A floating-point exception is caused by a floating-point instruction performing an operation resulting in one of following conditions:

- an operation raises IEEE floating-point exception (ftt = IEEE_754_exception) e.g. executing invalid operation such as 0/0 while the NVM bit of the TEM field id set (invalid exception enabled).

- sequence error: abnormal error condition in the FPU due to the erroneous use of the floating-point instructions in the supervisor software.

- hardware_error: uncorrectable parity error is detected in the FP register file

The trap is deferred to the next floating-point instruction (FPop, FP load/store, FP branch) following the trap-inducing instruction. When the trap is taken the floating-point deferred-queue (FQ) contains the trap-inducing instruction.

GRIP

Apr 2024, Version 2024.1

720

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

After the trap is taken the *qne* bit of the FSR is set and remains set until the FQ is emptied. STDFQ instruction reads a double-word from the floating-point deferred queue, the first word is the address of the instruction and the second word is the instruction code.

54.5 Implementation

54.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset and resets a subset of its internal registers.

55 GRGPRBANK - General Purpose Register Bank

55.1 Overview

The core provides an array of programmable registers. The registers drive an output vector that can be used to control other parts of the design.

55.2 Operation

The core contains registers of configurable number and length that is mapped into APB address space. The concatenated values of these registers are propagated to an output vector. All registers are reset to the same value, which is specified via a VHDL generic.

The core can optionally support a reset vector that allows setting the reset value on each bit. The core can also support a read vector that supply a different read-out value than the value of the registers. This can be used to implement read-only/write-only registers.

55.3 Registers

The core is programmed through registers mapped into APB address space.

Table 830. General purpose register registers

APB address offset	Register
0x00	General purpose register 0
0x04	General purpose register 1
...	...
4*(N-1)	General purpose register (N-1)

r		rw

31:regbits   RESERVED (not present if regbits = 32)

regbits-1:0   Register bits. Position i corresponds to bit (N*regbits+i) in the core's output vector

55.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x08F. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

55.5 Implementation

55.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset for its internal registers.

56 GRGPIO - General Purpose I/O Port

56.1 Overview

The general purpose input output port core is a scalable and provides optional interrupt support. The port width can be set to 2 - 32 bits through the *nbits* VHDL generic. Interrupt generation and shaping is only available for those I/O lines where the corresponding bit in the *imask* VHDL generic has been set to 1.

Each bit in the general purpose input output port can be individually set to input or output, and can optionally generate an interrupt. For interrupt generation, the input can be filtered for polarity and level/edge detection.

It is possible to share GPIO pins with other signals. The output register can then be bypassed through the bypass register.

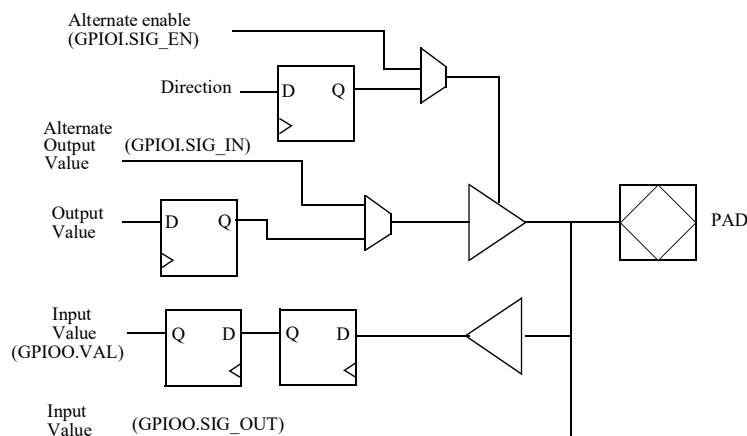
The figure 142 shows a diagram for one I/O line.


Figure 142. General Purpose I/O Port diagram

56.2 Operation

The I/O ports are implemented as bi-directional buffers with programmable output enable. The input from each buffer is synchronized by two flip-flops in series to remove potential meta-stability. The synchronized values can be read-out from the I/O port data register. They are also available on the GPIOO.VAL signals. The output enable is controlled by the I/O port direction register. A '1' in a bit position will enable the output buffer for the corresponding I/O line. The output value driven is taken from the I/O port output register.

The core can be implemented with one of three different alternatives for interrupt generation. Either each I/O line can drive a separate interrupt line on the APB interrupt bus, the interrupt line to use can be assigned dynamically for each I/O line, or one interrupt line can be shared for all I/O lines. In the fixed mapping with a separate interrupt line for each I/O line, the interrupt number is equal to the I/O line index plus an offset given by the first interrupt line assigned to the core, *pirq*, (PIO[1] = interrupt *pirq*+1, etc.). If the core has been implemented to support dynamic mapping of interrupts, each I/O line can be mapped using the Interrupt map register(s) to an interrupt line starting at interrupt *pirq*. When the core is implemented to drive one, fixed, shared interrupt line for all I/O lines, the core will drive interrupt line *pirq* only. The value of *pirq* can be read out from the core's AMBA plug'n'play information.

Interrupt generation is controlled by three registers: interrupt mask, polarity and edge registers. To enable an interrupt, the corresponding bit in the interrupt mask register must be set. If the edge register is '0', the interrupt is treated as level sensitive. If the polarity register is '0', the interrupt is active

GRIP
Apr 2024, Version 2024.1

725

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

low. If the polarity register is '1', the interrupt is active high. If the edge register is '1', the interrupt is edge-triggered. The polarity register then selects between rising edge ('1') or falling edge ('0').

The core can be implemented with a Interrupt flag register that can be used to determine if, and which, GPIO pin that caused an interrupt to be asserted. The core implements the Interrupt flag register, and the Interrupt available register, if the IFL field in the core's capability register is non-zero.

A GPIO pin can be shared with other signals. The ports that should have the capability to be shared are specified with the *bypass* generic (the corresponding bit in the generic must be 1). The unfiltered inputs are available through GPIOO.SIG_OUT and the alternate output value must be provided in GPIOI.SIG_IN. The bypass register then controls whether the alternate output is chosen. The direction of the GPIO pin can also be shared, if the corresponding bit is set in the *bpdir* generic. In such case, the output buffer is enabled when GPIOI.SIG_EN is active. The direction of the pin can also be made to depend on the bypass register. See the documentation of the *bpmode* VHDL generic for details.

A GPIO pin can also be toggled when a pulse is detected on an internal signal. If the pulse VHDL generic is nonzero, then the Pulse register is available in the core.

56.3 Registers

The core is programmed through registers mapped into APB address space.

18   PU: Pulse register implemented: If this field is '1' then the core implements the Pulse register.

This field is available in revision 2 and above of the GPIO port. This field is read-only.

17   IER: Input Enable register implemented. If this field is '1' then the core implements the Input enable register.

This field is available in revision 2 and above of the GPIO port. This field is read-only.

16   IFL: Interrupt flag register implemented. If this field is '1' then the core implements the Interrrupt available and Interrupt flag registers (registers at offsets 0x40 and 0x44).

This field is available in revision 2 and above of the GPIO port. This field is read-only.

12   8   IRQGEN: Interrupt generation setting: If irqgen = 0, I/O line n will drive interrupt line pirq + n, up to NAHBIRQ-1. No Interrupt map registers will be implemented. This is the default, and traditional, implementation of the core.

If irqgen = 1, all I/O lines capable of generating interrupts will use interrupt pirq and no Interrupt map registers are implemented.

If irqgen > 1, the core will include Interrupt map registers allowing software to dynamically map which lines that should drive interrupt lines [pirq : pirq+irqgen-1].

The value of pirq can be read out from the core's plug&play information.

This field is available in revision 2 and above of the GPIO port. This field is read-only.

4: 0   NLINES. Number of pins in GPIO port - 1. Compatibility note: This field is available in revision 2 and above of the GPIO port. This field is read-only.

56.3.9   Interrupt Map Register n

*Table 844.*0x20+un - IRQMAPRn - Interrupt map register n

31 29 28		24 23 21 20		16 15 13 12		8 7 6 4		0
RESERVED	IRQMAP[4*n]	RESERVED	IRQMAP[4*n+1]	RESERVED	IRQMAP[4*n+2]	RESERVED	IRQMAP[4*n+3]	
0	0	0	0	0	0	0	0	
r	rw	r	rw	r	rw	r	rw	

31:   0   IRQMAP[i] : The field IRQMAP[i] determines to which interrupt I/O line i is connected. If IRQ-MAP[i] is set to *x*, IO[i] will drive interrupt *pirq+x*. Where *pirq* is the first interrupt assigned to the core. Several I/O can be mapped to the same interrupt.

The core has one IRQMAP field per I/O line. The Interrupt map register at offset 0x20+*4*n* contains the IRQMAP fields for IO[*4*n : 4*n+3*]. This means that the fields for IO[0:3] are located on offset 0x20, IO[4:7] on offset 0x24, IO[8:11] on offset 0x28, and so on. An I/O line's interrupt generation must be enabled in the Interrupt mask register in order for the I/O line to drive the interrupt specified by the IRQMAP field. The Interrupt map register(s) can only be written if the core was implemented with support for interrupt mapping.

56.3.10 Interrupt Available Register

*Table 845.*0x40 - IAVAIL - Interrupt available register

31	0
IMASK	
*	
r	

31:   0   IMASK: Interrupt mask bit field. If IMASK[n] is 1 then GPIO line n can generate interrupts.

This register is not available in all implementations. See capability register.

56.3.11 Interrupt Flag Register

*Table 846.*0x44 - IFLAG - Interrupt flag register

31	0
IFLAG	
0	
wc	

31:   0   IFLAG : If IFLAG[n] is set to '1' then GPIO line n has generated an interrupt. Write '1' to the orresponding bit to clear. Writes of '0' have no effect.

This register is not available in all implementations, see capability register.

56.3.12 Input Enable Register

*Table 847.*0x48 - IPEN - Input enable register

31	0
IPEN	
0	
rw	

31:   0   IPEN : If IPEN[n] is set to '1' then values from GPIO line n will be visible in the data register. Otherwise the GPIO line input is gated-off to disable input signal propagation.

This register is not available in all implementations, see capability register.

31: 0   PULSE : If PULSE[n] is set to '1' then I/O port output register bit n will be inverted whenever GPIOI.SIG_IN[n] is high.

This register is not available in all implementations, see capability register.

56.3.14 Logical-OR/AND/XOR Register

*Table 849.*0x54-0x7C - LOR,LAND,LXOR - Logical-OR/AND/XOR registers

31	0
VALUE	
-	
w*	

31: 0   The logical-OR/AND/XOR registers will update the corresponding register according to:

New value = <Old value> logical-op <Write data>

There exists logical-OR, AND and XOR registers for the Input enable, I/O port output, I/O port direction and Interrupt mask registers.

56.4   Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x01A. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

56.5   Implementation

56.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. See also the description for the *syncrst* VHDL generic for how the core implements reset.

56.6   Configuration options

Table 850 shows the configuration options of the core (VHDL generics).

*Table 850.*Configuration options

Generic	Function	Allowed range	Default
pindex	Selects which APB select signal (PSEL) will be used to access the GPIO unit	0 to NAHBIRQ-1	0

bpdir	Defines which I/O lines are provided output enable bypass capabilities. Note that line 31 (out of lines 0 to 31 in a 32-bit GPIO port) cannot be configured for bypass.	0 - 16#7FFFFFFF#	0
pirq	First interrupt line that the core will drive. The core will only drive interrupt lines up to line NAHBIRQ-1. If NAHBIRQ is set to 32 and *pirq* is set to 16, the core will only be able to generate interrupts for I/O lines 0 - 15.	0 - NAHBIRQ-1	0
irqgen	This generic configures interrupt generation. If *irqgen* = 0, I/O line *n* will drive interrupt line *pirq* + *n*, up to NAHBIRQ-1. No Interrupt map registers will be implemented. This is the default, and traditional, implementation of the core. If *irqgen* = 1, all I/O lines capable of generating interrupts will use interrupt *pirq* and no Interrupt map registers will be implemented. If *irqgen* > 1, the core will include Interrupt map registers allowing software to dynamically map which lines that should drive interrupt lines [*pirq* : *pirq*+*irqgen*-1]	0 - NAHBIRQ-1	0
iflagreg	If this generic is set to 1 then the core will be implemented with the Interrupt available and Interrupt flag registers. If this generic is set to 1 then the IFL field in the core's capability register is also set.	0 - 1	0
bpmode	Controls if output enable bypass depends on the bypass register and the behaviour of the gpioi.sig_en inputs. If bpmode = 0 then gpioi.sig_en(i) enables GPIO line *i* and connects gpioi.sig_in(i) to the output, regardless of the value in the bypass register. If bpmode = 1 then the corresponding bit in the bypass register must be set to '1' for the output enable bypass to be active. When the bypass register is active then the gpioi.sig_en(i) controls the output enable of the corresponding GPIO line and gpioi.sig_in(i) is connected to the corresponding output. In both cases, bit *i* in the bpdir VHDL generic must be set for the gpioi.sig_en(i) signal to have any effect.	0 - 1	0
inpen	If this generic is non-zero, then the core will be implemented with the Input enable register that can be used to prevent input signal propagation.	0 - 1	0

57 GRGPREG - General Purpose Register

57.1 Overview

The core provides a programmable register that drives an output vector that can be used to control miscellaneous options in a design.

57.2 Operation

The core contains one register of configurable length that is mapped into APB address space. The value of this register is propagated to an output vector. The reset value of the register can be specified via VHDL generics, or via an input vector.

57.3 Registers

The core is programmed through registers mapped into APB address space.

Table 855. General purpose register registers

APB address offset	Register
0x00	General purpose register bits 31:0
0x04	General purpose register bits 63:0

57.3.1 General Purpose Register

Table 856. 0x00 - GPREG0 - General purpose register

31	nbits	nbits-1	0
RESERVED		REGISTER BITS	
0		*	
r		rw	

31:nbits	RESERVED (not present if nbits >= 32)
nbits-1:0	Register bits. Position i corresponds to bit i in the core's output vector

57.3.2 General Purpose Register (extended)

Table 857. 0x04 - GRPEG1 - General purpose register (extended)

31	nbits-32	nbits-33	0
RESERVED		REGISTER BITS	
0		*	
r		rw	

31:nbits-32	RESERVED (not present if nbits = 64 or nbits <= 32)
nbits-33:0	Register bits. Position i corresponds to bit 31+i in the core's output vector (not present if nbits < 33)

57.4 Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x087. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

GRIP
Apr 2024, Version 2024.1

736

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

57.5 Implementation

57.5.1 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). The core makes use of synchronous reset for its internal registers.

57.6 Configuration options

Table 858 shows the configuration options of the core (VHDL generics).

*Table 858.*Configuration options

Generic name	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR.	0 - 16#FFF#	16#FFF#
nbits	Number of register bits	1 - 64	16
rstval	Reset value for bits 31:0	0 - 16#FFFFFFFF#	0
rstval2	Reset value for bits 63:32	0 - 16#FFFFFFFF#	0
extrst	Use input vector *resval* to specify reset value. If this generic is 0 the register reset value is determined by VHDL generics *rstval* and *rstval2*. If this generic is 1, the reset value is specified by the input vector *resval*.	0 - 1	0

57.7 Signal descriptions

Table 859 shows the interface signals of the core (VHDL ports).

*Table 859.*Signal descriptions

Signal name	Field	Type	Function	Active
RST	N/A	Input	Reset	Low
CLK	N/A	Input	Clock	-
APBI	*	Input	APB slave input signals	-
APBO	*	Output	APB slave output signals	-
GRGPREGO	N/A	Output	Value of register mapped into APB address space	-
RESVAL	N/A	Input	(Optionally) specifes register reset value	-

* see GRLIB IP Library User's Manual

57.8 Library dependencies

58 GRHSSL - SpaceFibre and WizardLink controller with DMA engine

58.1 Overview

GRHSSL provides an interface between the system bus (such as AHB or AXI) and a high-speed serial link. It can implement either SpaceFibre or WizardLink controllers, or both. The SpaceFibre controller complies with the SpaceFibre specification ECSS-E-ST-50-11C, whereas the WizardLink codec has been designed to inter-operate with the TLK2711 SerDes transceiver from Texas Instrument, although the IP can interface other SerDes devices.

The core features a flexible DMA layer with a configurable number of DMA channels, each one with its own bus master interface to fetch and store descriptors and data from/to external memory. There are wrappers available adapting the generic bus master interfaces to either AMBA AHB 2.0 or AXI4. The packets are autonomously handled by the DMA engine, both in transmission and reception. The user controls the process via hardware descriptors. The optional Remote Memory Access Protocol (RMAP) target, adhering to the ECSS-E-ST-50-52C standard, can be implemented in the SpaceFibre layer.

The IP is configured through registers accessed through an AHB slave interface. SpaceFibre and WizardLink have separate sets of AHB registers, meaning that the IP will include two AHB I/O banks if both controllers are generated.

If both controllers are present, only one can be active at a time, which is selectable at run time via the AHB registers. The active controller will drive the bus master and SerDes interfaces.

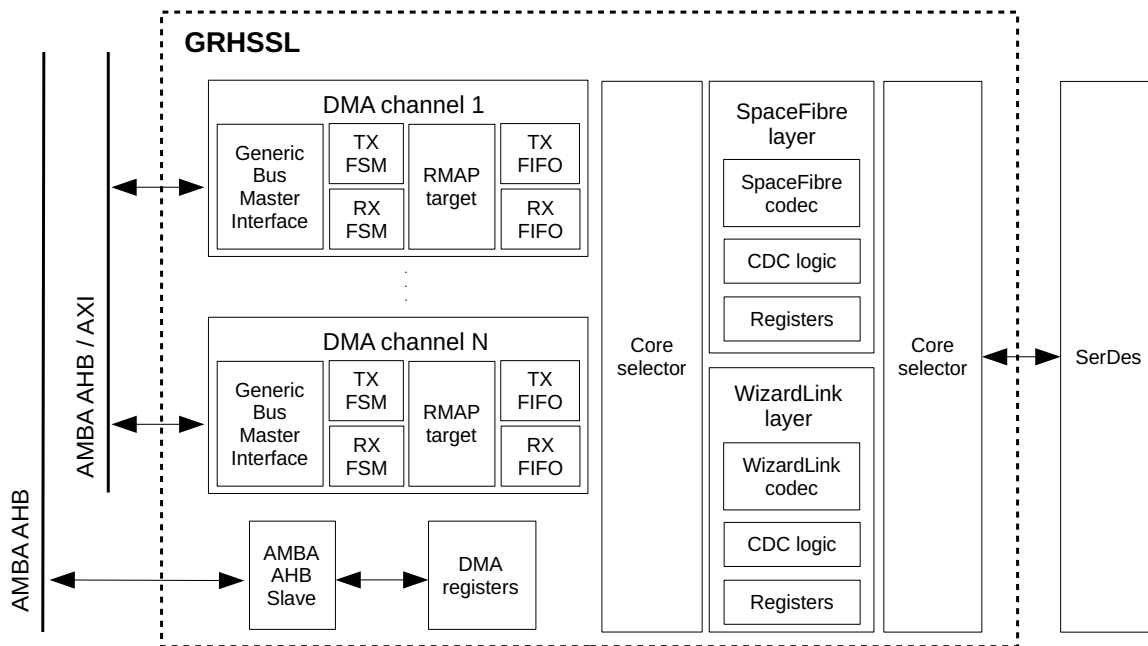
The block of GRHSSL can be seen in the picture below.


Figure 144. GRHSSL block diagram

58.2 Operation

58.2.1 Functional description

The IP can be split into the following parts from a functional point of view:

- SpaceFibre controller.
- WizardLink controller.

GRIP
Apr 2024, Version 2024.1
740
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- DMA engine with optional RMAP target for SpaceFibre.

- AHB slave interface.

- Clock-domain-crossing synchronization mechanism.

- DMA FIFOs.

The SpaceFibre controller in GRHSSL is the GRSPFI IP, which is described in a separate entry of this document. Please refer to that chapter for a detailed description of the IP functionality, configuration and register interface. GRSPFI is generated if the VHDL generic *spfi* is set to 1. If so, GRHSSL will include a dedicated AHB I/O bank for the SpaceFibre registers, regardless of whether WizardLink is also present or not.

The WizardLink controller in GRHSSL is the GRWIZL IP, which is described in a separate entry of this document. Please refer to that chapter for a detailed description of the IP functionality, configuration and register interface. GRWIZL is generated if the VHDL generic *wizl* is set to 1. If so, GRHSSL will include a dedicated AHB I/O bank for the WizardLink registers, regardless of whether SpaceFibre is also present or not.

The DMA engine is shared by both SpaceFibre and WizardLink controller. It contains four finite-state machines:

- SpaceFibre TX FSM

- SpaceFibre RX FSM

- WizardLink TX FSM

- WizardLink RX FSM

The active protocol determines which pair of FSMs can be in a state other than idle. When selected, the corresponding DMA channels will internally drive the bus master interfaces and will connect the inputs and outputs of the selected codec to the SerDes interface.

Note that GRWIZL does not support more than one bus master interface. If the IP is instantiated with multiple DMA channels, the rest is only used for SpaceFibre packets, and remain unused when operating in WizardLink mode.

The DMA engine also performs the clock-domain crossing synchronization between the AMBA and codec clock domains by means of handshake mechanisms and dual port FIFOs. It also contains the AHB registers used to configure and control the IP.

58.2.2 Protocol support

The SpaceFibre codec has been designed in accordance with the SpaceFibre standard ECSS-E-ST-50-11C. It is a Single-Lane implementation of the protocol; therefore the optional Multi-Lane layer is not part of the IP. The optional RMAP target has been implemented as per the ECSS-E-ST-50-52C specification.

The WizardLink codec has been designed to interface the TLK2711 transceiver with minimal protocol overhead. Other SerDes models are supported by the IP.

58.2.3 Endianness

The core is designed for big-endian and little-endian systems.

Please refer to the GRSPFI and GRWIZL sections of this manual for further detail regarding how the endianness support is implemented in each core.

58.3 Protocol selection

When both controllers are instantiated, the user shall select which protocol is active. This can be done in runtime by means of AHB registers.

GRIP

Apr 2024, Version 2024.1

741

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

Both GRSPFI and GRWIZL contains an Enable register that allows to set the respective codec as the active controller. These registers are called SpaceFibre Enable Register and WizardLink Enable Register. Note that these registers become read-only if GRHSSL only implements a single protocol.

The user must ensure that the active controller is completely idle before switching modes. This means that the DMA engine must be off, both transmitter and receiver for all DMA channels. Switching modes while the IP is still processing a descriptor or a packet will most likely corrupt the normal operation and/or provoke link errors.

The general scenario is to select the active protocol as part of the setup of the IP, without needing to switch to the alternative mode at any later time. Only in special cases (e.g. two GRHSSL IPs interfacing one another, or if GRHSSL interfaces a remote node that also supports dual protocol) it is expected to switch the functional mode in the middle of the operation.

58.4   Registers

The core is programmed through registers mapped into AHB address space. Only 32-bit single accesses to the registers are supported.

SpaceFibre and WizardLink registers are implemented in separate AHB I/O areas. Please refer to the respective chapters in this document (GRSPFI and GRWIZL) for a complete description of their register interfaces.

58.5   Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler). The device identifier changes depending on the configuration of the IP:

- 0x0BC (GRSPFI) when GRHSSL only implements SpaceFibre (generics *spfi* = 1 and *wizl* = 0)

- 0x0C7 (GRWIZL) when GRHSSL only implements WizardLink (generics *spfi* = 0 and *wizl* = 1)

- 0x0C8 (GRHSSL) when both controllers are implemented (generics *spfi* = 1 and *wizl* = 1)

For description of vendor and device identifiers see GRLIB IP Library User's Manual.

58.6   Configuration options

Table 861 shows the configuration options of the core (VHDL generics).

*Table 861.*Configuration options

Generic name	Function	Allowed range	Default
tech	Technology for the internal memories	0 - NTECH	inferred (0)
hmindex	AHB master index of the first DMA channel. The rest of the DMA channels are assigned an index depending on the settings of the generic *incr_hmindex*. Only present in the AHB wrapper.	0 - NAHBMST-1	0
hsindex	AHB slave index	0 - NAHBSLV-1	0
haddr_spfi	Addr field of the SpaceFibre AHB bar	0 - 16#FFF#	0
hmask_spfi	Mask field of the SpaceFibre AHB bar	0 - 16#FFF#	16#FF0#
haddr_wizl	Addr field of the WizardLink AHB bar	0 - 16#FFF#	0
hmask_wizl	Mask field of the WizardLink AHB bar	0 - 16#FFF#	16#FF0#
hirq	Interrupt line used by GRHSSL	0 - NAHBIRQ-1	0
use_8b10b	If set, internal 8B10B encoding and decoding is activated in both SpaceFibre and WizardLink codecs.	0 - 1	1
use_sep_txclk	If set, the SerDes transmission clock is decoupled from the SpaceFibre/WizardLink core clock. An additional transmit buffer is instantiated for this reason.	0 - 1	0

*Table 861.*Configuration options

Generic name	Function	Allowed range	Default
sel_16_20_bit_-mode	If set, the SerDes interface is 16+2 bit (without 8B10B) or 20 bit (with 8B10B) wide instead of 36/40 bit. If set, *use_sep_txclk* must also be set. Applies to both codecs.	0 - 1	0
ticks_2us	Clock ticks corresponding to 2 us. Only used by the SpaceFibre codec.	1 - 8192	125
tx_skip_freq	Frequency of SpaceFibre SKIP word transmission in clock cycles.	1 - 8192	5000
prbs_init1	If set, the INIT1 sequence during SpaceFibre lane initialization is embedded into a stream of pseudo-random numbers.	0 - 1	1
depth_rbuf_data	Log(Depth) of the SpaceFibre data retry buffer.	1 - 32	8
depth_rbuf_fct	Log(Depth) of the SpaceFibre FCT retry buffer.	1 - 32	4
depth_rbuf_bc	Log(Depth) of the SpaceFibre broadcast retry buffer.	1 - 32	8
num_vc	Number of SpaceFibre virtual channels.	1 - 32	4
fct_multiplier	Multiplier used in the SpaceFibre internal FCT logic. The value of the FCT counter is compared with 64*_fct_-multiplier_ to decide if the far end can receive new words.	1 - 8	1
depth_vc_rx_buf	Log(Depth) of SpaceFibre virtual channel input buffer.	1 - 32	10
depth_vc_tx_buf	Log(Depth) of SpaceFibre virtual channel output buffer.	1 - 32	10
remote_fct_cnt_-max	Width of the SpaceFibre remote FCT counter.	1 - 32	9
width_bw_credit	Width of the SpaceFibre bandwidth credit counter.	0 - 16#FFFFFFFF#	20
min_bw_credit	SpaceFibre minimum bandwidth credit threshold limit.	0 - 16#FFFFFFFF#	52428
idle_time_limit	SpaceFibre bandwidth idle time limit in clock cycles.	0 - 65535	62500
num_dmach	Number of DMA channels. Note that only the first DMA channel is used when WizardLink is the active protocol.	1 - 8	1
num_txdesc	Size of the TX descriptor table in number of descriptors.	64, 128, 256, 512	64
num_rxdesc	Size of the RX descriptor table in number of descriptors.	128, 256, 512, 1024	128
depth_dma_fifo	Depth of the DMA FIFOs. Sets the number of entries in the transmitter and receiver FIFOs (2 FIFOs per DMA channel). The FIFOs are shared by both codecs.	16 - 256	32
depth_bc_fifo	Depth of the BC FIFO. Sets the number of entries in the receiver FIFO. Only used by the SpaceFibre layer.	1 - 32	4
depth_wizl_tx_buf	Log(Depth) of the WizardLink codec internal TX buffer, expressed as number of address bits.	1 - 32	10
depth_wizl_rx_buf	Log(Depth) of the WizardLink codec internal RX buffer, expressed as number of address bits.	1 - 32	10
incr_hmindex	If set, the AHB master indices of the DMA channels are assigned incrementally, starting with hmindex. Otherwise, all AHB master indices are set to hmindex. Only present in the AHB wrapper.	0 - 1	1
use_async_rxrst	Force asynchronous reset in the recovered clock domain, regardless of the general GRLIB settings.	0 - 1	0
ft_core_vc	Enable fault-tolerance against SEU errors for the FIFOs in the SpaceFibre Virtual Channel Layer and in the WizardLink codec. Possible options are byte parity protection (ft = 1), TMR registers (ft = 2), SECDED BCH (ft = 4) or technology specific protection (ft = 5). If set to 0, no protection is implemented.	0 - 2, 4 - 5	0

*Table 861.*Configuration options

Generic name	Function	Allowed range	Default
ft_core_rt1	Enable fault-tolerance against SEU errors for the large FIFOs in the SpaceFibre Retry Layer (Data and Broadcast). The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_core_rt2	Enable fault-tolerance against SEU errors for the small FIFOs in the SpaceFibre Retry Layer (FCT and pointers). The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_core_if	Enable fault-tolerance against SEU errors for the FIFOs in the Interface Layer of the SpaceFibre and the Wizard-Link codecs. The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_dma_data	Enable fault-tolerance against SEU errors for the TX/RX FIFOs in the DMA layer. The core supports the same configurations as above.	0 - 2, 4 - 5	0
ft_dma_bc	Enable fault-tolerance against SEU errors for the SpaceFibre Broadcast Channel FIFOs in the DMA layer. The core supports the same configurations as above.	0 - 2, 4 - 5	0
scantest	Enable Scan Test support.	0 - 1	0
ahbbits	Width of AHB read/write data buses and maximum access size. Only present in the AHB wrapper.	32, 64, 128	AHBDW
lendian	Select endianness of the system: 0 for big-endian, 1 for little-endian. Only present in the AXI wrapper.	0 - 1	1
spfi	If set, the SpaceFibre codec is instantiated in the design.	0 - 1	1
wizl	If set, the WizardLink codec is instantiated in the design.	0 - 1	0
rmap	If set, every DMA channel will feature a hardware RMAP target and RMAP CRC logic. Only used by the SpaceFibre layer.	0 - 1	0
rmapcrc	Include RMAP CRC logic in every DMA channel without implementing a full RMAP target. Only used by the SpaceFibre layer.	0 - 1	0
ccsdscrc	Enable CCSDS/CCITT CRC-16 and 16-bit ISO-checksum (J.G. Fletcher, ISO 8473-1:1998) logic in every DMA channel. It requires that either *rmap* or *rmapcrc* is also set to 1. Only used by the SpaceFibre layer.	0 - 1	0
nodeaddr	When set to 0 - 254: this generic specifies the reset value for the default address field. When set to 255: Reset value for the node address is taken from the CFG.NODEADDR input signal. Only used by the SpaceFibre layer.	0 - 255	254
destkey	Reset value for the core destination key. Only used by the SpaceFibre layer.	0 - 255	0
numextvc	Number of external FIFO interfaces that can be used to bypass the DMA engine when transmitting and receiving packets over a specific virtual channel. Only used by the SpaceFibre layer.	0 - 32	0
numextbc	If set, implement an external FIFO interface that can be used to bypass the DMA engine when transmitting and receiving broadcast messages. Only used by the SpaceFibre layer.	0 - 1	0
numextwc	If set, implement an external FIFO interface that can be used to bypass the DMA engine when transmitting and receiving WizardLink data. Only used by the WizardLink layer.	0 - 1	0

59   GRIOMMU - AHB/AHB bridge with access protection and address translation

59.1   Overview

The core is used to connect two AMBA AHB buses clocked by synchronous clocks with any frequency ratio. The two buses are connected through an interface pair consisting of an AHB slave and an AHB master interface. AHB transfer forwarding is performed in one direction, where AHB transfers to the slave interface are forwarded to the master interface. The core can be configured to provide access protection and address translation for AMBA accesses traversing over the core. Access protection can be provided using a bit vector to restrict access to memory. Access protection and address translation can also be provided using page tables in main memory, providing full IOMMU functionality. Both protection strategies allow devices to be placed into a configurable number of groups that share data structures located in main memory. The protection and address translation functionality provides protection for memory assigned to processes and operating systems from unwanted accesses by units capable of direct memory access.

Applications of the core include system partitioning, clock domain partitioning, system expansion and secure software partitioning.

Features offered by the core include:

*   Single and burst AHB transfer forwarding

*   Access protection and address translation that can provide full IOMMU functionality

*   Devices can be placed into groups where a group shares page tables / access restriction vectors

*   Hardware table-walk

*   Efficient bus utilization through (optional) use of SPLIT response, data prefetching and posted writes. **NOTE:** SPLIT responses require an AHB arbiter that allows assertion of HSPLIT during second cycle of SPLIT response. This is supported by GRLIB's AHBCTRL IP core.

*   Read and write combining, improves bus utilization and allows connecting cores with differing AMBA access size restrictions.

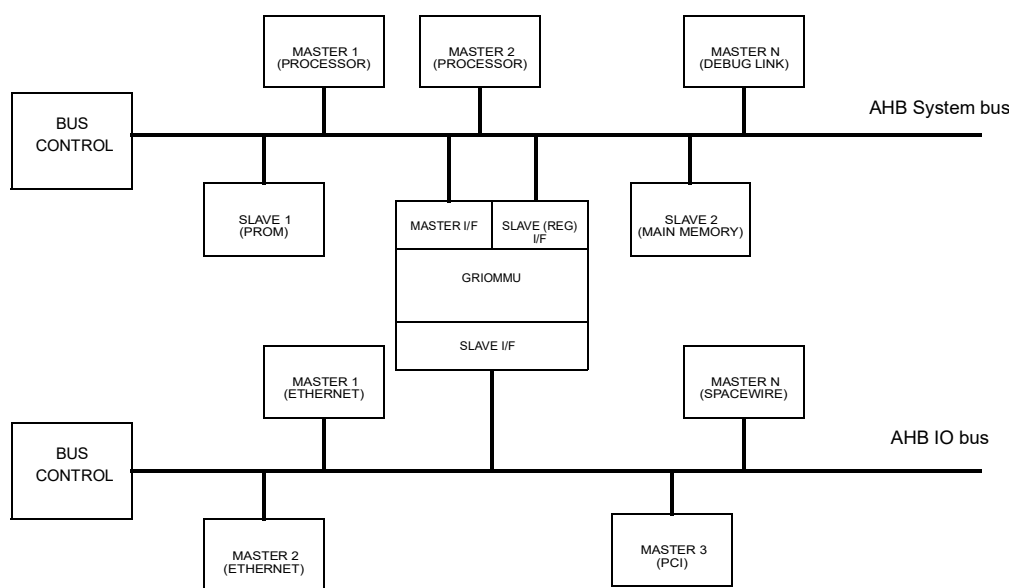
*   Deadlock detection logic enables use of two uni-directional bridges to build a bi-directional bridge. The core can be connected with an another instance of the core, or with a uni-directional AHB/AHB bridge core (AHB2AHB), to form a bi-directional bridge.


Figure 145. System with core providing access restricion/address translation for masters on AHB IO bus

59.2 Bridge operation

59.2.1 General

The first sub sections below describe the general AHB bridge function. The functionality providing access restriction and address translation is described starting with section 59.3. In the description of AHB accesses below the core propagates accesses from the IO bus to the System bus, see figure 145.

The address space occupied by the core on the IO bus is configurable and determined by Bank Address Registers in the slave interface's AHB Plug&Play configuration record.

The core is capable of handling single and burst transfers of all burst types. Supported transfer sizes (HSIZE) are BYTE, HALF-WORD, WORD, DWORD, 4WORD and 8WORD.

For AHB write transfers write data is always buffered in an internal FIFO implementing posted writes. For AHB read transfers the core uses GRLIB's AMBA Plug&Play information to determine whether the read data will be prefetched and buffered in an internal FIFO. If the target address for an AHB read burst transfer is a prefetchable location the read data will be prefetched and buffered.

The core can be implemented to use SPLIT responses or to insert wait states when handling an access. With SPLIT responses enabled, an AHB master initiating a read transfer to the core is always splitted on the first transfer attempt to allow other masters to use the slave bus while the core performs read transfer on the master bus. The descriptions of operation in the sections below assume that the core has been implemented with support for AMBA SPLIT responses. The effects of disabling support for AMBA SPLIT responses are described in section 59.2.11.

If interrupt forwarding is enabled the interrupts on the IO bus interrupt lines will be forwarded to the system bus and vice versa.

59.2.2 AHB read transfers

When a read transfer is registered on the slave interface connected to the IO bus, the core gives a SPLIT response. The master that initiated the transfer will be de-granted allowing other bus masters to use the slave bus while the core performs a read transfer on the master side. The master interface then requests the bus and starts the read transfer on the master side. Single transfers on the slave side are normally translated to single transfers with the same AHB address and control signals on the master side, however read combining can translate one access into several smaller accesses. Translation of burst transfers from the slave to the master side depends on the burst type, burst length, access size and core configuration.

If the read FIFO is enabled and the transfer is a burst transfer to a prefetchable location, the master interface will prefetch data in the internal read FIFO. If the splitted burst on the slave side was an incremental burst of unspecified length (INCR), the length of the burst is unknown. In this case the master interface performs an incremental burst up to a specified address boundary (determined by the VHDL generic *rburst)*. The core can be configured to recognize an INCR read burst marked as instruction fetch (indicated on HPROT signal). In this case the prefetching on the master side is completed at the end of a cache line (the cache line size is configurable through the VHDL generic *iburst*). When the burst transfer is completed on the master side, the splitted master that initiated the transfer (on the slave side) is allowed in bus arbitration by asserting the appropriate HSPLIT signal to the AHB controller. The splitted master re-attempts the transfer and the core will return data with zero wait states.

If the read FIFO is disabled, or the burst is to non-prefetchable area, the burst transfer on the master side is performed using sequence of NONSEQ, BUSY and SEQ transfers. The first access in the burst on the master side is of NONSEQ type. Since the master interface can not decide whether the splitted burst will continue on the slave side or not, the system bus is held by performing BUSY transfers. On the slave side the splitted master that initiated the transfer is allowed in bus arbitration by asserting the HSPLIT signal to the AHB controller. The first access in the transfer is completed by returning read data. The next access in the transfer on the slave side is extended by asserting HREADY low. On the

GRIP

+46 31 7758650 | frontgrade.com/gaisler

master side the next access is started by performing a SEQ transfer (and then holding the bus using BUSY transfers). This sequence is repeated until the transfer is ended on the slave side.

In case of an ERROR response on the master side the ERROR response will be given for the same access (address) on the slave side. SPLIT and RETRY responses on the master side are re-attempted until an OKAY or ERROR response is received.

59.2.3   AHB write transfers

The core implements posted writes. During the AHB write transfer on the slave side the data is buffered in the internal write FIFO and the transfer is completed on the slave side by always giving an OKAY response. The master interface requests the bus and performs the write transfer when the master bus is granted. If the burst transfer crosses the write burst boundary (defined by VHDL generic *wburst*), a SPLIT response is given. When the core has written the contents of the FIFO out on the master side, the core will allow the master on the slave side to perform the remaining accesses of the write burst transfer.

Writes are accepted with zero wait states if the core is idle and the incoming access is not locked. If the incoming access is locked, each access will have one wait state. If write combining is disabled a non-locked BUSY cycle will lead to a flush of the write FIFO. If write combining is enabled or if the incoming access is locked, the core will not flush the write FIFO during the BUSY cycle.

59.2.4   Deadlock conditions

When two cores are used to form a bi-directional bridge, a deadlock situation can occur if the cores are simultaneously accessed from both buses. The core that has been configured as a slave contains deadlock detection logic which will resolve a deadlock condition by giving a RETRY response, or by issuing SPLIT complete followed by a new SPLIT response. When the core resolves a deadlock while prefetching data, any data in the prefetch buffer will be dropped when the core's slave interface issues the AMBA RETRY response. When the access is retried it may lead to the same memory locations being read twice.

Deadlock detection logic for bi-directional configurations may lead to deadlocks in other parts of the system. Consider the case where a processor on bus A on one side of the bidirectional bridge needs to perform an instruction fetch over the bridge before it can release a semaphore located in memory on bus A. Another processor on bus B, on the other side of the bridge, may spin on the semaphore waiting for its release. In this scenario, the accesses from the processor on bus B could, depending on system configuration, continuously trigger a deadlock condition where the core will drop data in, or be prevented from initiating, the instruction fetch for the processor on bus A. Due to scenarios of this kind the bridge should not be used in bi-directional configurations where dependencies as the one described above exist between the buses connected by the bridge.

Other deadlock conditions exist with locked transfers, see section 59.2.5.

59.2.5   Locked transfers

The core supports locked transfers. The master bus will be locked when the bus is granted and remain locked until the transfer completes on the slave side. Locked transfers can lead to deadlock conditions, the core's VHDL generic *lckdac* determines if and how the deadlock conditions are resolved.

With the VHDL generic *lckdac* set to 0, locked transfers may *not* be made after another read access which received SPLIT until the first read access has received split complete. This is because the core will return split complete for the first access first and wait for the first master to return. This will cause deadlock since the arbiter is not allowed to change master until a locked transfer has been completed. The AMBA specification requires that the locked transfer is handled before the previous transfer, which received a SPLIT response, is completed.

With *lckdac* set to 1, the core will respond with an AMBA ERROR response to locked access that is made while an ongoing read access has received a SPLIT response. With *lckdac* set to 2 the core will

GRIP
Apr 2024, Version 2024.1

752

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

save state for the read access that received a SPLIT response, allow the locked access to complete, and then complete the first access. All non-locked accesses from other masters will receive SPLIT responses until the saved data has been read out.

If the core is used to create a bi-directional bridge there is one more deadlock condition that may arise when locked accesses are made simultaneously in both directions. If the VHDL generic *lckdac* is set to 0 the core will deadlock. If *lckdac* is set to a non-zero value the slave bridge will resolve the deadlock condition by issuing an AMBA ERROR response to the incoming locked access.

59.2.6 Read and write combining

Read and write combining allows the core to assemble or split AMBA accesses on the core's slave interface into one or several accesses on the master interface. This functionality can improve bus utilization and also allows cores that have differing AMBA access size restrictions to communicate with each other. The functionality attained by read and write combining depends on the VHDL generics *rdcomb* (defines type of read combining), *wrcomb* (defines type of write combining), *slvmstaccsz* (defines maximum AHB access size supported by the core's slave interface) and *mstmaccsz* (defines maximum AHB access size that can be used by core's master interface). These VHDL generics are described in section 59.12.4. The table below shows the effect of different settings. BYTE and HALF-WORD accesses are special cases. The table does not list illegal combinations, for instance *mstmaccsz /= slvmaccsz* requires that *wrcomb /= 0* and *rdcomb /= 0*.

Table 864. Read and write combining

Access on slave interface	Access size	wrcomb	rdcomb	Resulting access(es) on master interface
BYTE or HALF-WORD single read access to any area	-	-	-	Single access of same size
BYTE or HALF-WORD read burst to prefetchable area	-	-	-	Incremental read burst of same access size as on slave interface, the length is the same as the number of 32-bit words in the read buffer, but will not cross the read burst boundary.
BYTE or HALF-WORD read burst to non-prefetchable area	-	-	-	Incremental read burst of same access size as on slave interface, the length is the same as the length of the incoming burst. The master interface will insert BUSY cycles between the sequential accesses.
BYTE or HALF-WORD single write	-	-	-	Single access of same size
BYTE or HALF-WORD write burst	-	-	-	Incremental write burst of same size and length, the maximum length is the number of 32-bit words in the write FIFO.
Single read access to any area	Access size <= mstmaccsz	-	-	Single access of same size
Single read access to any area	Access size > mstmaccsz	-	1	Sequence of single accesses of mstmaccsz. Number of accesses: (access size)/mstmaccsz
Single read access to any area	Access size > mstmaccsz	-	2	Burst of accesses of size mstmaccsz. Length of burst: (access size)/mstmaccsz
Read burst to prefetchable area	-	-	0	Burst of accesses of incoming access size up to address boundary defined by rburst.
Read burst to prefetchable area	-	-	1 or 2	Burst of accesses of size mstmaccsz up to address boundary defined by rburst.
Read burst to non-prefetchable area	Access size <= mstmaccsz	-	-	Incremental read burst of same access size as on slave interface, the length is the same as the length of the incoming burst. The master interface will insert BUSY cycles between the sequential accesses.

*Table 864.*Read and write combining

Access on slave interface	Access size	wrcomb	rdcomb	Resulting access(es) on master interface
Read burst to non-prefetch-able area	Access size > mstmaccsz	-	1 or 2	Burst of accesses of size mstmaccsz. Length of burst: (incoming burst length)*(access size)/mstmaccsz
Single write	Access size <= mstmaccsz	-	-	Single write access of same size
Single write	Access size > mstmaccsz	1	-	Sequence of single access of mstmaccsz. Number of accesses: (access size)/mstmaccsz.
Single write	Access size > mstmaccsz	2	-	Burst of accesses of mstmaccsz. Length of burst: (access size)/mstmaccsz.
Write burst	-	0	-	Burst of same size as incoming burst, up to address boundary defined by VHDL generic wburst.
Write burst	-	1 or 2	-	Burst write of maximum possible size. The core will use the maximum size (up to mstmaccsz) that it can use to empty the write buffer.

Read and write combining prevents the bridge from propagating fixed length bursts and wrapping bursts. See section 59.2.7 for a discussion on burst operation.

Read and write combining with VHDL generics *wrcomb/rdcomb* set to 1 cause the core to use single accesses when dividing an incoming access into several smaller accesses. This means that another master on the bus may write or read parts of the memory area to be accessed by the core before the core has read or written all the data. In bi-directional configurations, an incoming access on the master core may cause a collision that aborts the operation on the slave core. This may cause the core to read the same memory locations twice. This is normally not a problem when accessing memory areas. The same issues apply when using an AHB arbiter that performs early burst termination. The standard GRLIB AHBCTRL core does not perform early burst termination.

To ensure that the core does not re-read an address, and that all data in an access from the core's slave interface is propagated out on the master interface without interruption the VHDL generics *rdcomb* and *wrcomb* should both be set to 0 or 2. In addition to this, the AHB arbiter may not perform early burst termination (early burst termination is not performed by the GRLIB AHBCTRL arbiter).

Read and write combining can be limited to specified address ranges. See description of the *comb-mask* VHDL generic for more information. Note that if the core is implemented with support for prefetch and read combining, it will not obey combmask for prefetch operations (burst read to prefetchable areas). Prefetch operations will always be performed with the maximum allowed size on the master interface.

59.2.7 Burst operation

The core can be configured to support all AMBA 2.0 burst types (single access, incrementing burst of unspecified length, fixed length incrementing bursts and wrapping bursts). Single accesses and incrementing bursts of unspecified length have previously been discussed in this document. An incoming single access will lead to one access, or multiple accesses for some cases with read/write combining, on the other side of the bridge. An incoming incrementing burst of unspecified length to a prefetchable area will lead to the prefetch buffer (if available) being filled using the same access size, or the maximum allowed access size if read/write combining is enabled, on the master interface.

If the core is used in a system where no fixed length bursts or incremental bursts will be used in accesses to the bridge, then set the *allbrst* generic to 0 and skip the remainder of this section.

The VHDL generic *allbrst* controls if the core will support fixed length and wrapping burst accesses. If *allbrst* is set to 0, the core will treat all burst accesses as incrementing of unspecified length. For fixed length and wrapping bursts this can lead to performance penalties and malfunctions. Support for

fixed length and wrapping bursts is enabled by setting *allbrst* to 1 or 2. Table 59.2.7 describes how the core will handle different burst types depending on the setting of *allbrst*.

Table 865. Burst handling

Value of allbrst generic	Access type*	Undefined length incrementing burst INCR	Fixed length incrementing burst INCR{4,8,16}	Wrapping burst WRAP{4,8,16}
0	Reads to non-prefetchable area	Incrementing burst with BUSY cycles inserted. Same behaviour with read and write combining.	Fixed length burst with BUSY cycles inserted. If the burst is short then the burst may end with a BUSY cycle. If access combining is used the HBURST signal will get incorrect values.	Malfunction. Not supported
	Reads to prefetchable area	Incrementing burst of maximum allowed size, filling prefetch buffer, starting at address boundary defined by prefetch buffer.		Malfunction. Not supported
	Write burst	Incrementing burst	Incrementing burst, if write combining is enabled, and triggered, the burst will be translated to an incrementing burst of undefined length. VHDL generic *wrcomb* should not be set to 1 (but to 0 or 2) in this case	Write combining is not supported. Same access size will be used on both sides of the bridge.
1	Reads to non-prefetchable area	Incrementing burst with BUSY cycles inserted. Same behaviour with read and write combining.	Same burst type with BUSY cycles inserted. If read combining is enabled, and triggered by the incoming access size, an incremental burst of unspecified length will be used. If the burst is short then the burst may end with a BUSY cycle.	Same burst type with BUSY cycles inserted. If read combining is enabled, and triggered by the incoming access size, an incremental burst of unspecified length will be used. This will cause AMBA violations if the wrapping burst does not start from offset 0.
	Reads to prefetchable area	Incrementing burst of maximum allowed size, filling prefetch buffer.	For reads, the core will perform full (or part that fits in prefetch buffer) fixed/wrapping burst on master interface and then respond with data. No BUSY cycles are inserted. If the access made to the slave interface is larger than the maximum supported access size on the master interface then a incrementing burst of unspecified length will be used to fill the prefetch buffer. This (read combining) is not supported for wrapping bursts.	
	Write burst		Same as for allbrst = 0	
2	Reads to non-prefetchable area	Incrementing burst with BUSY cycles inserted. Same behaviour with read and write combining.	Reads are treated as a prefetchable burst. See below.	
	Reads to prefetchable area	Incrementing burst of maximum allowed size, filling prefetch buffer, starting at address boundary defined by prefetch buffer.	Core will perform full (or part that fits in prefetch buffer) fixed/wrapping burst on master interface and then respond with data. No BUSY cycles are inserted. If the access made to the slave interface is larger than the maximum supported access size on the master interface then a incrementing burst of unspecified length will be used to fill the prefetch buffer. This (read combining) is not supported for wrapping bursts.	
	Write burst		Same as for allbrst = 0	

 * Access to prefetchable area where the core's prefetch buffer is ised (VHDL generic pfen /= 0).

59.2.8 Transaction ordering, starvation and AMBA arbitration schemes

The core is configured at implementation to use one of two available schemes to handle incoming accesses. The core will issue SPLIT responses when it is busy and on incoming read accesses. If the core has been configured to use first-come, first-served ordering it will keep track of the order of incoming accesses and serve the requests in the same order. If first-come, first-served ordering is disabled the core will give some advantage to the master it has a response for and then allow all masters in to arbitration simultaneously, moving the decision on which master that should be allowed to access the core to the bus arbitration.

When designing a system containing a core the expected traffic patterns should be analyzed. The designer must be aware how SPLIT responses affect arbitration and how the selected transaction ordering in the core will affect the system. The two different schemes are further described in sections 59.2.9 and 59.2.10.

59.2.9 First-come, first-served ordering

First-come, first served ordering is used when the VHDL generic *fcfs* is non-zero.

With first-come, first-served ordering the core will keep track of the order of incoming accesses. The accesses will then be served in the same order. For instance, if master 0 initiates an access to the core, followed by master 3 and then master 5, the core will propagate the access from master 0 (and respond with SPLIT on a read access) and then respond with SPLIT to the other masters. When the core has a response for master 0, this master will be allowed in arbitration again by the core asserting HSPLIT. When the core has finished serving master 0 it will allow the next queued master in arbitration, in this case master 3. Other incoming masters will receive SPLIT responses and will not be allowed in arbitration until all previous masters have been served.

An incoming locked access will always be given precedence over any other masters in the queue.

A burst that has initiated a pre-fetch operation will receive SPLIT and be inserted last in the master queue if the burst is longer than the maximum burst length that the core has been configured for.

It should be noted that first-come, first-served ordering may not work well in systems where an AHB master needs to have higher priority compared to the other masters. The core will not prioritize any master, except for masters performing locked accesses.

59.2.10 Bus arbiter ordering

Bus arbiter ordering is used when VHDL generic *fcfs* is set to zero.

When several masters have received SPLIT and the core has a response for one of these masters, the master with the queued response will be allowed in to bus arbitration by the core asserting the corresponding HSPLIT signal. In the following clock cycle, all other masters that have received SPLIT responses will also be allowed in bus arbitration as the core asserts their HSPLIT signals simultaneously. By doing this the core defers the decision on the master to be granted next to the AHB arbiter. The core does not show any preference based on the order in which it issued SPLIT responses to masters, except to the master that initially started a read or write operation. Care has been taken so that the core shows a consistent behavior when issuing SPLIT responses. For instance, the core could be simplified if it could issue a SPLIT response just to be able to change state, and not initiate a new operation, to an access coming after an access that read out prefetched data. When the core entered its idle state it could then allow all masters in bus arbitration and resume normal operation. That solution could lead to starvation issues such as:

T0: Master 1 and Master 2 have received SPLIT responses, the core is prefetching data for Master 1

T1: Master 1 is allowed in bus arbitration by setting the corresponding HSPLIT

T2: Master 1 reads out prefetch data, Master 2 HSPLIT is asserted to let Master 2 in to bus arbitration

GRIP
Apr 2024, Version 2024.1
756
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

T3: Master 2 performs an access, receives SPLIT, however the core does not initiate an access, it just stalls in order to enter its idle state.

T4: Master 2 is allowed in to bus arbitration, Master 1 initiates an access that leads to a prefetch and Master 1 receives a SPLIT response

T5: Master 2 performs an access, receives SPLIT since the core is prefetching data for master 1

T6: Go back to T0

This pattern will repeat until Master 1 backs away from the bus and Master 2 is able to make an access that starts an operation over the core. In most systems it is unlikely that this behavior would introduce a bus lock. However, the case above could lead to an unexpectedly long time for Master 2 to complete its access. Please note that the example above is illustrative and the problem does not exist in the core as the core does not issue SPLIT responses to (non-locked) accesses in order to just change state but a similar pattern could appear as a result of decisions taken by the AHB arbiter if Master 1 is given higher priority than Master 2.

In the case of write operations the scenario is slightly different. The core will accept a write immediately and will not issue a SPLIT response. While the core is busy performing the write on the master side it will issue SPLIT responses to all incoming accesses. When the core has completed the write operation on the master side it will continue to issue SPLIT responses to any incoming access until there is a cycle where the core does not receive an access. In this cycle the core will assert HSPLIT for all masters that have received a SPLIT response and return to its idle state. The first master to access the core in the idle state will be able to start a new operation. This can lead to the following behavior:

T0: Master 1 performs a write operation, does NOT receive a SPLIT response

T1: Master 2 accesses the core and receives a SPLIT response

T2: The core now switches state to idle since the write completed and asserts HSPLIT for Master 2.

T3: Master 1 is before Master 2 in the arbitration order and we are back at T0.

In order to avoid this last pattern the core would have to keep track of the order in which it has issued SPLIT responses and then assert HSPLIT in the same order. This is done with first-come, first-served ordering described in section 59.2.9.

59.2.11 AMBA SPLIT support

Support for AMBA SPLIT responses is enabled/disabled through the VHDL generic *split*. SPLIT support should be enabled for most systems. The benefits of using SPLIT responses is that the bus on the core's slave interface side can be free while the core is performing an operation on the master side. This will allow other masters to access the bus and generally improve system performance. The use of SPLIT responses also allows First-come, first-served transaction ordering.

For configurations where the core is the only slave interface on a bus, it can be beneficial to implement the core without support for AMBA SPLIT responses. Removing support for SPLIT responses reduces the area used by the core and may also reduce the time required to perform accesses that traverse the core. It should be noted that building a bi-directional core without support for SPLIT responses will increase the risk of access collisions.

If SPLIT support is disabled the core will insert wait states where it would otherwise issue a SPLIT response. This means that the arbitration ordering will be left to the bus arbiter and the core cannot be implemented with the First-come, first-served transaction ordering scheme. The core will still issue RETRY responses to resolve dead lock conditions, to split up long burst and also when the core is busy emptying it's write buffer on the master side.

The core may also be implemented with dynamic SPLIT support, this allows the use of SPLIT responses to be configurable via the core's register interface (see SP field in the core's Control register).

59.2.12 Core latency

The delay incurred when performing an access over the core depends on several parameters such as core configuration, the operating frequency of the AMBA buses, AMBA bus widths and memory access patterns. This section deals with latencies in the core's bridge function. Access protection mechanisms may add additional delays, please refer to the description of access protection for a description of any additional delays.

Table 866 below shows core behavior in a system where both AMBA buses are running at the same frequency and the core has been configured to use AMBA SPLIT responses. Table 867 further down shows core behavior in the same system without support for SPLIT responses.

Table 866. Example of single read with FFACT = 1, and SPLIT support

Clock cycle	Core slave side activity	Core master side activity
0	Discovers access and transitions from idle state	Idle
1	Slave side waits for master side, SPLIT response is given to incoming access, any new incoming accesses also receive SPLIT responses.	Discovers slave side transition. Master interface output signals are assigned.
2		If bus access is granted, perform address phase. Otherwise wait for bus grant.
3		Register read data and transition to data ready state.
4	Discovers that read data is ready, assign read data output and assign SPLIT complete	Idle
5	SPLIT complete output is HIGH	
6	Typically a wait cycle for the SPLIT:ed master to be allowed into arbitration. Core waits for master to return. Other masters receive SPLIT responses.	
7	Master has been allowed into arbitration and performs address phase. Core keeps HREADY high	
8	Access data phase. Core has returned to idle state.	

Table 867. Example of single read with FFACT = 1, without SPLIT support

Clock cycle	Core slave side activity	Core master side activity
0	Discovers access and transitions from idle state	Idle
1	Slave side waits for master side, wait states are inserted on the AMBA bus.	Discovers slave side transition. Master interface output signals are assigned.
2		Bus access is granted, perform address phase.
3		Register read data and transition to data ready state.
4	Discovers that read data is ready, assign HREADY output register and data output register.	Idle
5	HREADY is driven on AMBA bus. Core has returned to idle state	

While the transitions shown in tables 866 and 867 are simplified they give an accurate view of the core delay. If the master interface needs to wait for a bus grant or if the read operation receives wait states, these cycles must be added to the cycle count in the tables. The behavior of the core with a fre-

quency factor of two between the buses is shown in tables 868 and 869 (best case, delay may be larger depending on which slave clock cycle an access is made to the core).

Table 868. Example of single read with FFACT = 2, Master freq. > Slave freq, without SPLIT support

Slave side clock cycle	Core slave side activity	Master side clock cycle	Core master side activity
0	Discovers access and transitions from idle state	0	Discovers slave side transition. Master interface output signals are assigned.
1	Slave side waits for master side, wait states are inserted on the AMBA bus.		
2		1	Bus access is granted, perform address phase.
3			
4		2	Register read data and transition to data ready state.
5			
6	Discovers that read data is ready, assign HREADY output register and data output register.	3	Idle
7	HREADY is driven on AMBA bus. Core has returned to idle state		

Table 869. Example of single read with FFACT = 2, Master freq. > Slave freq, without SPLIT support

Slave side clock cycle	Core slave side activity	Master side clock cycle	Core master side activity
0	Discovers access and transitions from idle state	0	Idle
		1	
1	Slave side waits for master side, wait states are inserted on the AMBA bus.	2	Discovers slave side transition. Master interface output signals are assigned.
		3	Bus access is granted, perform address phase.
2	Discovers that read data is ready, assign HREADY output register and data output register.	4	Register read data and transition to data ready state.
		5	Idle
3	HREADY is driven on AMBA bus. Core has returned to idle state	6	
		7	

Table 870 below lists the delays incurred for single operations that traverse the bridge while the bridge is in its idle state. The second column shows the number of cycles it takes the master side to perform the requested access, this column assumes that the master slave gets access to the bus immediately and that each access is completed with zero wait states. The table only includes the delay incurred by traversing the core. For instance, when the access initiating master reads the core's prefetch buffer, each additional read will consume one clock cycle. However, this delay would also have been present if the master accessed any other slave.

Write accesses are accepted with zero wait states if the bridge is idle, this means that performing a write to the idle core does not incur any extra latency. However, the core must complete the write operation on the master side before it can handle a new access on the slave side. If the core has not transitioned into its idle state, pending the completion of an earlier access, the delay suffered by an access be longer than what is shown in the tables in this section. Accesses may also suffer increased delays during collisions when the core has been instantiated to form a bi-directional bridge. Locked accesses that abort on-going read operations will also mean additional delays.

GRIP
Apr 2024, Version 2024.1

759

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

If the core has been implemented to use AMBA SPLIT responses there will be an additional delay where, typically, one cycle is required for the arbiter to react to the assertion of HSPLIT and one clock cycle for the repetition of the address phase.

Note that if the core has support for read and/or write combining, the number of cycles required for the master will change depending on the access size and length of the incoming burst access. For instance, in a system where the bus in the core's master side is wider than the bus on the slave side, write combining will allow the core to accept writes with zero wait states and then combine several accesses into one or several larger access. Depending on memory controller implementation this could reduce the time required to move data to external memory, and will reduce the load on the master side bus.

Table 870. Access latencies

Access	Master acc. cycles	Slave cycles	Delay incurred by performing access over core
Single read	3	1	$1 * clk_{slv} + 3 * clk_{mst}$
Burst read with prefetch	$2 + (burst\ length)^x$	2	$2 * clk_{slv} + (2 + burst\ length) * clk_{mst}$
Single write^{xx}	(2)	0	0
Burst write^{xx}	(2 + (burst length))	0	0

^{x} A prefetch operation ends at the address boundary defined by the prefetch buffer's size

^{xx} The core implements posted writes, the number of cycles taken by the master side can only affect the next access.

59.2.13 Endianness

The core is designed for big-endian systems.

59.3 General access protection and address translation

59.3.1 Overview

The core provides two types of access protection. The first option is to use a bit vector to implement access restriction on a memory page basis. The second option is to use a page-table to provide access restriction and address translation. Regardless of the protection strategy, the core provides means to assign masters on the IO bus in groups where each group can be associated with a data structure (access restriction vector or page table) in memory. The core can be implemented to support a dynamically configurable page size from 4 to 512 KiB, or a fixed page size of 4 KiB.

When a master on the IO bus initiates an access to be propagated by the core, the core will first look at the incoming master's group assignment setting to determine to which group the master belongs. When the group is known, the core can propagate or inhibit the access based on the group's attributes, or determine the address of the in-memory data structures to use for access checks (and possibly address translation). The in-memory data structure may be cached by the core, otherwise the information will be fetched from main memory.

Once the core has the necessary information to process the incoming access, the access will be either allowed to propagate through the core or, in case the access is to a restricted memory location, be inhibited. If the access is inhibited, the core will issue an AMBA ERROR response to the master if the incoming access is a read access. The core implements posted writes, therefore write operations will not receive an AMBA ERROR response. An interrupt can, optionally, be asserted when an access is inhibited. The AHB failing access register can be configured to log the first or most recent access that was inhibited.

When enabled, the core always checks access permissions when a master initiates an access. For the access protection and translation operation to be effective the masters are required to adhere to the AMBA 2.0 specification and not issue burst transfers that cross a 1 KiB address boundary.

GRIP

Apr 2024, Version 2024.1

760

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

It is possible for masters to access the core's register interface through the core. In this case the core will perform an access to itself on the System AHB bus. For configurations where the core is used to form a bi-directional core, any data structures read by the core must be located on the same bus as the core's master interface. The core cannot access data structures that are placed on the same bus as masters that the core protects against, in other words data structures must be accessible on a slave on the System bus, see figure 145.

59.3.2 Delays incurred from access protection

The time required for the core's master interface to start an access may be delayed by access protection checks. Table 871 below shows the added delays, please refer to section 59.2.12 for a description of delays from the core's bridge operation.

Table 871. Access protection check latencies

Protection mode	Delay in clock cycles on master side
Disabled	0
Write-protection only and read access	0
Master assigned to group in passthrough or inactive group	1
Access Protection Vector, cache hit	1
Access Protection Vector cache miss, cache disabled/not implemented	Minimum[x] 4 clock cycles
IOMMU Protection, cache hit	1
IOMMU Protection, TLB miss, TLB disabled/not implemented	Minimum[x] 4 clock cycles

[x] The core may suffer additional AMBA bus delays when accessing the vector in memory. 4 cycles is the minimum time required and assumes that the core is instantly granted access to the bus and that data is delivered with zero wait states.

59.4 Access Protection Vector

The Access Protection Vector (APV) consists of a continuous bit vector where each bit determines the access rights to a memory page. The bit vector provides access restriction on the full 4 GiB AMBA address space. The required size of the bit vector depends on the page size used by the core, see table below:

Table 872. Bit vector size vs. page size

Page size	Bit vector size
4 KiB	128 KiB
8 KiB	64 KiB
16 KiB	32 KiB
32 KiB	16 KiB
64 KiB	8 KiB
128 KiB	4 KiB
256 KiB	2 KiB
512 KiB	1 KiB

Each group can have a bit vector with a base address specified by a field in the group's Group Control Register. When a master performs an access to the core, the master's group number is used to select one of the available bit vectors. The AMBA access size used to fetch the vector is fixed at implementation time and can be read out from the core's Capability register 1. If the AMBA access size to use is 32-bits (WORD sized) and the page size is 4 KiB, bits 31:17 of the incoming address (HADDR) are used to index a word in the bit vector, and bits HADDR[16:12] are used to select one of the 32 bits in the word. For each increase in AMBA access size (DWORD, 4WORD, 8WORD), one bit less of the

GRIP
Apr 2024, Version 2024.1

761

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

physical address is used to index the vector and this bit is instead used to select one specific bit in the data read from memory. Similarly, for each increase in page size one bit less of the physical address is used.

The lowest page is protected by the most significant bit in the bit vector. This means that page 0 is protected by the most significant bit in byte 0 read from the bit vector's base address (using big endian addressing). When performing WORD accesses, the lowest page is protected by bit 31 in the accessed word (using the bit numbering convention used throughout this document).

If the bit at the selected position is '0', the access to the page is allowed and the core will propagate the access. If the selected bit is '1', and the access is an read access, an AMBA ERROR response is given to the master initiating the access. If the selected bit is '1', and the access is a write access, the write is inhibited (not propagated through the core).

59.4.1 Access Protection Vector cache

The core can be implemented with an internal memory that caches the Access Protection Vector. The cache size is configurable at implementation time and depends on a number of parameters that can be read out via Capability registers 0 and 1. If the core has been implemented with IOMMU functionality and a IOMMU Translation Lookaside Buffer (TLB), the RAMs in the APV cache will be shared with the IOMMU TLB.

The cache is implemented as a direct-mapped cache built up of one data RAM and one tag RAM. The number of locations in each RAM is the number of lines in the cache. The width of the data RAM (cache line size) is the same as the size of the AMBA accesses used to fetch the APV from main memory. The width and contents of the tag RAM depends on the number of supported groups, cache line size and number of lines in the cache.

The address used to select a position in the RAMs, called the set address, must have *log2(number of lines in the cache)* bits. The number of address bits taken from the physical address required to uniquely address one position in the bit vector depends on the cache line size. The number of required bits for each allowed cache line size is shown in table 873 below.

*Table 873.*Cache line size vs. physical address bits

Cache line size in bits	Bits of physical address needed to identify one position depending on page size							
	4 KiB	8 KiB	16 KiB	32 KiB	64 KiB	128 KiB	256 KiB	512 KiB
32	15	14	13	12	11	10	9	8
64	14	13	12	11	10	9	8	7
128	13	12	11	10	9	8	7	6
256	12	11	10	9	8	7	6	5

If the core has support for more than one group, the cache must also be tagged with the group ID. The number of bits required to uniquely select one group is *log2(number of groups)*.

This means that in order to be able to cache the full bit vectors for all supported groups the cache address (set address) must have *log2(number of groups) + (required physical address bits)* address bits. The number of required lines in the cache to be able to hold all vectors is:

*cache lines = (number of groups) * (2^{20} / (cache line size))*

If the cache size is not large enough to hold a copy of each position in the bit vector, part of the physical address and group will be placed in the cache tag RAM instead. If the number of lines in the cache allows keeping a cached data of all positions in all bit vectors, the set address and tag data arrangement shown in table 874 will be used.

For the set address/tag RAM tables below the following values are used:

Not present	Group ID	High bits of physical address	V

0   Valid (V) - Signals that addressed position in cache contains valid data

In the first arrangement, where *(set address bits) = (group ID bits) + (physical address bits)*, there will never be a collision in the cache. In the two other arrangements there is not room for all positions in the bit vector(s). This means that a cached copy for one memory page can be replaced with the bit vector for another memory page. Since the physical address is used as the set address, accesses from a master assigned to one group may evict cached bit vector data belonging to another group. This may not be wanted in systems where interference between groups of masters should be minimized. In order to minimize inter-group interference, the core can be implemented with support for using as much of the group ID as possible in the set address, this functionality is called group-set-addressing.

The core has support for group-set-addressing if the CA field in Capability register 0 is non-zero. If the number of set address bits (cache lines) is large enough to cache all bit vectors, the set address and

tag RAM arrangement will be as described by table 874. If the number of set address bits will allow the whole group ID to be part of the set address, the arrangement will be:

Table 877. Group set address: Set address bits < (group ID bits) + (Physical address bits)

Set address:

31	SB	GB-1	0
Not present	Low bits of physical address	Group ID	

Contents of Tag RAM:

31	1	0
Not present	High bits of physical address	V

0	Valid (V) - Signals that addressed position in cache contains valid data

If only part of the group ID can be used for the set address, the arrangement will be:

Table 878. Group set address: Set address bits < (group ID bits)

Set address:

31	GB-SB-1	0
Not present	Low part of Group ID	

Contents of Tag RAM:

31	1	0
Not present	Physical address	High part of group ID	V

0	Valid (V) - Signals that addressed position in cache contains valid data

Group-set-addressing is enabled via the GS field in the core's Control register.

59.4.2 Constraining the memory area covered by the APV cache

In a typical system, the normal case for an AMBA master core is to perform accesses to main memory. In order to reduce latency, the protection data for these accesses is ideally cached within the core. However, main memory is not likely to occupy the full AMBA address range. If accesses outside a certain access range is expected to be rare, and if it is not critical if these accesses suffer a higher latency, it can be beneficial to restrict the memory range for which the core caches the Access Protection Vector. The benefit of this is that the cache size can be reduced while the same hit rate is kept for the specified memory area, alternatively the hit rate could possibly be increased while keeping the cache size constant.

The core can be configured at implementation to only cache the bit vector for a specified memory range. Capability register 1 contains an address and a mask that describes this area. Bit vector data for the specified memory range will be cached by the core. Bit vector data for accesses made outside the memory range will not be placed in the cache, and will instead be fetched for memory on each access. The impact of having a non-zero mask in Capability register 1 is that for each '1' in the mask, one physical address bit can be removed from the cache set address in the examples given earlier in this section.

59.4.3 Access Protection Vector cache flush operation

If the contents of a vector is modified the core cache must be flushed by writing to the TLB/Cache Flush Register. The TLB/Cache Flush register contains fields to flush the entire cache or to flush the lines belonging to a specified group. In order to flush entries for a specific group, group-set-addressing must be implemented and enabled. Performing a group flush without group-set-addressing may only flush part of the cache and can lead to unexpected behavior.

The core will not propagate any transfers while a cache flush operation is in progress.

59.5 IO Memory Management Unit (IOMMU) functionality

The IOMMU functionality of the core provides address translation and access protection on the full 4 GiB AMBA address space. The size of the address range where addresses are translated is specified by the IOMMU Translation Range (ITR) field in the core's Control register:

*Size of translated address range in MiB = 16 MiB * 2^{ITR}*

The maximum allowed value of the ITR field is eight, which means that the IOMMU can provide address translation to an area of size $16*2^8 = 4096$ MiB, which is the full 32-bit address space. When ITR is set to eight and a page size of 4 KiB is used, bits 31:12 of the incoming IO address are translated to physical addresses, using IO Page Tables entries describes below. Bits 11:0 of the incoming access are propagated through the IOMMU. For each increase in page size one more bit will be directly propagated through the IOMMU instead of being translated.

If ITR is less then eight the most significant bits of the IO address must match the value of the TMASK field in Capability register 2. If an access is outside the range specified by TMASK the access will be inhibited. Table 879 shows the effect of different ITR values. As an example, with ITR set to 2, the IOMMU will perform address translation for a range that spans 64 MiB. This range will be located at offset TMASK[31:26]. Accesses to addresses that do not have their most significant bits set to match TMASK[31:26] will be inhibited. The table also shows the number of pages within the decoded range and the memory required to hold the translation information (page tables) in main memory. The *pgsz* value is the value of the PGSZ field in the control register.

Table 879. Effects of IOMMU Translation Range setting

ITR	Size of translated range	TMASK bits used	Number of pages	Size of page tables
0	16 MiB	TMASK[31:24]	$4096 / 2^{pgsz}$	$16 / 2^{pgsz}$ KiB
1	32 MiB	TMASK[31:25]	$8192 / 2^{pgsz}$	$32 / 2^{pgsz}$ KiB
2	64 MiB	TMASK[31:26]	$16384 / 2^{pgsz}$	$64 / 2^{pgsz}$ KiB
3	128 MiB	TMASK[31:27]	$32768 / 2^{pgsz}$	$128 / 2^{pgsz}$ KiB
4	256 MiB	TMASK[31:28]	$655536 / 2^{pgsz}$	$256 / 2^{pgsz}$ KiB
5	512 MiB	TMASK[31:29]	$131072 / 2^{pgsz}$	$512 / 2^{pgsz}$ KiB
6	1024 MiB	TMASK[31:30]	$262144 / 2^{pgsz}$	$1 / 2^{pgsz}$ MiB
7	2048 MiB	TMASK[31]	$524288 / 2^{pgsz}$	$2 / 2^{pgsz}$ MiB
8	4096 MiB	TMASK not used	$1048576 / 2^{pgsz}$	$4 / 2^{pgsz}$ MiB

59.5.1 IO Page Table Entry

Address translation is performed by looking up translation information in a one-level table present in main memory. Part of the incoming address is used to index the table that consists of IO Page Table Entries. The format of an IO Page Table Entry (IOPTE) is shown in table 880 below.

Table 880. IOMMU Page Table Entry (IOPTE)

31							8	7	6	5	4	3	2	1	0
PPAGE								C	R		BO	BS	W	V	R

31:8	Physical Page (PPAGE) - Bits 27:8 of this field corresponds to physical address bits 31:12 of the page. With a 4 KiB page size, PPAGE[27:8] is concatenated with the incoming IO address bits [11:0] to form the translated address. For each increase in page size one bit less of PPAGE is used and one bit more of the incoming IO address is used: this means that with a 16 KiB page size , PPAGE[27:10] will be concatenated with the incoming IO address bits [13:0] to form the translated address.
	Bits 31:27 of this field are currently discarded by the IOMMU and are present in the data structure for forward compatibility with systems using 36-bit AMBA address space.
7	Cacheable (C) - This field is currently not used by the IOMMU
6:5	RESERVED
4	Bus select Override (BO) - If this field is set to '1' then the bus selection is made via the IOPTE.BS field.
3	Bus Select (BS) - Overrides master configuration register BS field when BO field in this PTE is set.
2	Writeable (W) - If this field is '1' write access is allowed to the page. If this field is '0', only read accesses are allowed.
1	Valid (V) - If this field is '1' the PTE is valid. If this field is '0', accesses to the page covered by this PTE will be inhibited.
0	RESERVED

When the core has IOMMU protection enabled all, incoming accesses from masters belonging to an active group, which is not in pass-through mode, will be matched against TMASK. If an access is outside the range specified by ITR/TMASK, the access will be inhibited and may receive an AMBA ERROR response (not applicable when the access is a posted write).

If the incoming access is within the range specified by ITR/TMASK, the core will use the incoming IO address to index the page table containing the address translation information for the master/IO address. The core may be implemented with an Translation Lookaside Buffer (TLB) that may hold a cached copy of the translation information. Otherwise the translation information will be fetched from main memory. The base address of the page table to use is given by the Group Configuration register to which the master performing the access is assigned. Please see the register description of the Group Configuration register for constraints on the page table base address. The core will use bits X:Y to index the table, where X depends on the value of the ITR field in the core's Control register, and Y depends on the page size (Y = 12 + PGSZ field in Control register).

When the core has fetched the translation information (IOPTE) for the accesses page it will check the IOPTE's Valid (V) and Writeable (W) fields. If the IOPTE is invalid, the access will be inhibited. If the Writeable (W) field is unset and the access is a write access, the access will be inhibited. Otherwise the core will, for a page size of 4 KiB, use the IOPTE field PPAGE, bits 27:8, and bits 11:0 of the incoming IO address to form the physical address to use when the access is propagated by the core (physical address: PPAGE[27:8] & IOADDR[11:0]).

If the valid (V) bit of the IOPTE is '0' the core may or may not store the IOPTE in the TLB (if implemented). This is controlled via the SIV field in the core's Control register.

59.5.2 Prefetch operations and IOMMU protection

During normal bridge operation, and with Access Protection Vector protection, the core determines if data for an access can be prefetched by looking at the IO address and the System bus plug and play

GRIP
Apr 2024, Version 2024.1

766

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

information. This operation cannot be done without introducing additional delays when the core is using IOMMU protection. The incoming IO address must first be translated before it can be determined if the access is to a memory area that can be prefetched. In order to minimize delays the core makes the assumption that any incoming burst access is to a prefetchable area. The result is that when using IOMMU protection all burst accesses will result in the core performing a prefetch operation.

59.5.3   Translation Lookaside Buffer operation

The core can be implemented with an internal memory that caches IO Page Table Entries. This memory is referred to as a Translation Lookaside Buffer (TLB). The TLB size is configurable at implementation time and depends on a number of parameters that can be read out via Capability registers 0 and 2. If the core has been implemented with Access Protection Vector functionality and an APV cache, the RAMs for the APV cache will be shared with the IOMMU TLB.

The TLB is implemented as a direct-mapped cache built up of one data RAM and one tag RAM. The number of locations in each RAM is the number of entries in the TLB. The width of the data RAM (entry size) is the same as the size of the AMBA accesses used to fetch page table entries from main memory. The width and contents of the tag RAM depends on the number of supported groups, entry size and number of entries in the TLB.

The address used to select a position in the RAMs, called the set address, must have *log2(number of entries in the TLB)* bits. The number of address bits taken from the physical address required to uniquely address one position in the TLB depends on the entry size. The number of required bits for each allowed entry size is shown in table 873 below, the values in the third column is the number of address bits that must be used to accommodate the largest translatable range (maximum value of ITR field in the core's Control register). Note that an entry size larger than 32 bits results in an TLB that holds multiple IOPTEs per entry.

Table 881. TLB entry size vs. physical address bits

Entry size in bits	Entry size in IOPTEs	Bits of physical address needed to identify one position depending on page size							
		4 KiB	8 KiB	16 KiB	32 KiB	64 KiB	128 KiB	256 KiB	512 KiB
32	1	20	19	18	17	16	15	14	13
64	2	19	18	17	16	15	14	13	12
128	4	18	17	16	15	14	13	12	11
256	8	17	16	15	14	13	12	11	10

If the core has support for more than one group, the TLB entries must also be tagged with the group ID. The number of bits required to uniquely select one group is *log2(number of groups)*.

This means that in order to be able to cache the page tables for all supported groups the TLB address (set address) must have *log2(number of groups) + (required physical address bits)* address bits. The number of required entries in the TLB to be able to hold all vectors is:

TLB entries = (number of groups) * (2^{20} / (entry size))

If the TLB is not large enough to hold a copy of each position in the page table, part of the physical address and group will be placed in the tag RAM. The core will implement the TLB depending on the parameters mentioned above. If the number of entries in the TLB allows keeping a copy of all positions in all page tables, the set address and tag data arrangement shown in table 882 will be used.

For the set address/tag RAM tables below the following values are used:

SB = Set address bits = log2(number of TLB entries)
HB = Required number of bits of physical address = See table 881 above.
GB = Required number of bits to select one group = *log2(number of groups)*

Table 882. Set address bits = (group ID bits) + (Physical address bits)

Set address:

31		(HB+BG-1) HB	(HB-1)	0
Not present		Group ID	Physical address	

Contents of Tag RAM:

31	0
Not present	V

0	Valid (V) - Signals that addressed position in cache contains valid data

If the number of entries in the TLB allows part of the group ID to be part of the set address, the arrangement will be:

Table 883. Set address bits < (group ID bits) + (Physical address bits)

Set address:

31		SB	HB	HB-1	0
Not present		Part of Group ID		Physical address	

Contents of Tag RAM:

31	0
Not present	Part of Group ID	V

0	Valid (V) - Signals that addressed position in cache contains valid data

If the number of entries in the TLB only allows part of the required physical address to be part of the set address, the arrangement will be:

Table 884. Set address bits < (group ID bits) + (Physical address bits)

Set address:

31	SB	0
Not present	Low bits of physical address	

Contents of Tag RAM:

31		HB-SB	1	0
Not present	Group ID	High bits of physical address		V

0	Valid (V) - Signals that addressed position in cache contains valid data

In the first arrangement, where *(set address bits) = (group ID bits) + (physical address bits)*, there will never be a collision in the TLB. In the two other arrangements there is not room for all entries in the page table(s). This means that a cached IOPTE for one memory page can be replaced with the IOPTE for another memory page. Since the physical address is used as the set address, accesses from a master assigned to one group may evict cached IOPTE's belonging to another group. This may not be wanted in systems where interference between groups of masters should be minimized. In order to minimize inter-group interference, the core can be implemented with support for using as much of the group ID as possible in the set address, this functionality is called group-set-addressing.

The core has support for group-set-addressing if the IT field in Capability register 0 is non-zero. If the number of set address bits (TLB entries) is large enough to cache all page tables, the set address and

tag RAM arrangement will be as described by table 882. If the number of set address bits will allow the whole group ID to be part of the set address, the arrangement will be:

Table 885. Group set address: Set address bits < (group ID bits) + (Physical address bits)

Set address:

31		SB	(GB-1)	0
Not present		Low bits of physical address	Group ID	

Contents of Tag RAM:

31		1	0
Not present		High bits of physical address	V

0	Valid (V) - Signals that addressed position in cache contains valid data

If only part of the group ID can be used for the set address, the arrangement will be:

Table 886. Group set address: Set address bits < (group ID bits)

Set address:

31	GB-SB-1	0
Not present	Low part of group ID	

Contents of Tag RAM:

31			1	0
Not present	Physical address	High part of Group ID	V	

0	Valid (V) - Signals that addressed position in cache contains valid data

Group-set-addressing is enabled via the GS field in the core's Control register.

59.5.4 TLB flush operation

If the contents of a page table is modified the TLB must be flushed by writing to the TLB/Cache Flush Register. The TLB/Cache Flush register contains fields to flush the entire TLB or to flush the entries belonging to a specified group. In order to flush entries for a specific group, group-set-addressing must be implemented and enabled. Performing a group flush without group-set-addressing may only flush part of the TLB and can lead to unexpected behavior.

When working in IOMMU mode, the core can be configured to not store a IOPTE in the TLB if the IOPTE's valid (V) bit is cleared. This behavior is controller via the SIV field in the core's Control register.

The core will not propagate any transfers while a flush operation is in progress.

59.6 Fault-tolerance

In order to attain fault-tolerance the core should be implemented with inferred memory technology for the read buffer, write buffer and any FCFS buffer. This will implement the buffers in flip-flops and the core must then be implemented using techniques such as radiation hardened registers or TMR insertion.

The Access Protection Vector cache and IOMMU TLB can be implemented with the same options as above or using non-protected memory cells. When using non-protected memory cells the core can be implemented to use byte-parity to protect entries in the cache/TLB. If an error is detected it will be processed as a cache/TLB miss and the data will be re-read from main memory. A detected error will also be reported via the core's status register and the core also has support for signaling errors via its statistic output.

Errors can be injected in the Access Protection Vector cache and IOMMU TLB via the Data and Tag RAM Error Injection registers.

59.7 Statistics

In order to record statistics, a LEON4 Statistics Unit should be connected to the core. The core has the following statistics outputs:

*Table 887.*IOMMU Statistics

Output	Description
hit	High for one cycle during TLB/cache hit.
miss	High for one cycle during TLB/cache miss
pass	High for one cycle during passthrough access
accok	High for one cycle during access allowed
accerr	High for one cycle during access denied
walk	High while core is busy performing a table walk or accessing the access protection vector
lookup	High while core is performing cache lookup/table walk
perr	High for one cycle when core detects a parity error in the APV cache

59.8 Multi-bus bridge

The core can be instantiated in a version with two AHB master interfaces. These interfaces can be connected to separate AHB buses. The top-level entity griommu_mb contains additional signals for the second AHB master interface. Using the griommu_mb entity will enable bus select fields in the core's master configuration registers and the LB field in the core's control register. The bus select fields in the Master configuration registers allows the user to select which AHB master interface that should be used for accesses initiated by a specific master. The control register field LB selects which AHB master interfaces that should be used when the core fetches IOPTEs or APV bit vector data from memory.

Note that the bus selection in registers is active even if the core is disabled through the core's control register.

59.9 ASMP support

In some systems there may be a need to have separated instances of software each controlling a group of masters. In this case, sharing of the IOMMU register interface may not be wanted as it would allow software to modify the protection settings for a group of masters that belongs to another software instance. The core can be implemented with ASMP support to support systems where software entities are separated by address space. In this case, the core's register interface is mirrored on different 4 KiB pages. Different write protection settings can be set for each mirrored block of registers. This allows use of a memory management unit to control that software running can write to one, and only one, subset of registers.

When ASMP support is enabled, the field NARB in Capability register 0 is non-zero. The value of NARB tells how many ASMP register blocks that are available. Each ASMP register block mirrors the standard register set described in section 59.10 with the addition that some registers may be write protected. Table 888 contains a column that shows if a register is writable when accessed from an ASMP register block. The core's Control register, Master configuration register(s), Diagnostic cache registers, the ASMP access control register(s) can never be written via ASMP register block. These registers are only available in the first register set starting at the core register set base address. ASMP register block *n* is mapped at an offset *n**0x1000 from the core's register base address.

Software should first set up the IOMMU and assign the masters into groups. Then the ASMP control registers should be configured to constrain which registers that can be written from each ASMP block. After this initialization is done, other parts of the software environment can be brought up.

GRIP
Apr 2024, Version 2024.1
770
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

As an example, consider the case where OS A will control masters 0, 1 and 4 while OS B will control masters 2 and 3. In this case it may be appropriate to map masters 0, 1 and 4 to group 0 and master 2 and 3 to group 1. The ASMP access control registers can then be configured to only allow accesses to the Group control register for group 0 from ASMP register block 1 and likewise only allow accesses to the Group control register for group 1 from ASMP register block 2.

OS A will then map in ASMP register block 1 (registers within page located at core base offset + 0x1000) and OS B will then map in ASMP register block 2 (registers within page located at core base offset + 0x2000). This way OS a will be able to change the base address and the properties of group 0, containing its masters, without being able to change the protection mechanisms of group 1 belonging to OS B. Note that since an OS is able to flush the TLB/cache it is able to impact the I/O performance of masters assigned to other OS instances. Also note that care must be taken when clearing status bits and setting the mask register that controls interrupt generation.

59.10 Registers

The core is programmed through registers mapped into AHB I/O address space. All accesses to register address space must be made with word (32-bit) accesses.

*Table 888.*GRIOMMU registers

AHB address offset	Register	Writable in ASMP block
0x00	Capability register 0	No
0x04	Capability register 1	No

15	IOMMU functionality enable (I) - If this bit is '1', the core has support for IOMMU functionality.
14	IOMMU TLB (IT) - If this bit is '1', the core has an IOMMU Translation Lookaside Buffer (TLB)
13	IOMMU Addressing (IA): 0: Core only supports standard addressing, group number is used as tag 1: Core supports using group ID as part of TLB set address
12	IOMMU TLB Address Pipeline (IP) - If this bit is set to '1' the core has a pipeline stage added on the TLB's address. This means one cycle additional latency.
11:9	RESERVED
8	Multi-bus (MB) - Set to 1 if core is connected to two system buses.
7:4	Number of groups (GRPS) - Number of groups that the core has been implemented to support - 1.
3:0	Numbers of masters (MSTS) - Number of masters that the core has been implemented to support - 1.

Reset value: Implementation dependent

59.10.2 Capability Register 1

*Table 890.*0x04 - LAP1 - Capability register 1

31		20	19	16	15		8	7	5	4	0
CADDR			CMASK		CTAGBITS			CISIZE		CLINES	
*			*		*			*		*	
r			r		r			r		r	

31:20	Access Protection Vector Cacheable Address (CADDR) - If the CMASK field of this register is non-zero the CADDR and CMASK fields specify the base address of the memory area protected by the part of the bit vector that can be cached by the core.
19:16	Access Protection Vector Cacheable Mask (CMASK) - Number of '1's in the Access Protection Vector Cachable mask. If the core is implemented with a Access Protection Vector cache and this value is non-zero, the CMASK field together with the CADDR field specify a memory area protected by a part of the bit vector that can be cached by the core. The CMASK value corresponds to the number of most significant bits of the CADDR field that are matched against the incoming AMBA address when determining if the protection bits for the memory area should be cached. As an example, if CMASK is 1 and CADDR is 0x000, the core will cache protection information for the address range 0x00000000 - 0x7FFFFFFF. With the same mask and CADDR = 0x800, the core would cache protection information for the address range 0x80000000 - 0xFFFFFFFF.
15:8	Access Protection Vector Cache Tag bits (CTAGBITS) - The width in bits of the Access Protection Vector cache's tags.
7:5	Access Protection Vector Access size (CSIZE) - This field indicates the AMBA access size used when accessing the Access Protection Vector in main memory. This is also the cache line size for the APV cache (if enabled). The values are: 000: 32-bit (4 byte) 001: 64-bit (8 byte) 010: 128-bit (16 byte) 011: 256-bit (32-byte)
4:0	Access Protection Vector Cache Lines (CLINES) - Number of lines in the Access Protection Vector cache. The number of lines in the cache is 2^{CLINES}.

59.10.3 Capability Register 2

*Table 891.*0x04 - CAP2 - Capability register 2

31		24	23		20	19	18	17	16	15			8	7		5	4		0
TMASK			RESERVED			MTYPE		TTYPE		TTAGBITS				ISIZE			TLBENT		
*			0			*		*		*				*			*		
r			r			r		r		r				r			r		

31:24	Translation Mask (TMASK) - The incoming IO address bits IOADDR[31:24] must match this field, depending on the setting of the ITR field in the core's Control register, for an address translation operation to be performed.
23:20	RESERVED
19:18	IOMMU Type (MTYPE) - Shows IOMMU implementation type. This field is always 0, other values are reserved for future versions of the core. If this field is non-zero, it should trigger a software alert as future versions of the core may not be backward compatible.
17:16	TLB Type (TTYPE) - Show implementation of Translation Lookaside Buffer. This field is always 0, other values are reserved for future versions of the core. If this field is non-zero, it should trigger a software alert as future versions of the core may not be backward compatible.
15:8	TLB Tag bits (TTAGBITS) - The width in bits of the TLB tag.
7:5	IOMMU Access size (ISIZE) - This field indicates the AMBA access size used when accessing page tables in main memory. This is also the line size for the TLB (if enabled). The values are: 000: 32-bit (4 byte) 001: 64-bit (8 byte) 010: 128-bit (16 byte) 011: 256-bit (32-byte)
4:0	TLB entries (TLBENT) - Number of entries in the TLB. The number of entries is 2^{TLBENT}.

Reset value: implementation dependent

59.10.4 Control Register

*Table 892.*0x10 - CTRL - Control register

31		21	20		18	17	16	15		12	11	10	9	8	7	6	5	4	3	2	1	0
RESERVED			PGSZ			LB	SP	ITR			DP	SIV	HPROT		AU	WP	DM	GS	CE	PM		EN
0			0			0	0	0			0	0	0		0	0	0	0	0	*		0
r			rw			rw	rw	rw			rw	rw	rw		rw	rw	rw	rw	rw	rw		rw

31:21	RESERVED
20:18	Page Size (PGSZ) - The value in this field determines the page size mapped by page table entries and bit vector positions. Valid values are: 000: 4 KiB 001: 8 KiB 010: 16 KiB 011: 32 KiB 100: 64 KiB 101: 128 KiB 110: 256 KiB 111: 512 KiB This field is only writable if the CS field in Capability register 0 is non-zero.
17	Lookup bus (LB) - The value of this bit controls AHB master interface to use for fetching bit vector and/or page table entries from memory when the core has been implemented with support for multiple buses (multiple AHB master interfaces). If this field is '0', the first master interface will be used for vector/table lookups. If this field is '1', the second master interface will be used for lookups. This field is only writable if the MB field in Capability register 0 is non-zero.

GRIP
Apr 2024, Version 2024.1

774

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 892.*0x10 - CTRL - Control register

16	SPLIT support (SP) - The value of this bit controls if the core can issue AMBA SPLIT responses to masters on the IO bus. If this bit is '1' the core will use AMBA SPLIT responses. If this bit is '0', the core will insert waitstates and not issue AMBA SPLIT responses. This bit is read-only if the core has been implemented with support for only one response mode. If this bit is writable, software must make sure that the IO bus is free and that the core is not handling any ongoing accesses before changing the value of this bit. The core performs rudimentary checks in order to determine if the slave side is idle before changing SPLIT behavior. Therefore AMBA SPLIT responses may not be disabled or enabled immediately after this bit is written.
15:12	IOMMU Translation Range (ITR) - This field defines the size of the address range translated by the core's IOMMU functionality. The size of the decoded address range is 16 MiB $* 2^{ITR}$ and the decoded memory area is located on an address with the most significant bits specified by the TMASK field in Capability register 2, unless ITR = 8 in which case the whole address space is covered by the translated range.
11	Disable Prefetch (DP) - When this bit is '1' the core will not perform any prefetch operations. This bit is read only if the core has been implemented without support for prefetching data. During normal operation prefetch of data improves performance and should be enabled (the value of this bit should be '0'). Prefetching may need to be disabled in scenarios where IOMMU protection is enabled, which leads to a prefetch operation on every incoming burst access, and when the core is used in bi-directional bridge configurations where dead locks may be resolved by the core dropping prefetch data.
10	Save Invalid IOPTE (SIV) - If this field is '1' the core will save IOPTEs that have their valid (V) bit set to '0' if the core has been implemented with a TLB. If this field is '0' the core will not buffer an IOPTE with valid (V) set to '0' and perform an page table lookup every time the page covered by the IOPTE is accessed. If the value of this field is changed, a TLB flush must be made to remove any existing IOPTEs from the core's internal buffer. Also if this field is set to '0', any diagnostic accesses to the TLB should not set the IOPTE valid bit to '0' unless the Tag valid bit is also set to '0'. This field is only accessible if the core has support for IOMMU protection and is implemented with a Translation Lookaside Buffer (TLB).

GRIP

Apr 2024, Version 2024.1

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 892.*0x10 - CTRL - Control register

9:8	HPROT encoding (HPROT) - The value of this field will be assigned to the AMBA AHB HPROT signal bits 3:2 when the core is fetching protection data from main memory. HPROT(3) signals if the access is cacheable and HPROT(2) signals if the access is bufferable.
	This field is only used when the core has been implemented with support for Access Protection Vector or IOMMU functionality.
7	Always Update (AU) - If this bit is set to '0' the AHB failing access register will only be updated if the Access Denied (AD) bit in the Status register is '0' when the access is denied. Otherwise the AHB failing access register will be updated each time an access is denied, regardless of the Access Denied (AD) bit's value.
6	Write Protection only (WP) - If this bit is set to '1' the core will only used the Access Protection Vector to protect against write accesses. Read accesses will be propagated over the core without any access restriction checks. This will improve the latency for read operations.
	This field has no effect when the core is using IOMMU protection (PM field = "01"). When using IOMMU protection all accesses to the range determined by TMASK and ITR will be checked against the page table, unless the access is from a master that is assigned to an inactive group or a group in pass-through mode.
5	Diagnostic Mode (DM) - If this bit is set to '1' the core's internal buffers can be accessed via the Diagnostic interface (see Diagnostic cache access register) when the DE field of the Status register has been set by the core. Set this bit to '0' to leave Diagnostic mode. While in this mode the core will not forward any incoming AMBA accesses.
4	Group-Set-addressing (GS) - When this bit is set to '1', the core will use the group number as part of the Access Protection Vector cache set address. This bit can only be set if fields A and CA, or I and IA, of Capability register 0 are non-zero.
3	Cache/TLB Enable (CE) - When this bit is set to '1', the core's internal cache/TLB is enabled. Note that the core can be implemented without internal cache/TLB. Capability register 0, fields AC and IT show if the core has internal cache.
2:1	Protection Mode (PM) - This value selects the protection mode to use. "00" selects Group Mode and/ or Access Protection Vector mode (if available). "01" selects IOMMU mode. This field is read only if the core only has support for one mode setting.
0	Enable (EN) - Core enable. If this bit is set to 1 the core is enabled. If this bit is set to 0 the core is disabled and in pass-through mode. After writing this bit software should read back the value. The change has not taken effect before the value of this bit has changed. The bit transition may be blocked if the core is in diagnostic access mode or otherwise occupied.

59.10.5 TLB/cache Flush Register

*Table 893.*0x14 - FLUSH - TLB/cache flush register

31		8	7	4	3	2	1	0
RESERVED			FGRP		RES		GF	F
0			0		0		0	0
r			rw		r		rw	rw

31:1	RESERVED
7:4	Flush Group (FGRP) - This field specifies the group to be used for a Group Flush, see GF field below.
3:2	RESERVED
1	Group Flush (GF) - When this bit is written to '1' the cache entries for the group selected by the FGRP field will be flushed. More precisely the core will use the FGRP field as (part of the) set address when performing the flush. This flush option is only available if the core has support for group set addressing (CA field of Capability register 1 is non-zero). This flush option must only be used if the GS bit in the Control register is set to '1', otherwise old data may still be marked as valid in the Access Protection Vector cache or IOMMU TLB. This bit will be reset to '0' when a flush operation has completed. A flush operation also affects the FL and FC fields in the Status register.
0	Flush (F) - When this bit is written to '1' the core's internal cache will be flushed. This bit will be reset to '0' when a flush operation has completed. A flush operation also affects the FL and FC fields in the Status register.

59.10.6 Status Register

*Table 894.*0x18 - STAT - Status register

31		6	5	4	3	2	1	0
RESERVED			PE	DE	FC	FL	AD	TE
0			0	0	0	0	0	0
r			uc	uc	uc	uc	uc	uc

31:6	RESERVED
5	Parity Error (PE) - The core sets this bit to '1' when it detects a parity error in the tag or data RAM of the APV cache. This field is cleared by writing '1' to this position, writes of '0' have no effect.
4	Diagnostic Mode Enabled (DE) - If this bit is set to '1' the core is in Diagnostic Mode where the core's internal buffers can be accessed via the Diagnostic access registers. While in this mode the core will not forward any incoming AMBA accesses.
3	Flush Completed (FC) - The core sets this bit to '1' when a flush operation completes. This field is cleared by writing '1' to this position, writes of '0' have no effect.
2	Flush started (FL) - The core sets this bit to '1' when a Flush operation has started. This field is cleared by writing '1' to this position, writes of '0' have no effect.
1	Access Denied (AD) - The core denied an AMBA access. This field is cleared by writing '1' to this position, writes of '0' have no effect.
0	Translation Error (TE) - The core received an AMBA ERROR response while accessing the bit vector or page tables in memory. This also leads to the incoming AMBA access being inhibited. Depending on the status of the Control register's AU field and this register's AD field this may also lead to an update of the AHB Failing Access register.

59.10.10 Group Control Register(s)

*Table 898.*0x80-0xAC - GRPCTRCO-15 - Group control register(s)

31		1	0
BASE[31:2+SIZE]		P	AG
0		0	0
rw		rw	rw

31: 2	Base address (BASE) - Group n's control register is located at offset 0x80 + n*0x4. This field contains the base address of the data structure for the group.
	The number of bits writeable in the data structure base address depends on the access size used to fetch entries in the Access Protection Vector and/or the IOMMU page table. The access size is given in the ISIZE and CSIZE Capability register fields.
	This field is only writable if the core has been implemented with support for Access Protection Vector and/or IOMMU functionality.
1	Pass-through (P) - If this bit is set to '1' and the group is active (see bit 0 below) the core will pass-through all accesses made by master in this group and not use the address specified by BASE to perform look-ups in main memory. Note that this also means that the access will pass through untranslated when the core is using IOMMU protection (even if the access is outside the translated range defined by TMASK in Capability register 2).
	If this bit is set to '0', the core will use the contents in its cache, or in main memory, to perform checks and possibly address translation on incoming accesses.
	If the core has been implemented without support for Access Protection Vector and IOMMU, this field is disabled.
0	Active Group (AG) - Indicates if the group is active. If this bit is set to '0', all accesses made by masters assigned to this group will be blocked.
	If the core has been implemented without support for Access Protection Vector and IOMMU, accesses will be propagated if this bit is set to '1'. If the core has been implemented with support for Access Protection Vector and/or IOMMU the core will check the P field of this register and possibly also the in-memory data structure before allowing or blocking the access.

59.10.11 Diagnostic Cache Access Register

*Table 899.*0xC0 - DIAGCTRL - Diagnostic cache access register

31	30	29	22	21	20	19	18	0
DA	RW	RESERVED		DP	TP	R	SETADDR	
0	0	0		0	0	0	NR	
rw	rw	r		rw	rw	r	rw*	

31	Diagnostic Access (DA) - When this bit is set to '1' the core will perform a diagnostic operation to the cache address specified by the SETADDR field. When the operation has finished this bit will be reset to '0'.
30	Read/Write (RW) - If this bit is '1' and the A field is set to '1' the core will perform a read operation to the cache. The result will be available in the Diagnostic cache access tag and data register(s). If this bit is set to '0' and the A field is set to '1', the core will write the contents of the Diagnostic cache access tag and data registers to the internal cache.
29:22	RESERVED
21	Data Parity error (DP) - This bit is set to '1' if a parity error has been detected in the word read from the cache's data RAM. This bit can be set even if no diagnostic cache access has been made and it can also be set after a cache write operation. This bit is read-only.
20	Tag Parity error (TP) - This bit is set to '1' if a parity error has been detected in the word read from the cache's tag RAM. This bit can be set even if no diagnostic cache access has been made and it can also be set after a cache write operation. This bit is read-only.
19	RESERVED

59.10.16 ASMP Access Control Register

Table 904. 0x100-0x10C - ASMPCTRL - ASMP access control register(s)

31 19	18	17	16	15 0
RESERVED	FC	SC	MC	GRPACCSZCTRL
0	0	0	0	0
r	rw	rw	rw	rw

31: 19	RESERVED
18	Flush register access control (FC) - If this bit is set to '1' in the ASMP control register at offset 0x100 + n*0x4 then the TLB/cache flush register in ASMP register block n is writable. Otherwise writes to the TLB/cache flush register in ASMP register block n will be inhibited.
17	Status register access control (SC) - If this bit is set to '1' in the ASMP control register at offset 0x100 + n*0x4 then the Status register in ASMP register block n is writable. Otherwise writes to the Status register in ASMP register block n will be inhibited.
16	Mask register access control (MC) - If this bit is set to '1' in the ASMP control register at offset 0x100 + n*0x4 then the Master register in ASMP register block n is writable. Otherwise writes to the Mask register in ASMP register block n will be inhibited.
15:0	Group control register access control (GRPACCSZCTRL) - ASMP register block n's group access control field is located at register address offset 0x100 + n*0x4. This field specifies which of the Group control registers that are writable from an ASMP register block. If GRPACCSZCTRL[i] in the ASMP access control register at offset 0x100 + n*0x4 is set to '1' then Group control register i is writable from ASMP register block n.

Reset value: 0x00000000

59.11 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x04F. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

If implemented, the core's second AHB master interface has 0x01 (Frontgrade Gaisler) and device identifier 0x010.

59.12 Implementation

59.12.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

59.12.2 Technology mapping

The core has two technology mapping generics *memtech* and fcfsmtech. *memtech* selects which memory technology that will be used to implement the FIFO memories. *fcfsmtech* selects the memory technology to be used to implement the First-come, first-served buffer, if FCFS is enaled.

59.12.3 RAM usage

The core instantiates one or several *syncram_2p* blocks from the technology mapping library (TECHMAP). If prefetching is enabled max(*mstmaccsz*, *slvaccsz*)/32 *syncram_2p* block(s) with organization (max(*rburst,iburst*)-max(*mstmaccsz*, *slvaccsz*)/32) x 32 is used to implement read FIFO (max(*rburst,iburst*) is the size of the read FIFO in 32-bit words). max(*mstmaccsz*, *slvaccsz*)/32 *syn-*

GRIP

+46 31 7758650 | frontgrade.com/gaisler

cram_2p block(s) with organization *(wburst* - max(*mstmaccsz*, *slvaccsz*)/32) x 32, is always used to implement the write FIFO (where *wburst* is the size of the write FIFO in 32-bit words).

If the core has support for first-come, first-served ordering then one *fcfs* x 4 *syncram_2p* block will be instantiated, using the technology specified by the VHDL generic *fcfsmtech*.

If the core has an Access Protection Vector cache and/or IOMMU TLB, the cache/TLB will be implemented using one *syncramft* block for the tag RAM and one *syncramft* block for the data RAM.

59.12.4 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

59.13 Configuration options

Table 905 shows the configuration options of the core (VHDL generics).

*Table 905.*Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
memtech	Memory technology		
iohsindex	Slave I/F AHB index on IO bus	0 to NAHBMST-1	0
syshmindex	Master I/F AHB index on System bus	0 to NAHBMST-1	0
syshmindex2	Master I/F AHB index for second AHB interface. Only available if the entity griommu_mb is instantiated.	0 to NAHBMST-1	0
syshsindex	Index for register slave AHB I/F connected to same bus as core Master I/F	0 to NAHBMST-1	0
syshmaddr	ADDR field of AHB slave BAR 0 on system bus	0 - 16#FFF#	0
syshmask	MASK field of AHB slave BAR 0 on system bus. The requied value of this generic depends on the setting of generic narb (see below).	0 - 16#FFF#	16#FFF#
syshirq	Interrupt line to use for IOMMU interrupts	1 - NAHBIRQ-1	1
dir	0 - clock frequency on the master bus is lower than or equal to the frequency on the slave bus 1 - clock frequency on the master bus is higher than or equal to the frequency on the slave bus (for VHDL generic *ffact* = 1 the value of dir does not matter)	0 - 1	0
ffact	Frequency scaling factor between AHB clocks on master and slave buses.	1 - 15	2
slv	Slave bridge. Used in bi-directional bridge configuration where *slv* is set to 0 for master bridge and 1 for slave bridge. When a deadlock condition is detected slave bridge (*slv*=1) will give RETRY response to current access, effectively resolving the deadlock situation. This generic must only be set to 1 for a bridge where the frequency of the bus connecting the master interface is higher or equal to the frequency of the AHB bus connecting to the bridge's slave interface. Otherwise a race condition during access collisions may cause the bridge to deadlock.	0 - 1	0
pfen	Prefetch enable. Enables read FIFO.	0 - 1	0

GRIP

784

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 905.*Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
irqsync	Interrupt forwarding. Forward interrupts from slave interface to master interface and vice versa. 0 - no interrupt forwarding, 1 - forward interrupts 1 - 15, 2 - forward interrupts 0 - 31. Since interrupts are forwarded in both directions, interrupt forwarding should be enabled for one bridge only in a bi-directional AHB/AHB bridge.	0 - 2	0
wburst	Length of write bursts in 32-bit words. Determines write FIFO size and write burst address boundary. If the wburst generic is set to 2 the bridge will not perform write bursts over a 2x4=8 byte boundary. This generic must be set so that the buffer can contain two of the maximum sized accesses that the bridge can handle.	2 - 32	8
iburst	Instruction fetch burst length. This value is only used if the generic *ibrsten* is set to 1. Determines the length of prefetching instruction read bursts on the master side. The maximum of (iburst,rburst) determines the size of the core's read buffer FIFO.	4 - 8	8
rburst	Incremental read burst length. Determines the maximum length of incremental read burst of unspecified length (INCR) on the master interface. The maximum of *rburst* and *iburst* determine the read burst boundary. As an example, if the maximum value of these generics is 8 the bridge will not perform read bursts over a 8x4=32 byte boundary. This generic must be set so that the buffer can contain two of the maximum sized accesses that the bridge can handle. For systems where AHB masters perform fixed length burst (INCRx , WRAPx) *rburst* should not be less than the length of the longest fixed length burst.	4 - 32	8
bar0	Address area 0 decoded by the bridge's slave interface. Appears as memory address register (BAR0) on the slave interface. The generic has the same bit layout as bank address registers with bits [19:18] suppressed (use functions ahb2ahb_membar and ahb2ahb_iobar in gaisler.misc package to generate this generic).	0 - 1073741823	0
bar1	Address area 1 (BAR1)	0 - 1073741823	0
bar2	Address area 2 (BAR2)	0 - 1073741823	0
bar3	Address area 3 (BAR2)	0 - 1073741823	0
sbus	The number of the AHB bus to which the slave interface is connected. The value appears in bits [1:0] of the user-defined register 0 in the slave interface configuration record and master configuration record.	0-3	0
mbus	The number of the AHB bus to which the master interface is connected. The value appears in bits [3:2] of the user-defined register 0 in the slave interface configuration record and master configuration record.	0-3	0

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 905.*Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
ioarea	Address of the I/O area containing the configuration area for AHB bus connected to the bridge's master interface. This address appears in the bridge's slave interface user-defined register 1. In order for a master on the slave interface's bus to access the configuration area on the bus connected to the bridge's master interface, the I/O area must be mapped on one of the bridge's BARs. If this generic is set to 0, some tools, such as Frontgrade Gaisler's GRMON debug monitor, will not perform Plug'n'Play scanning over the bridge.	0 - 16#FFF#	0
ibrsten	Instruction fetch burst enable. If set, the bridge will perform bursts of *iburst* length for opcode access (HPROT[0] = '0'), otherwise bursts of *rburst* length will be used for both data and opcode accesses.	0 - 1	0
lckdac	Locked access error detection and correction. Locked accesses may lead to deadlock if a locked access is made while an ongoing read access has received a SPLIT response. The value of *lckdac* determines how the core handles this scenario: 0: Core will deadlock 1: Core will issue an AMBA ERROR response to the locked access 2: Core will allow both accesses to complete. If the core is used to create a bidirectional bridge, a deadlock condition may arise when locked accesses are made simultaneously in both directions. With *lckdac* set to 0 the core will deadlock. With *lckdac* set to a non-zero value the slave bridge will issue an ERROR response to the incoming locked access.	0 - 2	0
slvmaccsz	The maximum size of accesses that will be made to the bridge's slave interface. This value must equal *mstmaccsz* unless *rdcomb* /= 0 and *wrcomb* /= 0.	32 - 256	32
mstmaccsz	The maximum size of accesses that will be performed by the bridge's master interface. This value must equal *mstmaccsz* unless *rdcomb* /= 0 and *wrcomb* /= 0.	32 - 256	32
rdcomb	Read combining. If this generic is set to a non-zero value the core will use the master interface's maximum AHB access size when prefetching data and allow data to be read out using any other access size supported by the slave interface. If slvmaccsz > 32 and mstmaccsz > 32 and an incoming single access, or access to a non-prefetchable area, is larger than the size supported by the master interface the bridge will perform a series of small accesses in order to fetch all the data. If this generic is set to 2 the core will use a burst of small fetches. If this generic is set to 1 the bridge will not use a burst unless the incoming access was a burst. Read combining is only supported for single accesses and incremental bursts of unspecified length.	0 - 2	0

Apr 2024, Version 2024.1

786

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

*Table 905.*Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
wrcomb	Write combining. If this generic is set to a non-zero value the core may assemble several small write accesses (that are part of a burst) into one or more larger accesses or assemble one or more accesses into several smaller accesses. The settings are as follows: 0: No write combining 1: Combine if burst can be preserved 2: Combine if burst can be preserved and allow single accesses to be converted to bursts (only applicable if slvmaccsz > 32) Only supported for single accesses and incremental bursts of unspecified length	0 - 2	0
combmask	Read/write combining mask. This generic determines which ranges that the core can perform read/write combining to (only available when rdcomb respectively wrcomb are non-zero). The value given for combmask is treated as a 16-bit vector with LSB bit (right-most) indicating address 0x0 - 0x10000000. Making an access to an address in an area marked as '0' in combmask is equivalent to making an access over a bridge with rdcomb = 0 and wrcomb = 0. However, combmask is not taken into account when the core performs a prefetch operation (see pfen generic). When a prefetch operation is initiated, the core will always use the maximum supported access size (when rdcomb /= 0).	0 - 16#FFFF#	16#FFFF#
allbrst	Support all burst types 2: Support all types of burst and always prefetch for wrapping and fixed length bursts. 1: Support all types of bursts 0: Only support incremental bursts of unspecified length See section 59.2.7 for more information. When allbrst is enabled, the core's read buffer (size set via rburst/iburst generics) must have at least 16 slots.	0 - 2	0
ifctrlen	Interface control enable. When this generic is set to 1 the input signals *ifctrl.mstifen* and *ifctrl.slvifen* can be used to force the AMBA slave respectively master interface into an idle state. This functionality is intended to be used when the clock of one interface has been gated-off and any stimuli on one side of the bridge should not be propagated to the interface on the other side of the bridge. When this generic is set to 0, the ifctrl.* input signals are unused.	0 - 1	0
fcfs	First-come, first-served operation. When this generic is set to a non-zero value, the core will keep track of the order of incoming accesses and handle the requests in the same order. If this generic is set to zero the bridge will not preserve the order and leave this up to bus arbitration. If FCFS is enabled the value of this generic must be higher or equal to the number of masters that may perform accesses over the bridge.	0 - NAHBMST	0
fcfsmtech	Memory technology to use for FCFS buffer. When VHDL generic *fcfs* is set to a non-zero value, the core will instantiate a 4 bit x *fcfs* buffer to keep track of the incoming master indexes. This generic decides the memory technology to use for the buffer.	0 - NTECH	0 (inferred)

*Table 905.*Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
scantest	Enable scan support	0 - 1	0
split	Use AMBA SPLIT responses. When this generic is set to 1 the core will issue AMBA SPLIT responses. When this generic is set to 0 the core will insert waitstates instead and may also issue AMBA RETRY responses. If this generic is set to 0, the *fcfs* generic must also be set to 0, otherwise a simulation failure will be asserted.	0 - 1	1
dynsplit	Dynamic SPLIT responses. If this generic is non-zero the Control register field SP will be writable. This allows software to control if the core should use AMBA SPLIT responses or waitstates on the IO bus. The VHDL generic *split* must be set to 1 if this generic is set to 1.	0 - 1	0
nummst	Number of masters connected to the bus that the core's slave interface connects to.	1 - NAHBMST-1	1
numgrp	Number of groups	1 - NAHBMST-1	1
stat	Enable statistics outputs	0 - 1	0
apv	Include support for Access Protection Vector (APV). Setting this generic to 1 includes support.	0 - 1	1
apvc_en	Access Protection Vector cache. 0: disabled, 1: enabled.	0 - 1	0
apvc_ways	Number of ways in Access Protection Vector cache	1 - 1	1
apvc_lines	Number of lines in each way of the Access Protection vector cache. The total size of the data cache in bytes will be apvc_ways * tbw_accsz/8 * apvc_lines. This value must be a power of two. If the core is implemented with an IOMMU TLB, the maximum value of this generic and VHDL generic *tlb_num* determines the number of lines in the cache.		16
apvc_tech	Access Protection Vector cache memory technology. This generic decides the technology setting for the cache's tag and data RAM.	0 - NTECH	0 (inferred)
apvc_gseta	Allow use of group ID as part of cache set address. This allows cache addressing scheme 2 to be used. The value 0 disables the use of group ID as part of the cache set address and 1 enables the functionality. If the core is implemented with an IOMMU TLB and VHDL generic *tlb_gseta* is set to non-zero value, this will also enable *apvc_gseta*. This generic may only be set to a non-zero value if VHDL generic *numgrp* > 1.	0 - 1	0
apvc_caddr	If generic *apvc_cmask* is non-zero this generic specifies the base address of the memory area that the core will cache protection information for.The area is specified in the same way as addresses for AHB slaves. To cache protection information for the block 0x40000000 - 0x7FFFFFFF, set this generic to 0x400 and *apvc_cmask* to 0xC00.	0 - 16#FFF#	0
apvc_cmask	Specifies size of memory block for which protection information will be cached by the core. If this generic is zero the core will cache protection information for the full AMBA address range. If this generic is 0x800 the core will cache information for half the AMBA address range, the base address for the cacheable area is specified by *apvc_caddr*.	0 - 16#FFF#	0

*Table 905.*Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
apvc_pipe	Insert pipelining registers on APV cache. The master -> group -> cache path may become critical in a design. If there are timing problem on the tag or cache RAM address inputs, set this generic to 1 and suffer one cycle in additional penalty on cache accesses. If the core is implemented with an IOMMU TLB and VHDL generic *tlb_pipe* is set to non-zero value, this will also enable *apvc_pipe*.	0 - 1	0
iommu	Enable IOMMU functionality	0 - 1	0
iommutype	Selects type of IOMMU functionality. Set to 0	0 - 1	0
tlb_num	Number of entries in the IOMMU translation lookaside buffer (TLB). A value of zero here implements the core without a TLB. The width of an entry is determined through the VHDL generic tbw_accsz. The total size of the TLB in bytes will be tbw_accsz/8 * tlb_num. This value must be a power of two. If the core has been implemented with an APV cache, the maximum value of this generic and VHDL generic *apvc_lines* determines the number of entries in the TLB.	0 - 64	0
tlb_type	Selects TLB implementation. Set to 0.	0 - 1	0
tlb_tech	TLB memory technology. This generic decides the technology setting to use for implementing the TLB. In the current version of the bridge this generic and VHDL generic *apvc_tech* must have the same value.	0 - NTECH	0 (inferred)
tlb_gseta	Allow use of group ID as part of TLB set address. This allows cache addressing scheme 2 to be used. The value 0 disables the use of group ID as part of the TLB set address and 1 enables the functionality. If the core is implemented with an APV cache and VHDL generic *apvc_gseta* is set to non-zero value, this will also enable *tlb_gseta*. This generic may only be set to a non-zero value if VHDL generic *numgrp* > 1.	0 - 1	0
tlb_pipe	Insert pipelining registers on TLB address. The master -> group -> TLB path may become critical in a design. If there are timing problem on the tag or cache RAM address inputs, set this generic to 1 and suffer one cycle in additional penalty on cache accesses. If the core is implemented with an APV cache and VHDL generic *apvc_pipe* is set to non-zero value, this will also enable *tlb_pipe*.	0 - 1	0
tmask	Translation mask. Specifies the value that the most significant bits of the IO address must have for an address to be translated. Bits 7:0 of this value specified TMASK[31:24]. The default value 0xff is recommended. However, this may not work well if the IO bus has a GRLIB plug'n'play area. Note that tmask must specify an address range that is covered by one of the core's memory bars. Otherwise the core will not be selected by the AHB bus controller when the tmask area is accessed.	0 - 16#ff#	16#ff#

Table 905. Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
tbw_accsz	AMBA access size to use when fetching entries of the Access Protection Vector and/or the IOMMU page table. This value also sets the Access Protection Vector cache line size and the TLB entry size. This value must not exceed the maximum access size for the AHB master interface.	32 - *mstmaccsz*	32
dpagesz	Support for dynamic page size. If this generic is set to 1 the core will support selecting the page size via the Control register. If this generic is set to 0, the page size is fixed to 4 KiB.	0 - 1	0
ft	Fault tolerance. This setting determines if the APV cache and/or TLB tag and data RAMs should be protected against faults. Possible values are: 0 - disabled, 1 - byte parity	0 - 1	0
narb	Number of ASMP register blocks. The core will be implemented with narb ASMP register blocks. the required syshmask settings for different narb values are: narb 0 : hmask 0xfff, narb 1 : hmask 0xfe, narb 2 -3 : hmask 0xfc, narb 4-7 : hmask 0xf80, narb 8 - 15 : hmask 0xf00		
multiirq	Enable interrupt propagation for second AHB master interface. This generic is only available if the the entity griommu_mb is instantiated. If this generic is set to '1', interrupt propagation, as configured via the irqsync generic, will also be done for the second AHB master interface.	0 - 1	0

59.14 Signal descriptions

Table 906 shows the interface signals of the core (VHDL ports).

Table 906. Signal descriptions (VHDL ports)

Signal name	Field	Type	Function	Active
RST		Input	Reset	Low
HCLKSYS		Input	AHB system bus clock	-
HCLKIO		Input	AHB IO bus clock	-
IO_AHBSI	*	Input	AHB slave input signals	-
IO_AHBSO	*	Output	AHB slave output signals	-
IO_AHBPNP	*	Input	AHB master output vector signals (on io/slave i/f side). Used to decode plug'n'play vendor/device ID of masters so that these values can be visible in the Master control register(s).	-
SYS_AHBMI	*	Input	AHB master input signals	-
SYS_AHBMO	*	Output	AHB master output signals	-
SYS_AHBPNP	*	Input	AHB slave input vector signals (on system/master i/f side). Used to decode cachability and prefetchability Plug&Play information on bus connected to the bridge's master interface.	-
SYS_AHBMI2	*	Input	AHB master input signals, second interface. Only available on griommu_mb entity.	-
SYS_AHBMO2	*	Output	AHB master output signals, second interface. Only available on griommu_mb entity.	-
SYS_AHBPNP2	*	Input	AHB slave input vector signals (on system/master i/f side). Used to decode cachability and prefetchability Plug&Play information on bus connected to the bridge's second master interface. Only available on griommu_mb entity.	-
SYS_AHBSI	*	Input	AHB slave input signals	-
SYS_AHBSO	*	Output	AHB slave output signals	-
WLK_AHBMI	*	Input	AHB master input signals	-
WLK_AHBMO	*	Output	AHB master output signals	-
LCKI	slck blck mlck	Input	Used in systems with multiple AHB/AHB bridges (e.g. bi-directional AHB/AHB bridge) to detect deadlock conditions. Tie to "000" in systems with only uni-directional AHB/AHB bus.	High
LCKO	slck blck mlck	Output	Indicates possible deadlock condition	High
STATO (clocked by HCLKSYS)	hit	Output	High for one cycle during TLB/cache hit.	High
	miss	Output	High for one cycle during TLB/cache miss	High
	pass	Output	High for one cycle during passthrough access	High
	accok	Output	High for one cycle during access allowed	High
	accerr	Output	High for one cycle during access OK	High
	walk	Output	High while core is busy performing a table walk or accessing the access protection vector	High
	lookup	Output	High while core is performing cache lookup/ table walk	High
	perr	Output	High for one cycle when core detects a parity error in the APV cache	High

60 GRIOMMU2 - AHB/AHB bridge with RISC-V IOMMU capabilities

60.1 Overview

GRIOMMU2 is an AHB/AHB bridge that incorporates translation capabilities based on the RISC-V IOMMU specification version 1.0. It comes in two versions: the *standard* version with only a traditional AHB 2.0 interface and an *advanced* version with both a traditional AHB 2.0 interface and also an striped AHB interconnect optimized for higher throughput. GRIOMMU2 consists of three main blocks: the RISCV IOMMU, the I/O bridge and the striped controller (only included for the advanced variant of the IP.

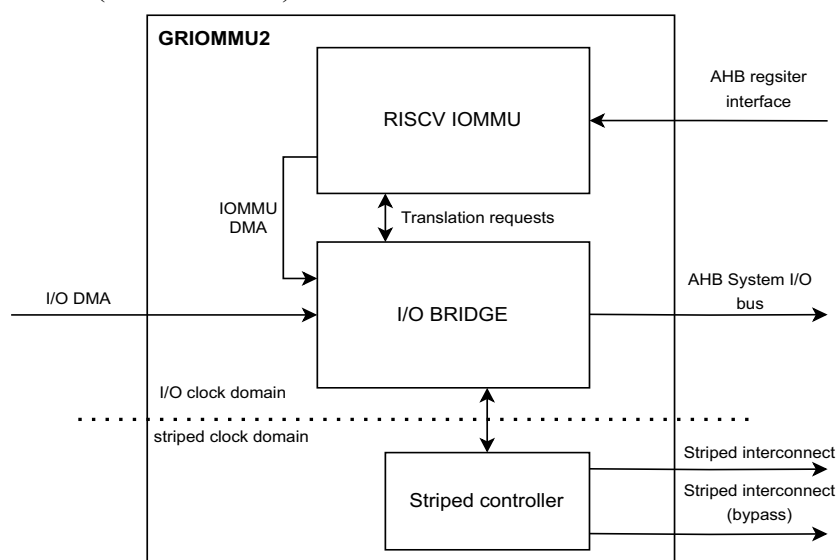
DMA master AHB signals connect directly to GRIOMMU2, with arbitration handled internally by the core. This design enables the core to accept and queue multiple translations at once, while the advanced bridge can handle up to 5 accesses concurrently. Address translations adhere to the RISC-V IOMMU specification, utilizing structures such as Device ID, Process ID, and standard RISC-V MMU page tables (Sv39 and Sv32).


Figure 146. Block diagram of GRIOMMU2 using the higher throughput striped AHB interconnect bridge.

60.2 Bridge operation

60.2.1 General

The RISC-V IOMMU specification defines five modes: "OFF," "BARE," "LVL1," "LVL2," and "LVL3." The mode of GRIOMMU2 is communicated to the bridge, dictating how incoming accesses should be handled.

In "OFF" mode, all DMA accesses immediately return an error response. In "BARE" mode, no translations are performed, and the bridge uses the address provided by the DMA master directly. For the other modes, a translation request is sent to the IOMMU core. Once the translation is completed, the bridge requests access to the bus. The DMA master can proceed with its access once bus access is granted.

The bridge's access patterns are optimized for 64-byte cachelines. Burst read accesses from the DMA side prefetch 64 bytes efficiently from the L2 Cache. Larger bursts are divided into multiple accesses. Single reads are forwarded as is, fetching only the required data.

Apr 2024, Version 2024.1

795

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

Write bursts aligned with full cachelines are transmitted as bursts on the bus. However, unaligned bursts or single accesses are handled as single writes.

60.2.2 Bus arbitration

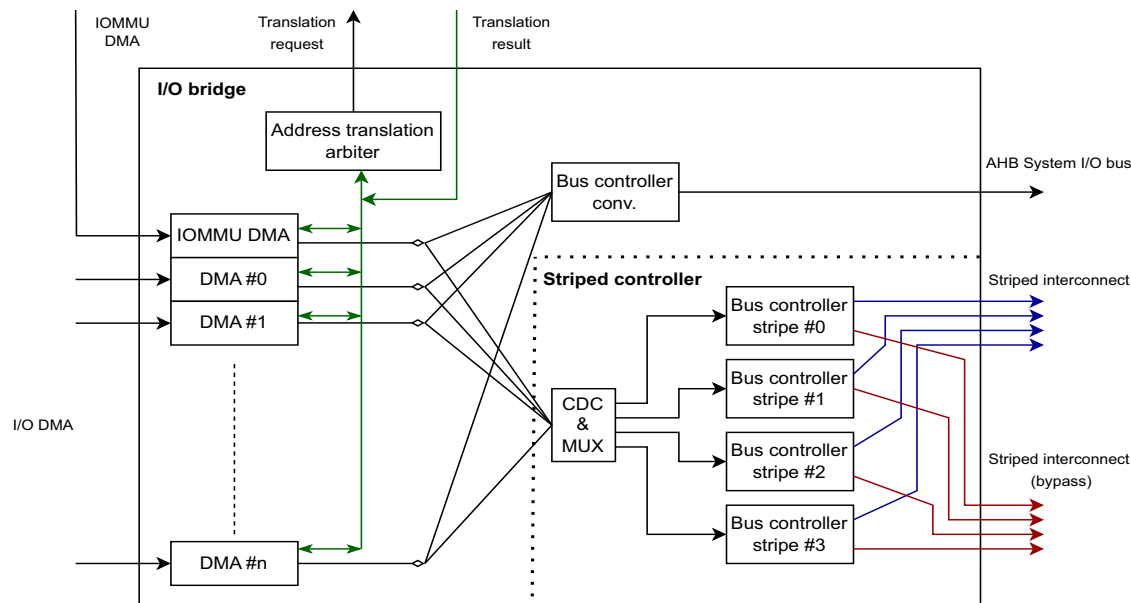
Access arbitration between DMA masters is handled within the IOMMU bridge. In the case of the advanced bridge where multiple buses are available, each is handled separately, which allows multiple DMA masters to make accesses at the same time. The bridge uses the same round robin arbitration scheme as the AHBCTRL IP. A block diagram of the arbitration logic for the advanced striped bridge can be seen in figure 147.


Figure 147. Bus arbitration logic block diagram for the advanced striped bridge.

60.2.3 IRQ forwarding

Some DMA sources will send interrupts after finishing a burst of accesses to inform the rest of the system of the changed state in-memory. Without synchronizing the IRQ inside GRIOMMU2, the interrupts can in some cases arrive before the memory access can be seen globally in the system. To avoid this issue, IRQs can be latched by GRIOMMU2 and released first once all previous memory accesses by that DMA device has been commited to globally memory.

60.2.4 AMBA SPLIT support

GRIOMMU2 supports AMBA split and retry. The DMA side will never create a split or retry response since they can not block each other anyways.

60.3 IO Memory Management Unit (IOMMU) functionality

60.3.1 General

The RISC-V IOMMU core interacts with the I/O bridge through two interfaces, the translation request interface and a DMA interface. The translation request interface passes a virtual address together with a Device ID, Process ID and other access related information to the IOMMU core in order for it to translate the virtual address into a physical address. The IOMMU core uses the DMA interface to access memory, where many of the structures that it works with reside. The DMA interface is handled

GRIP
Apr 2024, Version 2024.1

796

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

as an ordinary I/O DMA master but has special permissions in the I/O bridge so it always use physical addresses.

Once the bridge creates an address translation request, the access will move through a three stage TLB checker to see if the translation has been cached. If the TLB checker finds a full match, it will return the translated request and no table walks will be generated. If the TLB checker misses in one or more stages, the entry will be put into a circular buffer which will translate and respond to the request in order. TLB lookups are made during page walking as well, so partial hits will still speed up the translation process significantly.

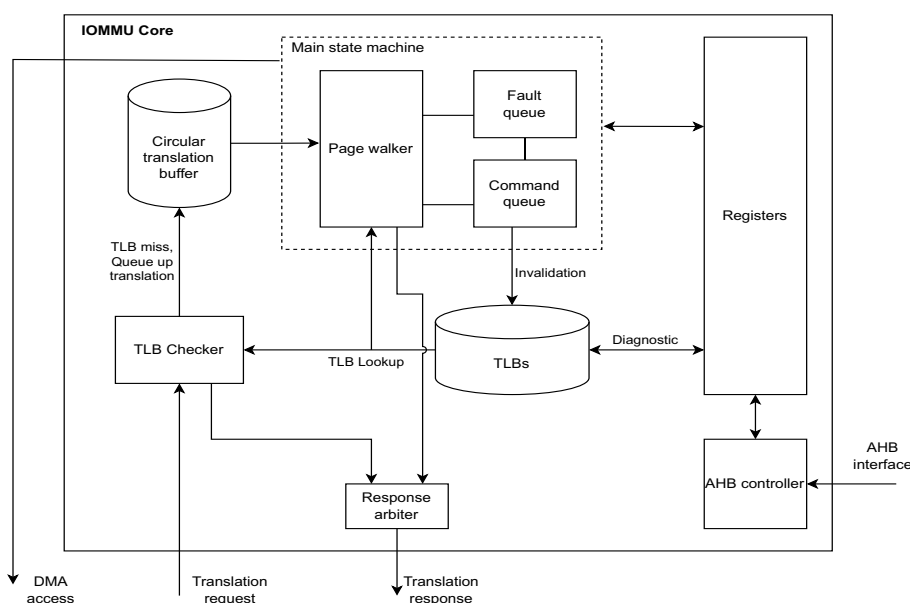
The main state machine within the IOMMU Core will monitor the circular buffer and translate the entries in order. During the translation, faults can occur. This triggers an error response to the IOMMU bridge and, if the fault queue is enabled, writes the fault to main memory. Similarly, an in-memory command queue can be used by the CPUs to invalidate TLB entries and fence GRIOMMU2.


Figure 148. GRIOMMU2 RISC-V IOMMU block diagram

60.3.2 Translation interface

The translation interface is utilized by the bridge to request translations from the IOMMU. A round-robin arbiter grants access to DMA sources when they have a valid virtual address, Device ID and in some cases Process ID. Other parameters such as access size and r/w are also propagated along the decoding parameters as it is used to identify MSI translations.

Once a DMA source requests a translation, it enters a wait state until the translation is completed. During this wait period, the DMA source does not block the interface, allowing other DMA sources to generate requests to the IOMMU. This, combined with the TLB checker, enables the IOMMU to serve TLB hits to DMA sources even when multiple misses are present in the translation pipeline.

The IOMMU uses the DMA source index to respond to translation requests and it should be noted that this is **not** the same as a Device ID (which is provided from outside of the core). This allows multiple different DMA sources to use the same Device ID which in practice would make them use the exact same translation structures.

+46 31 7758650 | frontgrade.com/gaisler

60.3.3 DMA interface

The IOMMU DMA interface functions as an AHB 2.0 master, allowing integration with the bridge and utilization of its arbiter and bridging functionalities. It supports both read and write operations in single or burst modes. The IOMMU determines the appropriate access size and burst mode based on the data being fetched. As an example; for a non-leaf Process ID entry, a single read access suffices. For the leaf, a burst is generated when the data bus is 64 bits, but a single read access is still sufficient for a 128-bit data bus.

Larger data structures like the device context are directly transferred to the IOMMU, unlike other DMA sources that operate exclusively on 32 bits.

60.3.4 Register interface

GRIOMMU2 implements an AHB 2.0 slave interface to interact with its registers. The register map conforms to the RISC-V IOMMU specification but also adds some custom features. The custom features are described in the register map description further down.

60.3.5 Translation structure

The translation process involves three components: Device ID (DID), Process ID (PID), and Virtual Address (VA). Initially, the IOMMU utilizes the DID and a base address register to fetch a Device Context (DC) from memory. The DC contains information on how to handle the translation in subsequent steps. This includes determining the activation of page tables or Message Signaled Interrupts (MSI), generating fault queue entries, and specifying the allowed privilege mode of the device.

If the PID is valid, a similar process is followed to retrieve the Process Context (PC). The PC provides additional information on locating the root Page Table Entry (PTE) in scenarios where single or two-stage translations are active. The decoding of the PC undergoes the same guest translations as the address decoding, enabling a virtual machine (VM) to establish its own PID decoding structures if needed.

Once the decoding of the DC and, if applicable, the PC is complete, the VA is used to perform a lookup for the corresponding Physical Address (PA). This lookup is carried out using the structures described in the RISC-V Privileged Specification, with GRIOMMU2 supporting either Sv32 or Sv39 formats for address translation.

60.3.6 Translation lookaside buffers (TLB)

The TLB sizes are determined using generics, providing flexibility in configuring the number of entries. Enable/disable functionality is achieved through the register interface. The replacement policy utilized is pseudo LRU, which selects the least recently used entry for eviction.

GRIOMMU2 has four separate TLBs implemented:

- CTX - Device ID & Process ID
- SV - Single & Two stage translations
- G - Guest translations
- MSI - MSI translations

Context-TLB:

The context TLB serves as a cache for the results of Device ID (DID) and Process ID (PID) decoding. When an entry in the TLB does not have a valid PID, it is disregarded in the matching logic, assuming that the translation request also lacks a valid PID. The relevant information obtained from the DID

GRIP
Apr 2024, Version 2024.1
798
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

and PID decoding is stored in the TLB, and if a hit occurs, this information is utilized in subsequent decoding steps.

SV-TLB:

The SV TLB serves as a cache for the outcomes of single or two stage translations. It stores information related to the virtual address, PSCID, and GSCID, provided there is a valid GSCID available. During the matching process, the SV TLB compares these parameters against the incoming virtual address to determine if there is a hit. PSCID and GSCID are obtained as part of the DID and PID decoding steps, respectively.

G-TLB:

The G TLB caches the results of only the Guest stage translations. It matches the GSCID and the GPA during the translation process. The GSCID is obtained during Device decoding, and the GPA is determined during the page walk.

MSI-TLB:

The MSI TLB caches the results of accesses to obtain a MSI-PTE used in the process to do MSI translation. The TLB matches against the GPA obtained in the two-stage address translation step together with the GSCID found in the DC. The MSI translation step only ever requires one access to happen, this means the potential performance gains from the MSI-TLB is in many cases much smaller than from the other TLB types.

TLB Invalidation:

TLB invalidation can be performed either through the command queue or via the diagnostics interface. This allows for the removal of outdated or irrelevant entries from the TLB. See the register description and RISC-V IOMMU specification for more details.

60.3.7 Diagnostics interface

It is possible to probe or change the contents of the four TLBs through a diagnostic interface. For each of the four TLBs a register area is set up where one entire TLB entry can be read, containing all the information that is cached. To set which specific TLB entry is being looked at, a different index register is used.

Each TLB entry in the diagnostic interface has a *locked* bit which can only be set through the diagnostic interface. When the locked bit is set, the TLB entry will never be overwritten by the IOMMU in normal address translation operations. However, invalidation commands sent through the command interface will still invalidate the entry as well as reset the locked bit.

60.3.8 In-memory fault queue

The reporting of faults during the IOMMU address translation process is handled through an in-memory queue data structure called the fault-queue. For each fault detected a 32 byte fault record is created and stored in memory. The fault records are stored in a circular buffer which has its base address and size as determined by the *fault-queue base* register. The tail of the queue can be seen in the *fault-queue tail* register and it indicates the index in the buffer where the next fault record will be written by the IOMMU. The head of the queue is set in the *fault-queue head* register and indicates which fault record that software should process next, after a record has been processed the head register should be advanced by writing to it. When the fault-queue is full an overflow bit is set and no more entries will be written until it has been reset.

In the 32 byte fault record, information about what caused the fault can be read. Some noteworthy fields that are stored here are a twelve bit *cause* encoding and the *DID*, *PID* and *address* of the translation request that triggered the fault.

GRIP

Apr 2024, Version 2024.1

799

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

It is possible to enable the fault-queue to send interrupts. If enabled, an interrupt will be sent after a fault record has been written to memory or when the fault queue has overflowed.

60.3.9 In-memory command queue

Similar to the fault queue, the command queue serves as a memory-based queue where processors can write commands to be executed by the IOMMU. Each command entry occupies 16 bytes of memory, and the queue structure resembles that of the fault queue.

The base address and size of the command queue are determined by a base register, specifying the starting location and total size of the queue in memory. Additionally, the command queue has a head and tail pointer. The command queue head (cqh) register indicates the location in memory from where the IOMMU should read the next command for execution. Processors update the cqh register after writing a command to memory, to notify the IOMMU of the new command.

Commands in the queue serve various purposes, such as invalidating TLB entries and fencing the IOMMU. Similar to the fault queue, the command queue can be configured to generate interrupts. Wired interrupts or Message Signaled Interrupts (MSIs) can be enabled to signal the completion of command queue operations.

60.3.10 IRQ

GRIOMMU2 supports both wired interrupts and MSIs. Interrupts can be generated in various scenarios, including after faults have been reported, when a command has been executed, or when an Hardware Performance Monitoring (HPM) counter has reached its overflow condition.

Interrupts can be generated as separate signals or MSIs, allowing individual handling of each interrupt event. Wired interrupts are also combined into a single signal which is propagated to the sideband signals on the AHB interface.

60.3.11 Bridge HPM

The Bridge Hardware Performance Monitor implements 64-bit counters for 6 events that can occur in the IOMMU bridge. The events that are counted are:

- Read access
- Writes access
- Page detect access
- Bypass access
- Error access
- Aborted access

Each counter has a DMA index mask, allowing the user to filter out which masters are sampled. All DMA sources can be counted at the same time, if the mask is set to all ones.

The read and write counters also have an address filter and mask to allow the user to filter on address. The filter is applied post-translation.

60.3.12 Omitted/Optional features

GRIOMMU2 does not implement certain optional features described in the RISC-V IOMMU specification. These features include PCIe-related functionalities and runtime Bi-endian support. Additionally, GRIOMMU2 does not support the Svnapot and Svpbmt extensions or the Sv48/Sv57 virtual memory systems.

31:25	Custom - Designated for custom use. Not used.
24	IRQ forwarding fencing enabled (IRQFFE) - Enables the IRQ forwarding to fence the interrupt until all transactions by the DMA device is done before forwarding the interrupt. This setting will stop all incoming transactions as well until the interrupt is handled.
23	IRQ forwarding enabled (IRQFEN) - Enable IRQ forwarding for interrupt from the *inirq* signals.
22	RESERVED
21	Enable TLB bypass (BPEN) - Enable TLB bypass functionality. If all required data for an address translation is already cached, the page walk state machine of the IOMMU is bypassed and an answer is sent after three clock cycles.
20	Enable MSI TLB (MSIEN) - Enables the MSI TLB. Disabling the MSI TLB will clear all valid bits.
19	Enable G TLB (GEN) - Enables G-stage (second stage) TLB. Disabling the G-stage TLB will clear all valid bits.
18	Enable SV TLB (SVEN) - Enables SV-stage (two stage) TLB. Disabling the SV-stage TLB will clear all valid bits.
17	Enable CTX TLB (CTXEN) - Enable CTX (combined DDT & PDT stage) TLB. Disabling the CTX TLB will clear all valid bits.
16	Invalidate locked TLB entries (INVL) - Enable the invalidation commands to be able to invalidate locked TLB entries (also removes the lock on invalidation). When bit is '0', invalidation commands will not modify locked entries.
15:3	RESERVED
2	Guest address translation allowed (GXL) - Determines which translation scheme is available for the second stage translation step. If '0' then Sv32, if '1' then Sv39. The value of GXL is set by the *Sv32* generic.
1	Wire-Signaled-Interrupt (WSI) - Interrupt scheme used by the core. When '1', interrupts generated by the IOMMU are signaled as wire-signaled-interrupts else they are signaled as message-signaled-interrupts. This setting does not affect the interrupt forwarding functionality.
0	Big endian (BE) - Endianess used by the core. When '0' little endian is used, when '1' big endian is used. The value of *BE* is set by the *endian* generic .

0x0		0	0	0x0		0	0
r		wc	wc	r		rw	rw

31:18	RESERVED	
17	Fault.queue busy (BUSY) - When the fault queue is set to be turned off (write '0' to *fqen*) there can be some cycles before it is actually disabled, during this time the *busy* bit is set.
	Register writes to *fqcsr* will be ignored while the *busy* bit is asserted.
16	Fault queue on (FQON) - The fault queue is active if *fqon* is '1'.
15:10	RESERVED
9	Fault-queue-overflow (FQOF) - The *fqof* bit is set if the IOMMU needs to queue a fault record but the fault queue is full (i.e. *fqt == fqh-1*).
8	Fault-queue-memory-fault (CQMF) - If a fault-queue access leads to a memory fault then the *fqmf* bit is set to 1 and the command-queue stalls until this bit is cleared.
	Type of accesses that can set *fqmf*: - Write of fault entry to memory.
7:2	RESERVED
1	Fault-queue interrupt enable (FIE) - Enables generation of interrupts from fault-queue when set to '1'.
0	Fault-queue enabled (FQEN) - Enables the fault-queue when set to '1'.
	Changing *fqen* from '0' to '1' sets the *fqof*, and *fqmf* bits to '0' and the *fqt* register to 0.
	When *fqen* is changed from '1' to '0' the fault queue may stay active (*fqon* has value '1') with the *busy* bit asserted until the next time the IOMMU is back in a idle state (in practice this means that the current address translation, command execution or fault write will need to be completed). When the fault queue has been turned off, the *cqon* and *busy* bits reads '0'.

60.4.31 Bridge hardware performance monitor

Table 953. BHPM - Bridge hardware performance monitor register layout

63	0	Byte offsett
Counter		+000h
Address filter	DMA mask	+008h
RESERVED	Address filter mask	+010h

There are six events counted by the bridge HPM, each having its own 64b counter register and one or more 32b filter registers. The register layout is described in table 953. The word offset for the 32b registers are the same for both little and big endian systems, that being: *DMA mask* (0x08), *Address filter (*0x0C) and *Address filter mask* (0x10),

The six available events and the register address for each event are: *Read access* (0x1100), *write access* (0x1120), *page detect* (0x1140), *bypass* (0x1160), *error* (0x1180) and *abort* (0x11a0). The events are explained in more detail in chapter 60.3.11. Only the *read access* and *write access* events have the address filter and mask registers defined, for the other events these areas are reserved

Table 954. +0x00 - BHPM counter

63	0
CNT	
0x0	
rw	

63:0		Counter (CNT) - Counts number of times an event has been triggered. Only events triggered by DMA masters masked by the *DMA mask* register as well which matches the address filter defined by the *Address filter* and *Address filter mask* registers are counted. Bit 63 of the BHPM counter is sticky and will not reset once the counter overflows.

824
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

60.6 Implementation

60.6.1 Reset

The core does not support *grlib_async_reset_enable*. All registers that react on the reset signal will have a synchronous reset.

60.6.2 Endianness

GRIOMMU2 supports big and little endian systems, the endianess is set by a generic. As per the RISCV IOMMU specification, the register interface of the IOMMU should be in little endian format, even in the case of a big endian system. However, there is a control bit in the register interface that can be used to override this behavior for 32b accesses to 64b registers to provide better support for LEON systems.

60.7 Configuration options

Table 958 shows the configuration options of the core (VHDL generics).

Table 958. Configuration options (VHDL generics)

Generic	Function	Allowed range	Default
mult	Frequency relationship between the data bus and the io peripherals. *mult* should be configured so: data freq. = io freq. * *mult*	1-	1
ndmamst	Number of DMA devices connected.	1 - 29	-
sbusw	AHB bus width for memory bus (both normal and bypass interface)	64, 128	-
paddrw	Address width used for striped memory bus (both normal and bypass interface).	32-39	-
cpumidx	AHB master index.	0 - 65535	-
cpumidx_bp	AHB master index, bypass interface.	0 - 65535	-
hindex	AHB slave index (register interface).	0 - 65535	-
ioaddr	AHB interface base address (register interface)	0 - 16#FFF#	-
iomask	AHB interface address mask (register interface).	0 - 16#FFF#	16#FE0#
hirq	AHB interrupt line used by the core.	0 - NAHBIRQ-1	0
rst_mode	Reset value of the ddtp.iommu_mode field. Default value of 1 is BARE mode.	0 - 15	1
dbg	Enable debug interface capabilities	0, 1	1
pclvl	Number of PDT page walk levels supported.	0 - 3	3
msi_flat	Enables translation of MSI capabilities.	0, 1	1
hpm	Number of performance monitoring entries enabled.	0 - 32	8
num_vec_bits	Determines the number of interrupt cause sources. For WSI, *num_vec_bits* is the number of bits that are writable in the *icvec* register, as well as the number of bits that make up the outgoing irq interrupt line. For MSI, *num_vec_bits* determines the number of active *msi_cfg_tbl* entries in the format: *#msi_cfg_tbl=2^num_vec_bits*.	0 - 4	0
Sv32	Set the IOMMU to use the Sv32 translation scheme instead of the default Sv39.	0, 1	0

61   GRPCI2 - 32-bit PCI(Initiator/Target) / AHB(Master/Slave) bridge

61.1   Overview

The GRPCI2 core is a bridge between the PCI bus and the AMBA AHB bus. The core is capable of connecting to the PCI bus via both a target and a initiator/master interface. The connection to the AMBA bus is an AHB master interface for the PCI target functionality and an AHB slave interface for the PCI initiator functionality. The core also contains a DMA controller. For the DMA functionality, the core uses the PCI initiator to connect to the PCI bus and an AHB master to connect to the AMBA bus. Configuration registers in the core are accessible via a AMBA APB slave interface.

The PCI and AMBA interfaces belong to two different clock domains. Synchronization is performed inside the core through FIFOs with configurable depth.

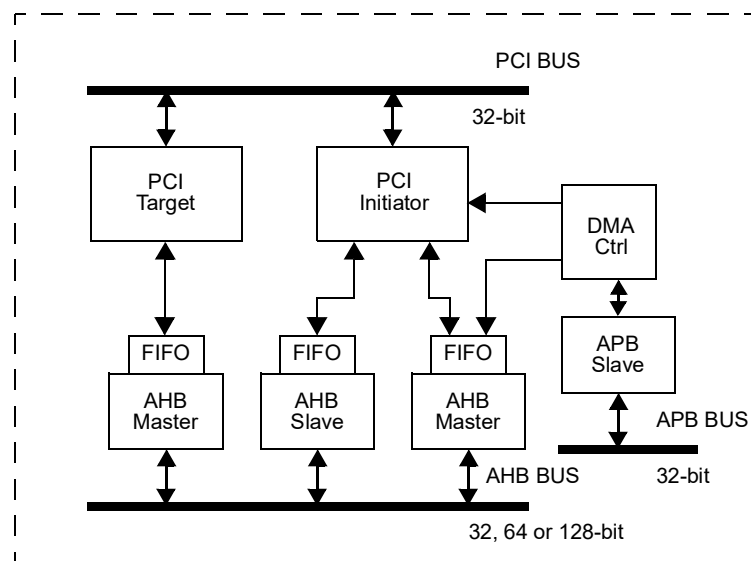
The PCI interface is compatible with the 2.3 PCI Local Bus Specification.


Figure 149. Block diagram

61.2   Configuration

The core has configuration registers located both in PCI Configuration Space (Compliant with the 2.3 PCI Local Bus Specification) and via an AMBA APB slave interface (for core function control and DMA control). This section defines which configuration options that are implemented in the PCI configuration space together with a list of capabilities implemented in the core. For a more detailed description of the core registers and DMA controller registers, see section Registers.

61.2.1   Configuration & Capabilities

Which of the core capabilities that are implemented is configured through VHDL generics at core instantiation. The implemented configuration can be determined by reading the Status & Capability register accessible via the APB slave interface.

- The PCI vendor and device ID is set with the VHDL generic *vendorid* and *deciceid*.

- The PCI class code and revision ID is set with the VHDL generic *classcode* and *revisionid*.

- 32-bit PCI initiator interface is implemented when the VHDL generic *master* is enabled.

- 32-bit PCI target interface is implemented when the VHDL generic *target* is enabled.

GRIP

Apr 2024, Version 2024.1   828   Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- DMA controller is implemented when the VHDL generic *dma* is enabled.

- The depth and number of FIFOs is configured with the VHDL generic *fifo_depth* and *fifo_count*.

- PCI BARs. The default size and number of BARs implemented is configured with the VHDL generic *bar0* to *bar5*.

- User defined register in Extended PCI Configuration Space can be enabled with the VHDL generic *ext_cap_pointer*.

- Device interrupt generation is enabled with the VHDL generic *deviceirq*.

- PCI interrupt sampling and forwarding is enabled with the VHDL generic *hostirq*.

- Support for two PCI functions is enabled with the VHDL generic multifunc.

61.2.2 PCI Configuration Space

The core implements the following registers in the PCI Configuration Space Header. For more detailed information regarding each field in these registers please refer to the PCI Local Bus Specification.

Table 961.GRPCI2: Implemented registers in the PCI Configuration Space Header

PCI address offset	Register
0x00	Device ID, Vendor ID
0x04	Status, Command
0x08	Class Code, Revision ID
0x0C	BIST, Header Type, Latency Timer, Cache Line Size
0x10 - 0x24	Base Address Registers
0x34	Capabilities Pointer
0x3C	Max_Lat, Min_Gnt, Interrupt Pin, Interrupt Line

61.2.2.1 Device ID and Vendor ID register

61.2.3   Extended PCI Configuration Space

This section describes the first item in the list of capabilities implemented in the Extended PCI Configuration Space. This capability is core specific and contains the PCI to AMBA address mapping and the option to change endianess of the PCI bus.

When user defined capability list items are implemented, the next pointer defines the offset of this list item. The AMBA address mapping for these registers can be accessed in the core specific item (first list item). The registers implemented in this AMBA address range must be compliant to the capability list items defined in the 2.3 PCI Local Bus Specification.

*Table 969.*GRPCI2: Internal capabilities of the Extended PCI Configuration Space

PCI address offset (with the Capabilities pointer as base)	Register
0x00	Length, Next Pointer, ID
0x04 - 0x18	PCI BAR to AHB address mapping
0x1C	Extended PCI Configuration Space to AHB address mapping
0x20	AHB IO base address and PCI bus config (endianess switch)

61.2.3.5 PCI BAR Size and Prefetch Register

Table 974. PCI BAR size and prefetch register (address offset 0x24 - 0x38)

31				4	3	2	1	0
PCI BAR size mask					Pre	RESERVED		Type

31 : 4	A size mask register for each PCI BAR. When bit[n] is set to '1' bit[n] in the PCI BAR register is implemented and can return a non-zero value. All bits from the lowest bit set to '1' up to bit 31 need to be set to '1'. When bit 31 is '0', this PCI BAR is disabled. The number of implemented bits in this field depends in the VHDL generic barminsize. The minimal size of the BAR is not allowed to be smaller than the internal FIFO.
3	Prefetch bit in PCI BAR register. When the EXTCAP.PF bit is valid (STATCAP.ECAP = '1') and set to '1', this configuration option change the access pattern towards the AMBA bus. When this bit is set to '1', burst accesses towards the target BAR will prefetch data on the AMBA bus. When this bit is set to '0', only single accesses will be generated towards the AMBA bus and no prefetching will be done. When the EXTCAP.PF bit is not valid (STATCAP.ECAP = '0') or set to '0', this configuration option only change the prefetchable bit in the BAR register and has no affect on the AMBA access pattern.
2 : 1	RESERVED
0	BAR type. 0 = Memory BAR, 1 = IO BAR

61.2.3.6 AHB Master Prefetch Burst Limit

Table 975. AHB master burst limit (address offset 0x3C)

31	30	16	15	0
SRF	RESERVED		Burst length	

31	Store Read FIFO. When set to 1, the prefetched FIFO will be stored until the next PCI access when the PCI target terminates the access with disconnect without data.
30 : 16	RESERVED
15 : 0	Maximum number of beats - 1 in the burst. (Maximum value is 0xFFFF => 0x10000 beats => 65kB address)

61.2.4 Multi-Function

The core supports up to two PCI functions starting from function 0. Each function has its own PCI configuration space located at offset 0x0 for function 0 and offset 0x100 for function 1. Some registers in the Extended PCI configuration space is shared between all functions. All functions also share the same Vendor ID.

61.3   Operation

61.3.1   Access support

The core supports both single and burst accesses on the AMBA AHB bus and on the PCI bus. For more information on which PCI commands that are supported, see the PCI target section and for burst limitations see the Burst section.

61.3.2   FIFOs

The core has separate FIFOs for each data path: PCI target read, PCI target write, PCI master read, PCI master write, DMA AHB-to-PCI, and DMA PCI-to-AHB. The number and depth of the FIFOs for each data path is configurable by VHDL generics.

GRIP
Apr 2024, Version 2024.1

834

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

61.3.3 Byte enables and byte twisting (endianess)

The core has the capability of converting endianess between the two busses. This means that all byte lanes can be swapped by the core as shown in figure below.
Figure 150. GRPCI2 byte twisting

Table 976 defines the supported AHB address/size and PCI byte enable combinations.

Table 976. AHB address/size <=> PCI byte enable combinations.

AHB HSIZE	AHB ADDRESS[1:0]	Little-endian CBE[3:0]	Big-endian CBE[3:0]
00 (8-bit)	00	1110	0111
00 (8-bit)	01	1101	1011
00 (8-bit)	10	1011	1101
00 (8-bit)	11	0111	1110
01 (16-bit)	00	1100	0011
01 (16-bit)	10	0011	1100
10 (32-bit)	00	0000	0000

As the AHB bus in GRLIB is defined as big-endian, the core is able to define the PCI bus as little-endian (as defined by the PCI Local Bus Specification) with endianess conversion or define the PCI bus as big-endian without endianess conversion.

The endianess of the PCI bus is configured via the core specific Extended PCI Configuration Space. The default value is set by a VHDL generic *conv_endian*.

61.3.4 PCI configuration cycles

Accesses to PCI Configuration Space are not altered by the endianess settings. The PCI Configuration Space is always defined as little-endian (as specified in the PCI Local Bus Specification). This means

GRIP
Apr 2024, Version 2024.1

835

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

that the PCI target does not change the byte order even if the endianess conversion is enabled and the PCI master always converts PCI Configuration Space accesses to little-endian.

Data stored in a register in the PCI Configuration Space as 0x12345678 (bit[31:0]) is transferred to the AHB bus as 0x78563412 (bit[31:0]). This means that non-8-bit accesses to the PCI Configuration Space must be converted in software to get the correct byte order.

61.3.5 Memory and I/O accesses

Memory and I/O accesses are always affected by the endianess conversion setting. The core should define the PCI bus as little-endian in the following scenarios: When the core is the PCI host and little-endian peripherals issues DMA transfers to host memory. When the core is a peripheral device and issues DMA transfers to a little-endian PCI host.

61.3.6 Bursts

PCI bus: The PCI target terminates a burst when no FIFO is available (the AMBA AHB master is not able to fill or empty the FIFO fast enough) or when the burst reached the length specified by the "AHB master burst limit" register. This register defines a boundary which a burst can not cross i.e. when set to 0x400 beats (address boundary at 4kB) the core only prefetch data up to this boundary and then terminates the burst with a disconnect.

The PCI master stops the burst when the latency timer times out (see the PCI Local Bus Specification for information on the latency timer) or for reads when the burst reaches the limit defined by "PCI master prefetch burst limit" register (if AHB master performing the access is unmasked). If the master is masked in this register, the limit is set to 1kB. The PCI master do not prefetch data across this address boundary.

AHB bus: As long as FIFOs are available for writes and data in a FIFO is available for read, the AHB slave do not limit the burst length. The burst length for the AHB master is limited by the FIFO depth. The AHB master only burst up to the FIFO boundary. Only linear-incremental burst mode is supported.

DMA: DMA accesses are not affected by the "AHB master prefetch burst limit" register or the "PCI master prefetch burst limit" register.

All FIFOs are filled starting at the same word offset as the bus access (i.e. with a FIFO of depth 8 words and the start address of a burst is 0x4, the first data word is stored in the second FIFO entry and only 7 words can be stored in this FIFO).

61.3.7 Host operation

The core provides a system host input signal that must be asserted (active low) for PCI system host operations. The status of this signal is available in the Status & Capability register accessible via the APB slave interface. The device is only allowed to generate PCI configuration cycles when this signal is asserted (device is the system host).

For designs intended to be host or peripherals only the PCI system host signal can be tied low or high internally in the design. For multi-purpose designs it should be connected to a pin. The PCI Industrial Computer Manufacturers Group (PCIMG) cPCI specification uses pin C2 on connector P2 for this purpose. The pin should have a pull-up resistor since peripheral slots leave it unconnected.

An asserted PCI system host signal makes the PCI target respond to configuration cycles when no IDSEL signal is asserted (none of AD[31:11] are asserted). This is done for the PCI master to be able to configure its own PCI target.

61.4 PCI Initiator interface

The PCI master interface is accessible via the AMBA AHB slave interface. The AHB slave interface occupies 1MB to 2GB of the AHB memory address space and 128kB to 256kB of AHB I/O address

GRIP
Apr 2024, Version 2024.1
836
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

space. An access to the AHB memory address area is translated to a PCI memory cycle. An access to the first 64kB of the AHB IO area is translated to a PCI I/O cycle. The next 64kB are translated to PCI configuration cycles. When the PCI trace buffer is implemented, it is accessible via the last 128kB of the AHB I/O area.

61.4.1 Memory cycles

A single read access to the AHB memory area is translated into a PCI memory read access, while a burst read translates into a PCI memory read multiple access. A write to this memory area is translated into a PCI write access.

The address translation is determined by AHB master to PCI address mapping registers accessible via the APB slave interface. Each AHB master on the AMBA AHB bus has its own mapping register. These registers contain the MSBs of the PCI address.

When the PCI master is busy performing a transaction on the PCI bus and not able to accept new requests, the AHB slave interface will respond with an AMBA RETRY response. This occurs on reads when the PCI master is fetching the requested data to fill the read FIFO or on writes when no write FIFO is available. This means that all masters on the AMBA bus accessing the AHB slave interface must be round-robin arbitrated without prioritization to avoid deadlock situations.

61.4.2 I/O cycles

Accesses to the lowest 64kB of the AHB I/O address area are translated into PCI I/O cycles. The address translation is determined by the "AHB to PCI mapping register for PCI I/O". This register sets the 16 MSB of the PCI address. The "AHB to PCI mapping register for PCI I/O" is accessible via the APB slave interface. When the "IB" (PCI IO burst) bit in the Control register (accessible via the APB slave interface) is cleared, the PCI master does not perform burst I/O accesses.

61.4.3 Configuration cycles

Accesses to the second 64kB address block (address offset range 64kB to 128kB) of the AHB I/O address area is translated into PCI configuration cycles. The AHB address is translated into PCI configuration address different for type 0 and type 1 PCI configuration cycles. When the "bus number" field in the control register (accessible via the APB slave interface) is zero, type 0 PCI configuration cycles is issued. When the "bus number" field is non-zero, type 1 PCI configuration cycles are issued to the PCI bus determine by this field. The AHB I/O address mapping to PCI configuration address for type 0 and type 1 PCI configuration cycles is defined in table 977 and table 978.

Only the system host is allowed to generate PCI configuration cycles. The core provides a system host input signal that must be asserted (active low) for PCI system host operations. The status of this signal is available in the Status & Capability register accessible via the APB slave interface. When the "CB" (PCI Configuration burst) bit in the Control register (accessible via the APB slave interface) is cleared, the PCI master does not perform burst configuration accesses.

61.4.3.1 Mapping of AHB I/O address to PCI Configuration Cycle, type 0

Table 977. GRPCI2 Mapping of AHB I/O address to PCI configuration cycle, type 0

31	16	15	11	10	8	7	2	1	0
AHB ADDRESS MSB		IDSEL		FUNC		REGISTER		BYTE	

31: 16	AHB address MSBs: Not used for PCI configuration cycle address mapping.
15: 11	IDSEL: This field is decoded to drive PCI AD[IDSEL+10]. Each of the signals AD[31:11] are suppose to be connected (by the PCI back plane) to one corresponding IDSEL line.
10: 8	FUNC: Selects function on a multi-function device.
7: 2	REGISTER: Used to index a PCI DWORD in configuration space.
1: 0	BYTE: Used to set the CBE correctly for non PCI DWORD accesses.

61.4.3.2 Mapping of AHB I/O address to PCI Configuration Cycle, type 1

Table 978. GRPCI2 Mapping of AHB I/O address to PCI configuration cycle, type 1

31	16	15	11	10	8	7	2	1	0
AHB ADDRESS MSB		DEVICE		FUNC		REGISTER		BYTE	

31: 16	AHB address MSBs: Not used for PCI configuration cycle address mapping.
15: 11	DEVICE: Selects which device on the bus to access.
10: 8	FUNC: Selects function on a multi-function device.
7: 2	REGISTER: Used to index a PCI DWORD in configuration space.
1: 0	BYTE: Used to set the CBE correctly for non PCI DWORD accesses.

61.4.4 Error handling

When a read access issued by the PCI master is terminated with target-abort or master-abort, the AHB slave generates an AMBA ERROR response when the "ER" bit in the control register is set. When the "EI" bit in the control register is set, an AMBA interrupt is generated for the error. The interrupt status field in the control register indicates the cause of the error.

61.4.5 Bus parking

The PCI initiator supports bus parking and will drive the PCI bus to a defined state when granted without requesting the bus. In systems with one single initiator the grant input to the PCI interface can be constantly asserted.

61.5   PCI Target interface

The PCI Target occupies memory areas in the PCI address space corresponding to the BAR registers in the PCI Configuration Space. Each BAR register (BAR0 to BAR5) defines the address allocation in the PCI address space. The size of each BAR is set by the "BAR size and prefetch" registers accessible via the core specific Extended PCI Configuration Space. The size of a BAR can be determined by checking the number of implemented bits in the BAR register. Non-implemented bits returns zero and are read only. The size of the BAR is not allowed to be smaller then the size of the internal FIFO.

61.5.1 Supported PCI commands

These are the PCI commands that are supported by the PCI target.

- **PCI Configuration Read/Write:** Burst and single access to the PCI Configuration Space. These accesses are not transferred to the AMBA AHB bus except for the access of the user defined capability list item in the Extended PCI Configuration Space.

GRIP

Apr 2024, Version 2024.1

838

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

- **Memory Read:** A read command to the PCI memory BAR is transferred to a single read access on the AMBA AHB bus.

- **Memory Read Multiple, Memory Read Line:** A read multiple command to the prefetchable* PCI memory BAR is transferred to a burst access on the AMBA AHB bus. This burst access prefetch data to fill the maximum amount of data that can be stored in the FIFO. When the BAR is not defied as prefetchable*, only signal accesses will be generated on the AMBA AHB bus and no prefetching is done.

   A BAR is defined as prefetchable* when the prefetchable bit in the BAR register is set to '1' and the register bit STATCAP.ECAP = '1' and EXTCAP.PF = '1'. In the case when STAT-CAP.ECAP = '0' or EXTCAP.PF = '0' all bars are defined as prefetchable independent of the configuration bit in the BAR register).

- **Memory Write, Memory Write and Invalidate:** These command are handled similarly and are transferred to the AMBA AHB bus as a single or burst access depending on the length of the PCI access (a single or burst access).

- **IO Read:** A read command to the PCI IO BAR is transferred to a single read access on the AMBA AHB bus.

- **IO Write:** A write command to the PCI IO BAR is transferred to the AMBA AHB bus as a single access.

61.5.2 Implemented PCI responses

The PCI target can terminate a PCI access with the following responses.

- **Retry:** This response indicates the PCI target is busy by either fetching data for the AMBA AHB bus on a PCI read or emptying the write FIFO for a PCI write. A new PCI read access will always be terminated with a retry at least one time before the PCI target is ready to deliver data.

- **Disconnect with data:** Terminate the transaction and transfer data in the current data phase. This occurs when the PCI master request more data and the next FIFO is not yet available or for a PCI burst access with the Memory Read command.

- **Disconnect without data:** Terminate the transaction without transferring data in the current data phase. This occurs if the CBE change within a PCI burst write.

- **Target Abort:** Indicates that the current access caused an internal error and the target is unable to finish the access. This occurs when the core receives a AMBA AHB error during a read operation.

61.5.3 Supported byte-enables (CBE)

The PCI-target only supports aligned 8-, 16-, and 32-bit accesses. The supported combinations of CBE are 0000, 1110, 1101, 1011, 0111, 1100, 0011. All other combinations of CBE are interpret as a 32-bit access (CBE = 0000) except for writes with CBE set to 1111, which is treated as a no-operation (no write will be performed).

61.5.4 PCI to AHB translation

Each PCI BAR has translation register (mapping register) to translate the PCI access to a AMBA AHB address area. These mapping registers are accessible via the core specific Extended PCI Configuration Space. The number of implemented bits in these registers correspond to the size of (and number of implemented bits in) the BARs registers.

+46 31 7758650 | frontgrade.com/gaisler

61.5.5 PCI system host signal

When the PCI system host signal is asserted the PCI target responds to configuration cycles when no IDSEL signal is asserted (none of AD[31:11] are asserted). This is done for the PCI master, in a system host position, to be able to configure its own PCI target.

61.5.6 Error handling

The PCI target terminates the access with target-abort when the PCI target requests data from the AHB bus which results in an error response on the AHB bus. Because the writes to the PCI target is posted, no error is reported on write AHB errors.

When a PCI master is terminated with a retry response it is mandatory for that master to retry this access until the access is completed or terminated with target-abort. If the master never retries the access, the PCI target interface would be locked on this access and never accept any new access. To recover from this situation, the PCI target has a option to discard an access if it is not retried within 2**15 clock cycles. This discard time out can be enabled via the "AHB IO base address and PCI bus config" located in the core specific Extended PCI Configuration Space.

61.6 DMA Controller

The DMA engine is descriptor base and uses two levels of descriptors.

61.6.1 DMA channel

The first level is a linked list of DMA channel descriptors. Each descriptor has a pointer to its data descriptor list and a pointer to the next DMA channel. The last DMA channel descriptor should always points to the first DMA channel for the list to be a closed loop. The descriptor needs to be aligned to 4 words (0x10) in memory and have the following structure.

Table 979. GRPCI2: DMA channel descriptor structure

Descriptor address offset	Descriptor word
0x00	DMA channel control
0x04	Next DMA channel (32-bit address to next DMA channel descriptor).
0x08	Next data descriptor in this DMA channel (32-bit address to next data descriptor).
0x0C	RESERVED

61.6.1.1 DMA Channel Control

Table 980. GRPCI2 DMA channel control

31		25	24		22	21	20	19		16	15		0
EN	RESERVED		CID			Type		RESERVED			Data descriptor count		

31		Channel descriptor enable (for version < 2, this bit should always be set to '1').
30: 25		RESERVED
24: 22		Channel ID. Each DMA channel needs a ID to determine the source of a DMA interrupt.
21: 20		Descriptor type. 01 = DMA channel descriptor.
19: 16		RESERVED
15: 0		Maximum number of data descriptors to be executed before moving to the next DMA channel. 0 indicates that all data descriptors should be executed before moving to the next DMA channel.

The number of enabled DMA channels must be stored in the "Number of DMA channels" field in the DMA control register accessible via the APB slave interface.

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

61.6.2 Data descriptor

The second descriptor level is a linked list of data transfers. The last descriptor in this list needs to be a disabled descriptor. To add a new data transfer, this disabled descriptor is updated to reflect the data transfer and to point to a new disabled descriptor. The control word in the descriptor should be updated last to enable the valid descriptor. To make sure the DMA engine reads this new descriptor, the enable bit in the DMA control register should be updated. The descriptor needs to be aligned to 4 words (0x10) in memory and have the following structure.

*Table 981.*GRPCI2: DMA data descriptor structure

Descriptor address offset	Descriptor word
0x00	DMA data control
0x04	32-bit PCI start address
0x08	32-bit AHB start address
0x0C	Next data descriptor in this DMA channel (32-bit address to next data descriptor).

61.6.2.1 DMA Data Control

Table 982. GRPCI2 DMA data control

31	30	29	28		22	21	20	19	18	16	15	0
EN	IE	DR	BE	RESERVED		Type		ER	RESERVED		LEN	

31	Data descriptor enable.
30	Interrupt generation enable.
29	Transfer direction. 0: PCI to AMBA, 1: AMBA to PCI.
28	PCI bus endianess switch. 1: defines the PCI bus to be little-endian for this transfer, 0: defines the PCI bus to be big-endian for this transfer.
27: 22	RESERVED (Must be set to zero)
21: 20	Descriptor type. 00 = DMA data descriptor.
19	Error status
18: 16	RESERVED
15: 0	Transfer length. The number of word of the transfer is (this field)+1.

61.6.3 Data transfer

The DMA engine starts by reading the descriptor for the first DMA channel. If the DMA channel is enabled the first data descriptor in this channel is read and executed. When the transfer is done the data descriptor is disabled and status is written to the control word. If no error occurred during the transfer, the error bit is not set and the transfer length field is unchanged. If the transfer was terminated because of an error, the error bit is set in the control word and the length field indicates where in the transfer the error occurred. If no error has occurred, the next data descriptor is read and executed. When a disabled data descriptor is read or the maximum number of data descriptors has been executed, the DMA channel descriptor is updated to point to the next data descriptor and the DMA engine moves on to the next DMA channel.

When a disabled channel descriptor is read, the DMA controller will move on to the next DMA channel without reading in any data descriptors form the disabled channel (Only applies to version 2 of the core).

When the DMA is disabled (via the APB interface), the channel descriptor is updated to point to the next data descriptor (Only applies to version 2 of the core).

GRIP
Apr 2024, Version 2024.1

841

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The DMA engine will stop when an error is detected or when no enabled data descriptors is found. The error type is indicated by bit 7 to bit 11 in the DMA control register. The error type bits must be cleared (by writing '1') before the DMA can be reenabled.

61.6.4 Interrupt

The DMA controller has an interrupt enable bit in the DMA control register (accessible via the APB slave interface) which enables interrupt generation.

Each data descriptor has an interrupt enable bit which determine if the core should generate a interrupt when the descriptor has been executed.

The VHDL generic *irqmode* determines if the DMA engine assert the same interrupt as the PCI core or the DMA uses the irq signal following the PCI core interrupt, see the IRQ mode field in the Status and Capability register for irq routing information.

61.7 PCI trace buffer

61.7.1 Trace data

The data from the trace buffer is accessible in the last 128 kB block of the AHB I/O address area. Each 32-bit word in the first 64kB of this block represents a sample of the AD PCI signal. The second 64kB of the block is the corresponding PCI control signal. Each 32-bit word is defined in table 983.

Note that it is not supported to access the trace buffer data at the same time the AMBA AHB slave interface is used also for PCI master accesses. Doing this could return corrupted data for the PCI master access.

61.7.1.1 PCI Control Signal Trace (32-bit word)

Table 983. GRPCI2 PCI control signal trace (32-bit word)

31 20	19 16	15	14	13	12	11	10	9	8	7	6	5	4	3	0

31: 20	RESERVED
19: 3	The state of the PCI control signals.
2: 0	RESERVED

61.7.2 Triggering function

The core can be programmed to trigger on any combination of the PCI AD and PCI Control signals by setting up the desired pattern and mask in the PCI trace buffer registers accessible via the APB slave interface. Each bit the PCI AD signal and any PCI control signal can be masked (mask bit equal to zero) to always match the triggering condition.

The "Trig count" field in the "PCI trace buffer: counter & mode" register defines how many times the trigger condition should occur before the trace buffer disarms and eventually stops sampling. The number of samples stored after the triggering condition occurs defines by the "Delayed stop" + 2.

To start sampling, the trace buffer needs to be armed by writing one to the start bit in the "PCI trace buffer: Control" register. The state of the trace buffer can be determine by reading the Armed and Enable/Running bit in the control register. When the Armed bit is set, the triggering condition has not occurred. The Enable/Running bit indicates that the trace buffer still is storing new samples. When the delayed stop field is set to a non zero value, the Enabled bit is not cleared until all samples are stored

GRIP

+46 31 7758650 | frontgrade.com/gaisler

in the buffer). The trace buffer can also be disarmed by writing the "stop" bit in the "PCI trace buffer: control" register.

When the trace buffer has been disarmed, the "trig index" in the "PCI trace buffer: control" register is updated with index of trace entry which match the triggering condition. The address offset of this entry is the value of the "trig index" field times 4.

61.7.3 Trace Buffer APB interface

A separate APB register can optionally be enabled for access of the PCI trace buffer. The register layout is the same as the core APB interface but only registers related to the PCI trace buffer is accessable. The trace buffer data is located at offset 0x20000 for PCI AD and offset 0x30000 for PCI control signals.

61.8 Interrupts

The core is capable of sampling the PCI INTA-D signals and forwarding the interrupt to the APB bus. The PCI INTA-D signals can be connected to one APB irq signal or to 4 different irq signals. This is configured by the VHDL generic *irqmode*. The "host INT mask" field in the control register is used only for sampling the valid PCI INT signal.

The core supports PCI interrupt generation. For single function configuration the dirq signal is sampled and forwarded to the PCI INTA signal. For a multi function (and multi interrupt) configured device, each bit of the dirq signal is connected to one of the PCI INTA..D signal (dirq[0] => INTA, dirq[1] => INTB, ...). The core has a mask bit (the "device INT mask" field in the control register) for each bit in the dirq vector. The core also has a PCI interrupt force bit in the control register to be able to force the PCI INT asserted. For a multi interrupt configuration the PCI interrupt force bit is masked by the "device INT mask" to be able to assert all PCI INT signals separately.

When the system error PCI signal (SERR) is asserted the core sets the system error bit in the "core interrupt status" field in the Status & Capability register. If the system interrupts is enabled the core will also generate a interrupt on the APB bus.

61.10 Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x07C. The DMA engine has device identifier 0x07D. The separate APB interface for the PCI Trace-Buffer has device identifier 0x07E. For description of vendor and device identifier see GRLIB IP Library User's Manual

61.11 Implementation

61.11.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual). By default, the core makes use of synchronous reset and resets a subset of its internal registers in the system clock domain.

The deassertion of the PCI reset is synchronized to the PCI clock and delayed 3 clock cycles.

The core can be configured to drive the AHB reset on the PCI reset signal. This option is used when the backplane does not have logic to drive the PCI reset.

The PCI reset signal can optionally be forwarded to the AHB reset via the ptarst signal. This functionality can be used then the AMBA clock domain needs to be reset when the PCI reset is asserted.

The core require that the PCI and AMBA clock domain is reset at the same time, i.e. the PCI reset and the AMBA reset needs to be asserted at the same time.

61.11.2 Technology mapping

The core has a technology mapping VHDL generic, *memtech*, which controls how the memory cell used will be implemented. See the GRLIB Users's Manual for available settings.

61.11.3 RAM usage

The FIFOs in the core is implemented with the *syncram_2pft* (with separate clocks for each port) component from the technology mapping library (TECHMAP). Each data path implements its FIFOs in a separate 32-bit wide syncram_2pft component. The depth of each of these RAMs is the FIFO depth * number of FIFOs.

61.11.4 Pull-ups

Please refer to the PCI Local Bus Specification on which of the PCI signals needs to have pull-ups for correct operations.

61.11.5 PHY

All logic and registers directly controlled by the PCI bus signals has be placed in a separate entity. This makes it easier to control the setup-, hold- and clock-to-out timing for the PCI bus signals. This logic can also be implemented as a netlist which can be manually placed before running place-and-route for the entire design. A netlist is provided for Axcelerator and RTAX targets.

61.11.6 Endianness

The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The core is designed for big-endian systems.

61.12 Configuration options

Table 1003 shows the configuration options of the core (VHDL generics).

*Table 1003.*Configuration options

Generic name	Function	Allowed range	Default
memtech	The memory technology used for the internal FIFOs.	0 - NTECH	0
tbmemtech	The memory technology used for trace buffers	0 - NTECH	0
oepol	Polarity of the pad output enable signal. 0 = active low, 1 = active high.	0 - 1	0
hmindex	AHB master index.	0 - NAHBMST-1	0
hdmindex	DMA AHB master index.	0 - NAHBMST-1	0
hsindex	AHB slave index.	0 - NAHBSLV-1	0
haddr	ADDR field of the AHB BAR (for PCI memory access).	0 - 16#FFF#	16#000#
hmask	MASK field of the AHB BAR.	0 - 16#FFF#	16#000#
ioaddr	ADDR field of the AHB IO BAR (for PCI configuration and PCI IO access).	0 - 16#FFF#	16#000#
pindex	APB slave index	0 - APBMAX-1	0
paddr	APB interface base address	0 - 16#FFF#	0
pmask	APB interface address mask	0 - 16#FFF#	16#FFF#
irq	Interrupt line used by the core.	0 - NAHBIRQ-1	0
irqmode	IRQ routing option: 00: PCI INTA..D, Error interrupt and DMA interrupt on the same IRQ signal 01: PCI INTA..D and Error interrupt on the same IRQ signal. DMA interrupt on IRQ+1 10: PCI INTA..D on IRQ..IRQ+3. Error interrupt and DMA interrupt on IRQ. 11: PCI INTA..D on IRQ..IRQ+3. Error interrupt on IRQ. DMA interrupt on IRQ+4	0 - 3	0
master	Enable the PCI master	0 - 1	1
target	Enable the PCI target	0 - 1	1
dma	Enable the PCI dma	0 - 1	1
tracebuffer	Enable and number of entries of the PCI trace buffer, Allowed values is 0, 32, 64, 128, ..., 16384.	0 - 16384	0
confspace	Enable the PCI Configuration Space when PCI target is disabled	0 - 1	1
vendorid	PCI vendor ID	0 - 16#FFFF#	0
deviceid	PCI device ID	0 - 16#FFFF#	0
classcode	PCI class code	0 - 16#FFFFFF#	0
revisionid	PCI revision ID	0 - 16#FF#	0
cap_pointer	Enabled and sets the offset of the first item in the Extended PCI Configuration Space	0 - 16#C0#	0
ext_cap_pointer	Offset of the first user defined item in the capability list	0 - 16#FC#	0
iobase	AHB base address of the AHB I/O area	0 - 16#FFF#	16#FFF#
extcfg	Default value of the user defined Extended PCI Configuration Space to AHB address mapping.	0 - 16#FFFFFFF#	0
bar0	Sets the default size of BAR0 in address bits.	0 - 31	0
bar1	Sets the default size of BAR1 in address bits.	0 - 31	0
bar2	Sets the default size of BAR2 in address bits.	0 - 31	0
bar3	Sets the default size of BAR3 in address bits.	0 - 31	0

62   GRPULSE - General Purpose Input Output

62.1   Overview

The General Purpose Input Output interface is assumed to operate in an AMBA bus system where the APB bus is present. The AMBA APB bus is used for control and status handling.

The General Purpose Input Output interface provides a configurable number of channels. Each channel is individually programmed as input or output. Additionally, a configurable number of the channels are also programmable as pulse command outputs. The default reset configuration for each channel is as input. The default reset value each channel is logical zero.

The pulse command outputs have a common counter for establishing the pulse command length. The pulse command length defines the logical one (active) part of the pulse. It is possible to select which of the channels shall generate a pulse command. The pulse command outputs are generated simultaneously in phase with each other, and with the same length (or duration). It is not possible to generate pulse commands out of phase with each other.

Each channel can generate a separate internal interrupt. Each interrupt is individually programmed as enabled or disabled, as active high or active low level sensitive, or as rising edge or falling edge sensitive.

62.1.1   Function

The core implements the following functions:

- Input
- Output
- Output pulse commands
- Input interrupts
- Status and monitoring

62.1.2   Interfaces

The core provides the following external and internal interfaces:

- Discrete input and output interface
- AMBA APB slave interface, with sideband signals as per [GRLIB] including:
- interrupt bus
- configuration information
- diagnostic information

                    1b=pulse command output

All bits are cleared to 0 at reset.

Only channels configured as outputs are possible to enable as command pulse outputs.

Note that only bits npulse-1 to 0 are implemented.

62.2.5 Pulse Counter Register

*Table 1011.*0x1C - GPIONTR - Pulse Counter Register

31	24	23	0
RESERVED		CNTR	
0		0	
r		rw	

23-0:   CNTR   Pulse counter value

The pulse counter is decremented each clock period, and does not wrap after reaching zero.

Command pulse channels, with the corresponding output data and pulse enable bits set, are (asserted) while the pulse counter is greater than zero.

Setting CNTR to 0 does not give a pulse.

Setting CNTR to 1 does give a pulse with of 1 Clk period.

Setting CNTR to 255 does give a pulse with of 255 Clk periods.

Note that only bits cntrwidth-1 to 0 need be implemented.

r		rw		r	

23-16:   POL   Interrupt polarity, 0b=active low or falling edge, 1b=active high or rising edge

Note that only bits that are enabled by the imask VHDL generic and that are in the range nchannel-1 to 0 are implemented.

62.2.8 Interrupt Edge Register

*Table 1014.*0x14 - GPIOEDGE - Interrupt Edge Register

31	24	23	16	15	0
RESERVED		EDGE		RESERVED	
0		0		0	
r		rw		r	

23-16:   EDGE   Interrupt edge or level, 0b=level, 1b=edge

Note that only bits that are enabled by the imask VHDL generic and that are in the range nchannel-1 to 0 are implemented.

62.3   Operation

62.3.1 Interrupt

Two interrupts are implemented by the interface:

    Index:Name:Description:

    0   PULSEPulse command completed

    31:0 IRQ   Filtered input interrupt

The PULSE interrupt is configured by means of the *pirq* VHDL generic.

GRIP
Apr 2024, Version 2024.1
861
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The IRQ interrupts are configured by means of the *imask* and *ioffset* VHDL generics, where *imask* enables individually the input interrupts, and *ioffset* adds an offset to the resulting index on the interrupt bus.

62.3.2 Reset

After a reset the values of the output signals are as follows:

Signal:Value after reset:

GPIOO.Dout[31:0]de-asserted

GPIOO.OEn[31:0]de-asserted

62.3.3 Asynchronous interfaces

The following input signals are synchronized to Clk:

- GPIOI.Din[31:0]

62.4 Vendor and device identifiers

The module has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x037. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

62.5 Implementation

62.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. See also the description for the *syncrst* VHDL generic for how the core implements reset.

63 GRPWM - Pulse Width Modulation Generator

63.1 Overview

GRPWM is a pulse width modulation (PWM) generator that supports several outputs, with different frequencies. The core is configured through a set of APB registers, described in section 63.3. The core supports both asymmetric and symmetric PWM generation. Each of the PWM outputs can be configured to be either a single PWM signal or a pair of PWM signals (where the two signals are each others' inverse), with configurable amount of dead band time in between them. The core also supports programming of the output polarity, setting the outputs to fixed values, and configurable interrupt schemes. Hardware support to simplify the generation of a PWM signal that emulate an arbitrary repetitive waveform is also included.

63.2 Operation

63.2.1 System clock scaling

In order to support a wide range of system clock and PWM frequencies the core includes programmable clock scalers. Each scaler is clocked by the system clock and decrement on each clock cycle. When a scaler underflows it is reloaded with the value of its reload register and a tick is generated. This tick can then be used to increment (or decrement) one or more PWM counters. The reload value(s) of the scaler(s) can be read and written through the APB register called *Scaler reload register*, described in section 63.3. The number of system clock scalers is configurable through the VHDL generic *nscalers* and the width of the scaler(s) is determined by the VHDL generic *sbits*.

63.2.2 Asymmetric and symmetric PWM generation

An asymmetric PWM is a pulse signal that is inactive at the beginning of its period and after a certain amount of time goes active, and then stays active for the rest of the period. A symmetric PWM is a pulse signal that is inactive for a certain amount of time at the beginning of the period and a certain amount of time at the end of the period, and stays active in between. The two inactive time periods are normally, but not necessarily, equally long.

For the core to generate a PWM, independent of whether asymmetric or symmetric method is used, software need to do the following (also see section 63.3 for more detailed description of register interface):

- Enable the core by writing the *en* bit in *Core control register*.
- Configure the scaler (see section 63.2.1) and set the PWM period in the *PWM period register*.
- Write the *PWM compare register* with the value at which the PWM's counter should match and switch the outputs.
- If dead band time should be generated, write the value at which the current PWM's dead band time counter should match to the *PWM dead band compare register*. Also set the *dben* bit in the *PWM control register* to 1. See section 63.2.4 for information on dead band time.
- Set the meth bit in PWM control register to either asymmetric och symmetric.
- Set the polarity of the PWM output be setting the *pol* bit in the *PWM control register*.
- If the PWM output should be paired with its inverse then set the *pair* bit in the *PWM control register* to 1, otherwise set it to 0. Note that each PWM always has two ouputs, but if the *pair* bit is set to 0 then the second output is constantly inactive or 0 when the *PWM control register* bit pz is set to 1.
- Program the interrupt, see section 63.2.5.
- Enable the PWM generation by writing the *en* bit in *PWM control register* to 1.

GRIP

Apr 2024, Version 2024.1

865

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

- If software wants the PWM output(s) to assume fix value(s) it can write the *fix* bits in the PWM *control register* appropriately.

Specific configuration required for symmetric PWM if dual compare mode should be used:

- If the core should update the PWM's compare register twice every PWM period, then set the *dcomp* bit in the *PWM control register* to a 1.

- If the *dcomp* bit in the *PWM control register* is set, and it is desired that the two inactive time periods are not of equal length, software needs to continuously update the *PWM compare register* with new values. Since the core updates its internal register at the start of and middle of the PWM period, software need to update the *PWM compare register* sometime during the first half of the period.

Note that the core's internal period register is updated from the *PWM period register* at the start of every period, both for asymmetric and symmetric PWM generation.

63.2.3 Waveform PWM generation

That, which in this document is referred to as a *waveform PWM* is not a PWM generated in a different way than the asymmetric or symmetric methods described above. In fact a waveform PWM is either generated asymmetrically or symmetrically. The difference is that when the compare registers are loaded with new values they are read from an internal RAM instead of the *PWM compare register*. The advantage with this is that if software wants to, for example, generate a PWM signals that emulates a sine wave, it can load a number of compare values into the RAM before starting the PWM generation. Once started, the core will read the RAM, increasing the address at every compare match, and generate the same pattern over and over without the need for software intervention. Note that any pattern that is loaded into the RAM is generated, the core is not limited to a sine wave. This feature is supported if the *wpwm* bit in *Capability register 2* is set to 1. The core only support one waveform PWM and it is always the PWM with the highest index. The index is determined by the VHDL generic *npwm*. If for example *npwm* = 4, then it is only PWM four that can be put in waveform mode. For details on how to configure the waveform mode and read/write the RAM please see the description of the *Waveform configuration register*, *Waveform RAM, wo*rd *X* registers, and *PWM control register* in section 63.3.

63.2.4 Dead band time

It is often desired to have a delay between when one of the PWM signals of a PWM pair goes inactive and when the other signal goes active. This delay is called dead band time. By default the core does not generate any dead band time, but can be configured to do so by setting the *dben* bit in the *PWM control register* to 0b1. When dead band time is enabled the core will start a counter each time a PWM pair switch its outputs. The output going inactive is not delayed while the output going active is delayed until the counter matches the value in the *PWM dead band compare register*. To support a wide range of applications the amount of dead band time inserted is programmable. The number of bits used in the *PWM dead band compare register* is configurable through the VHDL generic *dbbits*, and also a four bit system clock scaler can be enabled for each PWM's dead band counter by setting the *dbscaler* VHDL generic to 1.

63.2.5 Interrupts

Interrupts can programmed individually for each PWM to be generated at PWM compare match, at PWM period match, or not generated at all. This is programmed in each PWM's *PWM control register*. Each PWM also has a 6-bit interrupt counter that can be used to scale down the frequency at which the interrupts occur. When an interrupt is generated the bit in the *Interrupt pending register* for the PWM in question is set. The bits in the *Interrupt pending register* stay set until software clears them by writing 1 to them. Through the *sepirq* and *npwm* VHDL generics the core supports several different interrupt numbers, this is described in section *63.6*.

GRIP

Apr 2024, Version 2024.1

866

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

When an interrupt is generated, or when the interrupt scaler counter is increased, an output tick is generated on the core's *tick* output signal. The output tick bit has the same index as the PWM in question.

63.3 Registers

The core is programmed through registers mapped into APB address space.

*Table 1020.*GRPWM registers

APB address offset	Register
0x00	Core control register
0x04	Scaler reload register
0x08	Interrupt pending register
0x0C	Capability register 1
0x10	Capability register 2
0x14*	Waveform configuration registers
0x18 - 0x1C	Reserved, always zero.
0x20**	PWM period register
0x24**	PWM compare register
0x28**	PWM dead band compare register
0x2C**	PWM control register
0x8000***	Waveform RAM, word 0
0x8004***	Waveform RAM, word 1
...	...
0xFFFC***	Waveform RAM, word 8191

* This register is only implemented if the wpwm bit (bit 0) in *Capability register 2* is set to 1.

** This register is implemented once for every PWM (value of *npwm* VHDL generic decides the number of registers), with an offset of 0x10 from the previous PWM's register. The functionality is the same for each PWM.

*** The implementation of this register depends on if the *wpwm* bit (bit 0) in *Capability register 2* is set to 1 and if the waveform RAM is large enough (the value of the field *wabits* in *Capability register 2* reports the number of address bits - 1 that is used for the waveform RAM).

63.3.1 Core Control Register

*Table 1021.*0x00 - CTRL - Core control register

31		x+13	x+12		12	11	10		8	7		1	0
R			noup			R	scalersel			R			en
0			0			0	0			0			0
r			rw			r	rw			r			rw

31:x+13 Reserved, always zero. x is the value of bits 2:0 in *Capability register 1*

12+x:12 No update bits for each PWM. x is the value of bits 2:0 in *Capability register 1.* Bit 12 is for the first PWM, bit 13 for the second etc. If a bit is set to 0b1 then that PWM's internal period register, compare register, and dead band compare registers are not updated from the corresponding APB registers. These bits can be used by software if it wants to change more than one of the values and it is required that all values change in the same PWM period. It can also be used to synhronize the use of new values for different PWMs. Reset value 0b0..0.

11 Reserved, always zero.

10:8 System clock scaler select bits. These bits determine which of the implemented system clock scalers' reload value that can be read/written from the *Scaler reload register.*These bits are only present if the *nscalers* generic is greater than 1. Reset value is 0b000

7:1 Reserved, always zero.

0 Core enable bit. 0b0 = Core is disabled, no operations are performed and all outputs are disabled. 0b1 = Core is enabled, PWM outputs can be generated. Reset value is 0b0.

63.3.2 Scaler Reload Register

*Table 1022.*0x04 - SCALER - Scaler reload register

31	sbits	sbits-1	0
R		reload	
0		all 1	
r		rw	

31:sbits Reserved, always zero. If sbits = 32 then this field is not present. (sbits is the value of the *sbits* generic)

(sbits-1):0 The value of this field is used to reload the system clock scaler when it underflows. If the core is configured with more than one scaler (*nscalers* generic greater than 1) then the *scalersel* bits in the *Core control register* determine which of the scalers that is read/written. Reset value is 0b1..1 (all ones).

63.3.3 Interrupt Pending Register

*Table 1023.*0x08 - IPEND - Interrupt pending register

31	npwm	npwm-1	0
R		irq pending	
0		0	
r		wc	

31:npwm Reserved, always zero.

(npwm-1):0 Interrup pending bits for the PWM(s). When an interrupt event for a specific PWM occurs the core sets the corresponding bit in the interrupt pending register and generates an interrupt. Software can read this register to see which PWM that generated the interrupt.

63.3.6 Waveform Configuration Register

*Table 1026.*0x14 - WCFG - Waveform configuration register

31	30	29	28	wabits +17	wabits +16	16	15	wabits +1	0
wsynccfg	wsen		R		wsynccomp		R		wstopaddr
0	0		0		0		0		all 1
rw	rw		r		rw		r		rw

31:30   These bits are used to configure at which point in the PWM period matching the *wsynccomp* field (see description below) that the *wsync* ouput will be set high. 0b00 = The wsync ouput will be set at the start of the PWM period. 0b01 = The output will be set at the first compare match. 0b10 = If the *meth* bit in the *PWM Control Register* is set to one (symmetric) for the waveform PWM, then the output will be set at the middle of the PWM period. 0b11 = If the *meth* bit is set to one for the waveform PWM, then the output will be set at the second compare match.

29   Enables/disables the waveform sync signal. This bit is only present if the *wsync* bit in *Capability register 2* is set to 1. Reset value is 0b0

28:wabits+17   Reserved, always zero. wabits is the value of the *wabits* field in *Capability register 2*. Note that this field is not present if wabits is 12.

16+wabits:16   wabits is the value of the *wabits* field in *Capability register 2.* The number of words in the waveform RAM is the same as the maximum number of PWM periods that will occur before the waveform is restarted. The value of this field is used as an offset into the waveform PWM. A counter is increased every PWM period and when the counter matches this value the *wsync* output of the core will be set to 1 sometime during that period. These bits are only present if the *wsync* bit in *Capability register 2* is set to 1. Reset value is 0b0..0.

15:wabits+1   Reserved, always zero.

wabits:0   The value of this field is used by the core to wrap when accessing the waveform RAM. wabits is the value of the *wabits* field in *Capability register 2*. This field is reset to 0b1..1 (all ones) so that by default the core reads the whole RAM. If software wants to put a waveform in the RAM that does not fill the whole RAM it should set these bits to the address where the last waveform PWM compare value will be stored.

63.3.7 PWM Period Register

*Table 1027.*0x20 - PPERIOD - PWM period register

31	pbits	pbits-1	0
R		per	
0		0	
r		rw	

31:pbits   Reserved, always zero. If pbits = 32 then this field is not present. (pbits is the value of the *pbits* generic)

(pbits-1):0   When the PWM counter reaches this value a PWM period has passed. Depending on the method used to generate the PWM the output could then be switched. When this register is written the actual PWM period value used inside the core is not updated immediately, instead a shadow register is used to hold the new value until a new PWM period starts. Reset value 0b0..0 (all zeroes).

*Table 1028.*0x24 - PCOMP - PWM compare register

31	pbits	pbits-1	0
R		comp	
0		0	
r		rw	

31:pbits   Reserved, always zero. If pbits = 32 then this field is not present. (pbits is the value of the *pbits* generic)

(pbits-1):0   When the PWM counter reaches this value the PWM output is switched. Depending on the method used to generate the PWM this register is used once or twice during each PWM period. When this register is written the actual PWM compare value used inside the core is not updated immediately, instead a shadow register is used to hold the new value until a new PWM period starts. Reset value 0b0..0 (all zeroes).

63.3.9 PWM Dead Band Compare Register

*Table 1029.*0x28 - PDEAD - PWM dead band compare register

31	dbbits	dbbits-1	0
R		dbcomp	
0		0	
r		rw	

31:dbbits   Reserved, always zero. If dbbits = 32 then this field is not present. (dbbits is the value of the *dbbits* generic)

(dbbits-1):0 The dead band time has passed once the dead band counter reach the value of this field. When this register is written the actual compare value used inside the core is not updated immediately, instead a shadow register is used to hold the new value until a new PWM period starts. Reset value 0b0..0 (all zeroes).

63.3.10 PWM Control Register

*Table 1030.*0x2C - PCTRL - PWM control register

31 27	26	25 22	21	20 15	14	13	12 10	9	8	7	6	5 3	2	1	0
R	flip	dbscaler	dben	irqscaler	irqt	irqen	scalersel	wen	dcen	pz	meth	fix	pair	pol	en
0	0	0	0	0	0	0	0	0	0	0	*	0	1	*	0
r	rw	rw	rw	rw	rw	rw	rw	rw*	rw*	r	rw	rw	rw	rw	rw

31:27   Reserved, always zero.

26   Output flip bit. When this bit is set to 0b1 the PWM outputs are flipped.

25:22   Dead band scaler. These bits are used to scale the system clock when generating dead band time. This field is only present if the *dbscaler* generic is set to 1. When these bits are written the dead band scaler register inside the core is not updated immediately. Instead these bits are written to a reload register which updates the actual scaler when it underflows. This is done in order to prevent the dead band scaler register to change during the actual dead band time. Reset value is 0b0..0 (all zeroes).

21   Dead band enable. 0b0 = Dead band time generation is disabled, no dead band time will be inserted when the PWM output switch from deactive to active. 0b1 = Dead band time will be inserted when the PWM output switch from deactive to active. Reset value is 0b0.

20:15   Interrupt scaler. Determines how many compare/period matches that need to occur before an interrupt is generated. All zeroes means that an interrupt will occur every compare/period match, a one means that an interrupt will occur every second match etc. Note that when generating a symmetric PWM two compare matches occur during a PWM period but when generating an asymmetric PWM only one compare match occur during a period. Reset value is 0b0..0 (all zeroes).

14   Interrupt type. 0b0 = Generate interrupt on PWM period match. 0b1 = Generate interrupt on PWM compare match. Reset value is 0b0.

13   Interrupt enable/disable bit. 0b0 = Interrupt is disabled. 0b1 = Interrupt is enabled. Reset value is 0b0.

+46 31 7758650 | frontgrade.com/gaisler

*Table 1030.*0x2C - PCTRL - PWM control register

12:10	Scaler select bits. These bits are used to select which of the system clock scalers that will be used when generating the current PWM. This field is only present when the *nscalers* generic is greater than 1. These bits can only be set if the PWM is disabled, i.e. *en* bit (see below) set to 0b0. Reset value is 0b000.
9	Waveform PWM enable. This bit can only be set if the current PWM is the PWM with the highest index (determined by the generic *npwm*) and if the *wavepwm* field in *Capability register 2* is set to 1. Also the PWM need to be disabled, i.e. *en* bit (see below) set to 0b0. When this bit is set the core will reload the internal PWM compare registers with values from the waveform RAM instead of values from the *PWM compare register*. Reset value is 0b0.
8	Dual compare mode enable. If this bit is set to 0b1 and the *meth* bit (see below) is set to 0b1 (symmetric) then the core will update its internal PWM compare register twice every PWM period, once when the counter is zero and once when a period match occur and the counter starts counting downwards again. In this way it is possible to have two different compare values, one when counter is counting upwards and one when counter is counting downwards. If this bit is 0b0 the compare register is only updated when the counter is zero. This bit has no effect if an asymmetric PWM is generated. Reset value is 0b0. This bit is only present if the *dcmode* bit in the *Capability register* is set.
7	When this pair_zero bit is set to 0b1 and the pair bit is set to 0b0 the complement output is always set to zero. When this bit is set to 0b0 and the pair bit is set to 0b0 the complement output is inactive (depending on the polarity). When the pair bit is set to 0b1, this bit has no function.
6	PWM generation method select bit. This bit selects if an asymmetric or symmetric PWM will be generated, where 0b0 = asymmetric and 0b1 = symmetric. . The asymmetric and symmetric methods are only available if the generics *asympwm* and *sympwm* respectively are set to 1. This bit can only be set if the PWM is disabled, i.e. *en* bit (see below) set to 0b0. The core prevents software from setting this bit to an invalid value. Reset value is 0b0 if asymmetric PWM is supported otherwise 0b1.
5:3	PWM fix value select bits. These bits can be used to set the PWM output to a fix value. If bit 3 is set to 0b1 then bit 4 decides what value the PWM output will have. If the *pair* bit (see below) is set to 0b1 while bit 3 is set to 0b1 as well then bit 5 determines what value the complement output will have. Reset value is 0b000.
2	PWM pair bit. If this bit is set to 0b1 a complement output for this PWM will be generated, creating a PWM pair instead of a single PWM. The complement output will be the first ouput's inverse, with the exception that dead band time might be added when the values switch from deactive to active. Reset value is 0b1.
1	PWM polarity select bit. 0b0 = PWM is active low, 0b1 = PWM is active high. This bit can only be set if the PWM is disabled, i.e. *en* bit (see below) set to 0b0. Reset value equals *defpol* bit in *Capability Register 1*.
0	PWM enable/disable bit. 0b0 = PWM is disabled. 0b1 = PWM is enabled. When this bit is set to 1 (from 0) and the *wen* bit (see bit 9 above) is set the core's internal address counter for the waveform RAM is reset. Reset value is 0b0.

63.3.11 Waveform RAM, Word X

*Table 1031.*0x8000 - 0xFFFC - Waveform RAM, word X

31	wbits+1	wbits	0
R		waveform data	
0		NR	
r		rw	

31:wbits+1	Reserved, always zero. wbits is the value of the *wdbits* field in *Capability register 2*. Note that this field is not present if wbits = 31.
wbits:0	wbits is the value of the wdbits field in *Capability register 2*. Data in the waveform RAM at the address which the current register maps to can be read/written through these bits. This register can only be read/written if either the *wen* bit or *en* bit in the associated PWM's PWM control register are set to 0.

63.4   Vendor and device identifier

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x04A. For description of vendor and device identifiers see GRLIB IP Library User's Manual.

63.5 Implementation

63.5.1 Reset

The core changes reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core will add reset for all registers if the GRLIB config package setting *grlib_sync_reset_enable_all* is set.

The core does not support *grlib_async_reset_enable*. The registers driving PWM output are always implemented with asynchronous reset.

63.5.2 RAM usage

The core maps all usage of RAM on the *syncram* (or *syncramft* if *ft* generic is not set to 0) component from the technology mapping library (TECHMAP). RAM is only used if the core is configured with support for generation of a waveform PWM (*wavepwm* generic set to 1). The size of the instantiated RAM is determined by the *wbits* and *wdepth* generics. *wdepth* is the number of words that the RAM can hold, and *wbits* is the number of bits in each word. Fault tolerance - byte parity DMR or TMR - can be added to the RAM by setting the *ft* generic to 1 or 2. Note that the *ft* generic need to be set to 0 if the core is used together with the GPL version of GRLIB, since that version does not support any fault tolerance.

63.6 Configuration options

Table 1032 shows the configuration options of the core (VHDL generics).

*Table 1032.*Configuration options

Generic name	Function	Allowed range	Default
pindex	APB slave index	0 - NAPBSLV-1	0
paddr	ADDR field of the APB BAR.	0 - 16#FFF#	0
pmask	MASK field of the APB BAR. Need to be set to 16#F00# or smaller if the generic *wavepwm* is set to 1.	0 - 16#FFF#	16#F00#
pirq	APB irq number.	0 - NAHBIRQ-1	0
memtech	Memory technology used for waveform buffer. This generic has no impact if *wavepwm* is 0.	0 - NTECH	inferred
npwm	Number of PWM outputs.	1 - 8	3
pbits	Number of bits used for each PWM.	1 - 32	16
sbits	Number of bits in the system clock scaler(s).	1 - 32	16
nscalers	Number of system clock scalers.	1 - 8	1
dbbits	Number of bits used for the dead band configuration for each PWM.	1 - 32	8
dbscaler	Decides if a scaler is implemeted for the dead band configuration for each PWM. 1 = A four bit system clock scaler is implemented for each PWM. 0 = No scaling of the system clock when calculating the dead band time is implemented.	0 - 1	1
asympwm	Decides if assymetric PWM generation is implemented. This generic can not be set to 0 if the *sympwm* generic is set to 0 as well.	0 - 1	1
sympwm	Decides if symmetric PWM generation is implemented. This generic can not be set to 0 if the *asympwm* generic is set to 0 as well.	0 - 1	1

*Table 1032.*Configuration options

Generic name	Function	Allowed range	Default
dcmode	Enables dual compare mode. Core then supports updates of the PWM's compare registers twice during every (symmetric) PWM period. This generic has no effect if sympwm is set to 0.	0 - 1	0
wavepwm	Decides if the core implements support for generating a waveform PWM. If this generic is set to 1 then a RAM block of size *wdepth*wbits* bits will be instantiated.	0 - 1	1
wbits	The number of bits in each of the wdepth words in the internal RAM that holds the waveform. This generic has no impact if *wavepwm* is 0. This generic can not be larger than the *pbits* generic.	1 - 32	8
wdepth	The number of *wbits* wide words that need to fit in the internal buffer holding the waveform. If *wdepth* is not a power of two then the actual number of words that will fit in the buffer is the closest power of two above *wdepth*. This generic has no impact if *wavepwm* is 0.	1 - 8192	512
wsync	If this generic is set the core supports the generation of a synchronization signal. The synchronization signal can be configured to go active any time during the waveform PWM. This generic has no impact if *wavepwm* is 0.	0 - 1	1
sepirq	0 = One irq number (value of *pirq* generic) is used for all PWMs. 1 = Each PWM has it's own irq number, starting with the value of *pirq* and counting up to *pirq*+(*npwm*-1). 2 = The interrupt configuration depend on the *npwm* generic in the following way: If *npwm* < 3, each PWM has its own irq (*pirq* and possibly *pirq*+1). If *npwm* = 3 the PWMs share irq (*pirq*). If 3 < *npwm* < 6 the first three PWMs share irq (*pirq*) and the remaining PWM(s) have their own irq (*pirq*+1 and possibly *pirq*+2). If *npwm* >= 6 the first three PWMs share irq number *pirq*, the second three PWMs share irq number *pirq*+1, and (if implemented) the last two PWMs have their own irq (*pirq*+2 and *pirq*+3).	0 - 2	0
ft	This generic determines if fault tolerance should be added to the RAM that holds the waveform PWM. This generic has no impact if *wavepwm* is 0. 0 = no fault tolerance, 1 = Byte parity DMR, 2 = TMR. Note that this generic need to be set to 0 if the core is used together with the GPL verison of GRLIB, since that version does not include any fault tolerance.	0 - 2	0
defpol	This generic sets the default polarity of the PWM outputs. 0 = Active low polarity, outputs are high after reset/power-up. 1 = Active high polarity, outputs are low after reset/power-up.	0 - 1	1

64   GRRT - MIL-STD-1553B / AS15531 Remote Terminal Back-End

64.1   Overview

This core provides the back-end logic for a MIL-STD-1553B Remote Terminal, taking care of the details of the bus protocol. The core provides a simple signaling interface, that can be converted by a front-end to bus master accesses, direct block-RAM, FIFO or register accesses, depending on requirements.

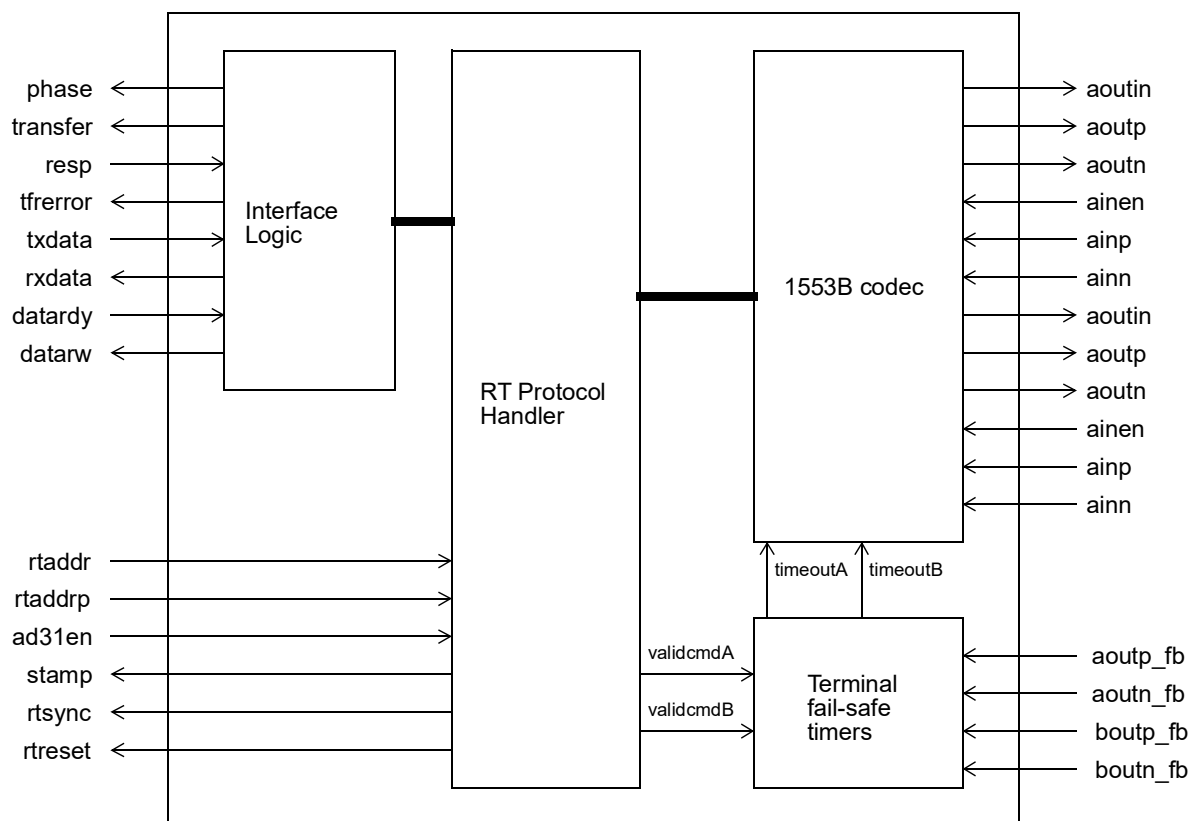
The RT supports single or dual-redundant buses, and all types of transfers allowed by the 1553B standard. The back-end includes 1553 codec, RT protocol handling state machines, and terminal fail-safe timers.


Figure 153. GRRT block diagram showing interfacing signals

64.2   Electrical interface

The core is connected to the MIL-STD-1553B bus wire through single or dual transceivers, isolation transformers and transformer or stub couplers as shown in figure 154. If single-redundancy is used, the unused bus receive P/N signals should be tied both-high or both-low. The transmit enable output is

GRIP

Apr 2024, Version 2024.1

878

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

inverted (called transmitter inhibit) as is the standard on most transceivers. See the standard and the respective component's data sheets for more information on the electrical connection.
Figure 154. Interface between core and MIL-STD-1553B bus (dual-redundant, transformer coupled)

64.3 Operation

64.3.1 Address configuration

The core's RT address is set through RT address and parity input signals. If the parity is not odd (the exclusive-or of the RT address lines and parity line is zero), the back-end will not respond to commands from the bus.

There is also an input bootstrap signal ad31en, determining whether the address 31 should be treated as a normal RT address or as the broadcast address. If ad31en is high and the RT is configured to address 31, it will respond on this address. If ad31en is low, then the RT will use address 31 as broadcast address and never respond on this address regardless of address configuration.

*Table 1037.*Possble address configurations

ad31en	rtaddr	rtaddrp	Regular address	Broadcast address
0	0..30	Correct	=rtaddr	31
		Wrong	None	None
	31	Correct (0)	None	31
		Wrong (1)	None	None
1	0,2,...,30	Correct	=rtaddr	None
		Wrong	None	None
	31	Correct (0)	=rtaddr(=31)	None
		Wrong (1)	None	None

64.3.2 Transfer handling

Each transfer is processed in the following four stages:

• Idle (phase="00") - waiting for command on the bus, "transfer" signal outputs at undefined

• Legalize (phase="01") - Waiting for front-end to respond to legalization request by setting resp inputs to legal (resp="01") or illegal (resp="10").

• Transfer (phase="11") - Transferring data words.

GRIP
Apr 2024, Version 2024.1
879
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Commit (phase="10") - Transfer completed, successfully if tferror=0. Waiting for frontend to deassert resp input, then goes back to idle.

After the front-end has legalized or illegalized the command by setting resp to "01" or "10", it should keep the resp signal set until the transfer has completed. In the idle and commit stages, the response should be set back to unknown ("00"). The core will delay going from idle to legalize state if the response signal is already set. This acts as a handshake and prevents earlier responses from getting used multiple times.

64.3.3 Data transfers

During the transfer phase, data words are transferred depending on direction (transfer bit 10).

For receive transfers, received data words will be available on the rxdata output when the datarw signal is high. For transmit transfers, outgoing data words are read from the txdata input when the datarw signal is high.

To provide flow control, the datardy input signals whether the user logic is ready for the datarw signal to be asserted.

The number of words to be transferred is given by bits 4:0 of the transfer output signal, all all-zero value indicates 32 data words. An exception to this is for mode commands with data, where the word count is always 1. In case of error, less words than expected may be transferred.

64.3.4 Error handling

Normally, the best way to handle errors in an RT is to ignore the failed command and let the BC perform the error recovery appropriate for the system. The design of the 1553 bus means the BC can always see an error occured so there is no need to signal this separately.

To simplify the user logic design, transfers will always go through all the four phases and spend at least one cycle in each state, even if an error occurs during the transfer. If an error occurs during the transfer or the request was illegalized by the user logic, the tfrerror output signal is asserted and kept high until the core has left the commit phase.

64.3.5 Response-time requirements

The core will wait for the user logic in three cases:

1. In the legalize phase, waiting for command legalization.

2. In the transfer phase, waiting for the datardy signal to go high.

3, In the commit phase, waiting for the resp signal to go low.

In these cases, the user logic must respond within a limited time in order for the core to continue. Failing to meet these limits will result in the RT not responding to the command or not sending the full word count. It does not cause any permanent error so after the user logic has caught up, it will again work as before.

For the datardy signaling, the maximum tolerated delay is 20 us (400 cycles at 20 MHz), which is the time it takes to send a data word on the 1553 bus.

To analyze the maximum value tolerated for the legalization interface one must consider the bus switching requirement, where another command may arrive on the other bus at any time and override the current command. This could happen while an old transfer is still in the legalize phase. Since the GRRT always processes commands through all four phases, the old command must be legalized, then go to the commit phase and wait for resp to go low, then the new command needs to be legalized. All this must complete within 8.5 us (170 cycles at 20 MHz).

GRIP
Apr 2024, Version 2024.1

880

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

64.3.6 Mode commands

The following mode commands without external data are supported by the core and can not be illegalized:

- Synchronize - will assert the rtsync output one cycle

- Transmit status word - transmits the current value of the 1553 status word

- Transmit last command - transmits the current value of the 1553 status word followed by the last valid command word received by the RT.

- Transmitter shutdown - Shuts down the transmitter on the other bus than the one where the command

- Override transmitter shutdown - Cancels an earlier transmitter shutdown command

- Inhibit terminal flag - Masks the terminal flag bit

- Override inhibit terminal flag bit - Cancels an earlier inhibit terminal flag command

- Reset remote terminal - Clears the transmitter shutdown and inhibit terminal flag status, and asserts the rtreset output for one cycle. The front-end can use this to reset the core, if appropriate.

They will be handled internally by the core, keeping the phase at idle state during the command.

The following mode commands without data are not supported and will be treated as an illegal command (the core will respond with the message error status bit set):

- Dynamic bus control (only applicable to backup bus controllers)

- Initiate self test (no self test implemented)

64.3.7 Mode commands with external data

Three mode commands with external data are supported by the core:

- Synchronize with data word - One received data word is transferred

- Transmit vector word - One data word to transmit is transferred

- Transmit BIT word - One data word is transferred

These will be handled using the same four-phase scheme as regular data transfers, however to identify the mode command bits 9:5 of the transfer output will be set to "00000" or "11111" and bits 4:0 are set to the mode command number. As for regular transfers, it is also possible for the front-end to illegalize these two commands if they are not implemented.

Not supported (always illegalized) mode commands with data are:

- Selected Transmitter Shutdown (not applicable for dual-redundant RTs)

- Override Selected Transmitter Shutdown (not applicable for dual-redundant RTs)

64.3.8 Timestamping

The core has a stamp output which is asserted for one cycle when the command word is received. This is mainly useful together with the rtsync for accurately time-stamping the synchronize mode command for time synchronization purposes.

64.4 Implementation

64.4.1 Clocking

The core operates in two clock domains, the front-end clock domain and the codec clock domain, with internal synchronization between the domains. The codec clock must be 20 or 24 MHz, configured

GRIP
Apr 2024, Version 2024.1

881

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

via the codecfreq generic, but the front-end clock can be any frequency from 10 MHz and up. All the signals interfacing the front-end are synchronous to the front-end clock.

If the front-end clock is the same (20 or 24 MHz) clock as the codec, the generic sameclk can be set to 1 to remove the internal synchronization registers to save some area.

64.4.2 Reset

The core does not change reset behaviour depending on settings in the GRLIB configuration package (see GRLIB User's Manual).

The core has two separate reset inputs for the two clock domain's registers. The resets can be configured as either synchronous or asynchronous.

64.5 Configuration options

Table 1038 shows the configuration options of the core (VHDL generics).

Table 1038. Configuration options

Generic	Function	Allowed range	Default
codecfreq	Codec clock frequency, 20 or 24 MHz	20 or 24	20
sameclk	Set to 1 if codec clock and user clock are tied to the same clock signal (removes synchronization registers)	0-1	1
syncrst	Chooses between synchronous ('1') or asynchronous ('0') reset.	0 - 1	1

64.6 Signal descriptions

Tables 1039 shows the interface signals of the core (VHDL ports).

Table 1039. Signal descriptions on AMBA side

Signal name	Type	Function	Active
CLK	Input	Clock, front-end clock domain	-
RST	Input	Reset, deasserted synchronously to CLK	Low
CLK1553	Input	Codec clock	
RST1553	Input	Reset, deasserted synchronously to CLK1553	Low
RTADDR	Input	RT address (bootstrap signal)	-
RTADDRP	Input	Odd parity for RTADDR (bootstrap signal)	-
RTSTAT	Input	RT status bits Bit 3 - Service request Bit 2 - Busy Bit 1 - Subsystem flag Bit 0 - Terminal flag	
AD31EN	Input	Address 31 configuration: 0 = Address 31 is broadcast address 1 = Address 31 is valid normal RT address Should be kept constant during operation	-
RTSYNC	Output	Asserted for synchonize mode command	High
RTRESET	Output	Asserted for reset remote terminal mode command	High

65   GRSCRUB - FPGA Scrubber Controller

65.1   Overview

Devices in the space environment are vulnerable to radiation-induced particles, and SRAM-based FPGAs are particularly susceptible to Single Event Upsets (SEU) that may affect the configuration memory. Soft errors in the FPGA configuration memory can change the device functionality and lead to errors and malfunction in the system. The scrubbing method is essential to avoid an accumulation of upsets in the FPGA configuration memory.

The GRSCRUB is an external FPGA scrubber controller responsible for programming and monitoring the FPGA configuration memory. The GRSCRUB IP is currently compatible with the Kintex UltraScale and Virtex-5 Xilinx FPGA families. The scrubbing functionality can be set to target the entire FPGA configuration memory or just a defined memory area.

The scrubbing mitigation technique only fixes bit-flips in the FPGA configuration memory, being up to the user to apply any additional method to mask errors and re-establish the state of the system. Scrubbing does not cover soft-errors affecting User memory data. All dynamic data stored in memory elements, such as shift-registers (SRL), LUT RAMs, and Block RAMs (BRAM), are not verified by the GRSCRUB.

Figure 155 shows the system block diagram. The GRSCRUB accesses the FPGA configuration memory through the SelectMap interface. In addition, the GRSCRUB accesses through an AMBA AHB or AXI4 bus a Golden memory that can be ROM or RAM. The original configuration bitstream is stored in the Golden memory, and it is used both to configure the FPGA at start-up and to repair the FPGA configuration memory in case of errors. The Golden memory also stores the mask data and the Cyclic Redundancy Check (CRC) codes used to check the configuration bitstream integrity. If a ROM memory is used, all the required data must be previously stored, such as the frame addresses and CRC codes, as further described, since some functionalities of the GRSCRUB that writes on the memory will not be executed.

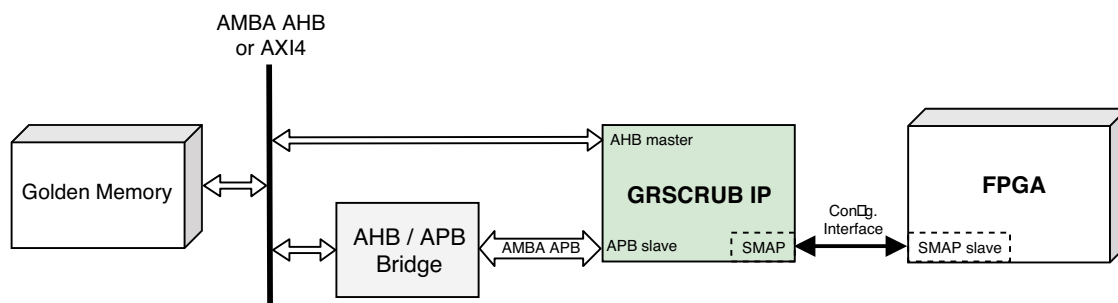
The GRSCRUB registers can be accessed and configured through the AMBA APB bus.


Figure 155. System block diagram

The SelectMap interface must be enabled in slave mode at the target FPGA to allow external control from the GRSCRUB. Figure 156 shows an example of the GRSCRUB and slave SelectMap connection in a Xilinx UltraScale FPGA. In the example, the GRSCRUB port signals are directly attached to the SelectMap pins. The system provides the SelectMap clock to the FPGA configuration interface (CCLK) and the GRSCRUB (SMAPCLKI). As further described, the GRSCRUB works in two clock domains, CLK that is the system clock, and SMAPCLKI that is the SelectMap clock used for synchronization. In addition, the GRSCRUB has a clock enable signal that controls whether the CCLK should be enabled or not. The FPGA mode pins M[2:0], which select the FPGA configuration interface used, must be configured to slave SelectMap. Thus, these pins must be connected to M[2:0] pins from the GRSCRUB or directly tied to high/low levels externally. For more details, see the documentation for the Xilinx FPGA family. Also, refer to the FPGA Data Sheet to define the proper voltage connection.

65.2 Soft error mitigation

Radiation-induced soft errors are errors provoked by radiation particles that affect the design without damaging the device permanently. SEUs, or bit-flips, in the FPGA configuration memory may lead to persistent errors in the system, changing the architectural implementation of the design. Soft errors can also affect the memory data, registers, and flip-flops, and cause errors in the system outputs. Single Events Transients (SET) are transient pulses that propagate through the combinational logic and may be captured by a memory cell. The Single Event Functional Interrupt (SEFI) occurs when a soft error affects the control logic or a state register and leads to hangs or crashes in the design.

The GRSCRUB targets soft errors affecting the FPGA configuration memory. It does not avoid bit-flips from happening or its effects on the design. The GRSCRUB aims to maintain the configuration memory consistent by repairing the logic and correcting bit-flips, avoiding the accumulation of faults. Memory elements that store dynamic data, such as BRAMs, distributed memory, and flip-flops, are not protected by the GRSCRUB. The scrubbing technique is able to verify only the static data in the configuration memory. The configuration memory stores the architectural logic information of a design and defines the function, behavior, and connectivity of each block. The GRSCRUB must be combined with additional fault mitigation methods at the user level to increase the overall system reliability.

Soft errors affecting the dynamic elements can be mitigated by applying fault tolerance techniques such as redundancy or Error Correction Code (ECC). Triplicating the logic is an efficient method to cope with the effects of single faults in the design. Additional user level techniques can also be applied to deal with Silent Data Corruptions (SDC) that are incorrect results outputs. Moreover, periodic reset may be required to reestablish the system state, and restore the initial state of flip-flops. Since SEFIs may also affect internal control elements of the FPGA or the configuration interface, a complete power cycle might be required to restore the system.

65.3 Operation

The GRSCRUB main operational modes are programming the FPGA and scrubbing the configuration memory correcting errors. Figure 157 describes the basic flow of these two operational modes (OPMODE). After system reset, the GRSCRUB remains in the idle state until the EN bit of the Configuration Mode Register (CONFIG) is set high. If the programming mode is selected, the GRSCRUB starts the configuration sequence to program the FPGA. At the end of the programming phase, the OPDONE bit of the Status Register (STATUS) is set high, and the GRSCRUB return to the idle state.

For the scrubbing operation mode, there are two types of execution: blind and readback scrubbing. Before enabling scrubbing, it is required to map the FPGA frame addresses by executing the Mapping operation mode or previously saving them on the Golden memory. The scrubbing can be defined as periodic with a delay between each memory scrubbing, or just one time. If a periodic execution is configured in the registers, the GRSCRUB repeats the scrubbing operation after a configured delay and only if it is still enabled. Otherwise, the OPDONE bit of the Status Register (STATUS) is set, and the GRSCRUB return to the idle state.

The following sections describe in more detail the GRSCRUB operational modes.

65.3.1 GRSCRUB operational modes

The GRSCRUB has five operation modes that can be selected in the OPMODE of the Configuration Mode Register (CONFIG) and are described in table 1041. The Idle mode is the default state of the GRSCRUB. The operational mode must be configured before, or at the same time, the GRSCRUB is enabled. Also, the OPDONE and SCRERR bits in the Status Register (STATUS) must be cleared, see section 65.13.1 for more details.

Note: After enabling the GRSCRUB to run an operation mode, the values of the configuration registers must not be changed. Otherwise, it can cause an error in the GRSCRUB execution. If the GRSCRUB is disabled during execution, it will stop the operation, send the command to desynchronize the FPGA slave SelectMap, and return to the idle state. Thus, the current operation mode will be aborted.

Table 1041. GRSCRUB operation modes description

Operation Mode	Code	Description
Idle	0000	Idle mode (default after reset).
Programming	0001	FPGA configuration. Program the configuration bitstream into the FPGA.
Scrubbing	0010	FPGA scrubbing. Perform the blind or readback scrubbing.
Mapping	0011	FPGA mapping frames address.
Golden CRC	0100	In this OPMODE the GRSCRUB computes a golden copy of the CRC data check and saves it on the Golden memory.

65.3.2 Idle mode

After reset, the GRSCRUB stays in idle mode waiting to be enabled. When the EN bit of the Configuration Mode Register (CONFIG) is disabled (logically 0), the GRSCRUB remains in idle mode.

Figure 157. GRSCRUB flow for programming and scrubbing operation modes

65.3.3 Programming mode

The GRSCRUB can configure the FPGA by programming the configuration bitstream through the configuration interface. The configuration bitstream must be stored into the Golden memory, and the configuration bitstream address must be set in the GRSCRUB registers.

The following steps must be performed before enabling the GRSCRUB to execute the programming mode:

- The configuration bitstream must be stored in the Golden memory;

- The GRSCRUB must be disabled to configure the registers;

- The OPDONE and SCRERR bits in the Status Register (STATUS) must be cleared;

- Set the Configuration Mode Register (CONFIG) with the programming OPMODE (0001);

GRIP

Apr 2024, Version 2024.1

888

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden

+46 31 7758650 | frontgrade.com/gaisler

- Set the low and high configuration bitstream addresses in the Low Golden Bitstream Address Register (LGBAR) and High Golden Bitstream Address Register (HGBAR), respectively;

- Set the FPGA Device Identifier Register (IDCODE).

After setting the registers, the GRSCRUB can be enabled by writing the logical 1 in the EN bit of the Configuration Mode Register (CONFIG). When the programming phase is finished, the OPDONE bit goes to high, and an interrupt is generated (if interrupts are enabled).

65.3.4 Scrubbing mode

The user can define the scrubbing operational mode as blind or readback. Since the FPGAs are frame-oriented, the configuration memory is verified considering the frame size. For instance, the frame length of the Xilinx UltraScale FPGA family is 123 words of 32 bits each, whereas it is 41 32-bit words for Virtex-5. The FPGA frame length and the total number of frames must be configured in the Frame Configuration Register (FCR).

A scrubbing run is defined as one execution of the blind or readback scrubbing in all the selected configuration frames. The scrubbing can be set to be periodic, which means that scrubbing runs are periodically executed in time.

Note: The scrubbing mitigation technique only fixes bit-flips in the FPGA configuration memory, it is up to the user to apply any additional method to mask errors and re-establish the state of the system. In addition, scrubbing does not cover soft-errors affecting User memory and dynamic data.

The steps below must be performed before enabling the GRSCRUB to execute the scrubbing mode. If a register has been previously set and the data has not changed, there is no need to reconfigure it.

- The configuration bitstream must be stored in the Golden memory;

- The frames addresses must be stored in the Golden memory;

- The FPGA must be previously programmed;

- The GRSCRUB must be disabled to configure the registers;

- The OPDONE and SCRERR bits in the Status Register (STATUS) must be cleared;

- Set the Configuration Mode Register (CONFIG) with the scrubbing OPMODE (0010);

- Set whether the scrubbing mode is blind (logical 0) or readback (logical 1) in the SCRM bit of the Configuration Mode Register (CONFIG). Blind scrubbing is set by default;

- Set whether the scrubbing run is just one time (logical 0) or periodic (logical 1) in the SCRUN bit of the Configuration Mode Register (CONFIG). One time is set by default. If a periodic run is set, the Delay Register (DELAY) should also be configured. No delay between runs is set by default;

- Set the low and high configuration bitstream addresses in the Low Golden Bitstream Address Register (LGBAR) and High Golden Bitstream Address Register (HGBAR), respectively;

- Set the address for the first golden frame in the Low Golden Start Frame Address Register (LGSFAR). Note that the first golden frame address is different from the low bitstream address. The LGSFAR should be the address in the Golden memory that saves the first word of the first frame in the bitstream;

- Set the address for the first frame of the FPGA configuration memory to be scrubbed in the Low Frame Address Register (LFAR);

- Set the FPGA Device Identifier Register (IDCODE);

- Set the number of frames and the frame length in the Frame Configuration Register (FCR).

Additional configuration is required for readback mode:

- The mask data must be stored in the Golden memory;

GRIP
Apr 2024, Version 2024.1

889

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Set the low mask address in the Low Golden Mask Address Register (LMASKAR);

- Set which data check is enabled to detect errors in the FFCEN and CRCEN bits of the Configuration Mode Register (CONFIG);

- Set if the readback scrubbing mode is only detection (logical 1) or detection and correction (logical 0) in the CORM bit of the Configuration Mode Register (CONFIG). Detection and correction is set by default;

- Set the Low Golden Frame Mapping Address Register (LFMAPAR) with the low address of the mapped frames in the Golden memory (only required if correction is selected);

- Optionally, to save the readback data in the Golden memory, the WRBKEN bit of the Configuration Mode Register (CONFIG) must be enabled. Also, the low memory address to save the readback data must be set in the Low Golden Readback Address Register (LGRBKAR). These steps are not required for other modes. Note that if the WRBKEN bit is enabled, the GRSCRUB does not detect or correct any error, it only copies the configuration data read from the FPGA to the Golden memory.

After setting the registers, the GRSCRUB can be enabled by writing 1 in the EN bit of the Configuration Mode Register (CONFIG). The OPDONE bit is only asserted if one time scrubbing is selected. The SCRUND bit goes high after each scrubbing execution.

I. Blind scrubbing mode

In the blind scrubbing operation mode, the GRSCRUB will rewrite each FPGA frame from the configuration memory without any verification. Thus, the blind scrubbing does not provide the error detection capability. The blind scrubbing is configured to reprogram the configuration memory frames set in the Frame Configuration Register (FRC) and Low Frame Address Register (LFAR). Thus, the total number of frames, frame length, and the starting FPGA frame address must be configured. Only frames from the configuration block must be set. The frames from the FPGA configuration block (type 000) includes the configuration elements CLBs, I/Os, and CLKs. Blind scrubbing does not rewrite User memory elements. See the FPGA Configuration Manual for more details about frame block types.

II. Readback scrubbing mode

In the readback scrubbing operation mode, the GRSCRUB verifies the integrity of each FPGA frame of the configuration memory, and then, in case of errors, rewrites the frame with correct data from the Golden memory. The error detection can be performed through CRC verification, and by comparing all frame bits with the golden copy. The latter is here defined as Full Frame Check (FFC). Each type of verification can be configured to be enabled or not. The CRC and FFC data checks are further described in the next sections.

The GRSCRUB can operate in three types of readback scrubbing modes: save the readback data into Golden memory; only error detection; and error detection and correction. For error detection operation, the mask data must be previously stored in the Golden memory.

The mode of saving the readback data into memory can only be used if the Golden memory is RAM, and it is useful when the user needs to check the readback data. The Low Golden Readback Data Address Register (LGRBKAR) must be set. On this mode, the mask data is not required.

The correction mode is used to correct a faulty frame during readback scrubbing. The GRSCRUB replaces the erroneous frame in the FPGA by the golden frame read from the Golden memory. To enable the error correction, the CORM bit in the Configuration Mode Register (CONFIG) must be set to 0. By default, the correction is enabled. However, if the CORM bit is set to 1, the errors are only detected and not corrected in the readback phase.

Figure 158 describes the GRSCRUB flow in scrubbing operation mode for readback execution with error detection and correction enabled. The GRSCRUB starts reading a frame word from the FPGA configuration memory. If CRC is enabled, the GRSCRUB computes the CRC signature of the word. In sequence, the word is compared with the golden copy, if FFC is enabled. At the end of the frame

GRIP
Apr 2024, Version 2024.1

890

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

the CRC code is checked and the frame is corrected if an error is detected. For FFC, the frame is corrected immediately when a faulty word is identified. After correcting a frame, the same frame is reread and rechecked to ensure the erroneous bits are fixed. If the corrected frame still presenting an error, it is defined as an uncorrectable error, and the next frame is read. In case of uncorrectable errors, the UNCORRECTABLE_BIT_ERROR is set, the SCRERR bit is asserted, and it is recommended to reprogram the FPGA.

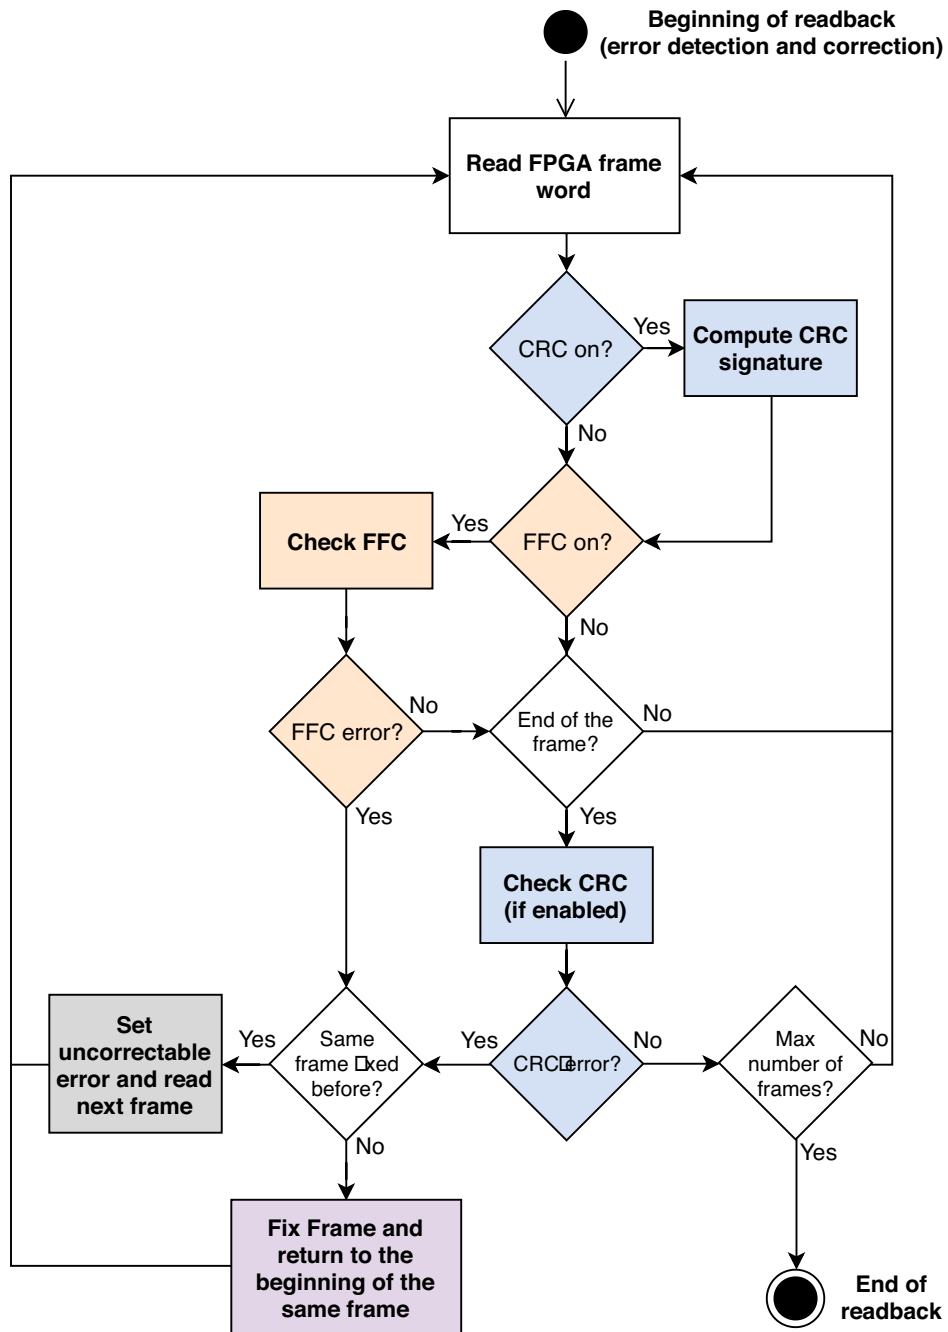
Differently from the blind scrubbing, the readback mode allows detecting errors and correcting the frame only if necessary, at the expense of more accesses to the Golden memory to read golden and mask data.


Figure 158. GRSCRUB flow in readback scrubbing mode for error detection and correction

GRIP

Apr 2024, Version 2024.1

891

Frontgrade Gaisler AB

Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

i. Cyclic Redundancy Check (CRC)

CRC is an error detection code that applies redundancy to check inconsistencies. A customized 32-bit CRC checksum algorithm is computed for each FPGA frame.

The CRC32 polynomial is:

$$x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x^1 + 1$$

The defined initial CRC signature for each frame is 0xFFFFFFFF. The first readback frame word is masked, using the corresponding mask word, then the CRC32 is applied using the signature. The output of this computation results in the next signature for the next readback frame word. That cycle is repeated for all words in the frame (frame length). The last computed signature corresponds to the frame CRC code.

During regular readback operation, the GRSCRUB reads the frame word from the FPGA, reads the mask word from the Golden memory, and computes the CRC signature. When it reaches the end of the frame, the generated CRC code is compared with the golden code from the Golden memory. If an error is detected, the faulty frame is corrected (if correction is enabled). Otherwise, the next frame is verified.

The CRC mode does not provide the total numbers of errors in the frame, and neither the error position. The number of errors detected present in Number of Errors Detected Register (ECNT) is related to the number of detected faulty frames. The CRC method has single error detection ensured. However, for more accurate error counting, the FFC method is recommended.

Before performing readback with CRC checking, the golden CRC codes must be previously saved into the Golden memory. The default configuration of the GRSCRUB assumes that the CRC codes are already saved on the Golden memory. Additionally, the GRSCRUB has the functionality of computing and saving the golden CRC codes, see section 65.3.6 for more details.

ii. Full Frame Check (FFC)

In the FFC mode, the GRSCRUB compares all the configuration frame words with the golden words. Thus, the number of error bits per readback word is known. However, when the correction is enabled, the frame is corrected whenever the first error is detected. Thus, even though more faulty bits might be present, only one error bit is counted for the frame. FFC is a more reliable method to detect errors then CRC since each word is compared with its golden. Therefore, all faulty bits can be detected.

65.3.5   Mapping mode

Before scrubbing the FPGA in readback mode with correction, the addresses of the configuration frames must be stored in the Golden memory. These addresses are required to fix a specific frame in the FPGA. The default configuration of the GRSCRUB assumes that the addresses are already saved on the Golden memory.

Additionally, the GRSCRUB has the functionality of mapping the frames and saving the addresses on the memory. Only frames defined as configuration block are mapped, which means that all block memories are excluded from the mapping. It is recommended first to power reset and program the FPGA before executing the mapping mode. Also, the Golden memory must be RAM to allow writing the addresses.

Depending on the FPGA internal architecture, there may exist dummy frames between rows addresses in the FPGA configuration memory. The called row boundary is an internal FPGA address alignment that must be considered during the mapping phase. Since these addresses are not accessible from the GRSCRUB, all dummy frame addresses are indicated as 0x00000000. The number of frames in the rows boundaries must be set in the ROWBND bit of FPGA Setup Register (SETUP). For instance, Xilinx Virtex-5 has two boundary frames between rows.

GRIP
Apr 2024, Version 2024.1

892

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

The steps below must be performed before enabling the GRSCRUB to execute the mapping mode. If a register has been previously set and the data has not changed, there is no need to reconfigure it.

- The GRSCRUB must be disabled to configure the registers;

- The OPDONE and SCRERR bits in the Status Register (STATUS) must be cleared;

- Set the Configuration Mode Register (CONFIG) with the mapping OPMODE (0011);

- Set the low mapping address in the Low Golden Frame Mapping Address Register (LFMAPAR);

- Set the address for the first frame of the FPGA configuration memory to be mapped in the Low FPGA Frame Address Register (LFAR). For instance, set the register to 0x00000000 to start from the first frame in the configuration memory.

- Set the number of rows boundaries in the ROWBND of the FPGA Setup Register (SETUP).

- Set the FPGA Device Identifier Register (IDCODE);

- Set the number of frames and the frame length in the Frame Configuration Register (FCR).

After setting the registers, the GRSCRUB can be enabled by writing the logical 1 in the EN bit of the Configuration Mode Register (CONFIG). When the mapping phase is finished, the OPDONE bit goes to high, and an interrupt is generated (if interrupts are enabled).

65.3.6 Golden CRC mode

The golden CRC codes must be stored in the Golden memory before enabling the readback scrubbing with CRC data check, see section 65.3.4 for more details about CRC. The GRSCRUB has the operation mode to compute and save the golden CRC codes. The Golden memory must be writable to allow writing the CRC golden codes.

The following steps must be performed before enabling the GRSCRUB to execute the golden CRC operational mode:

- The FPGA must be programmed;

- The frames addresses must be stored in the Golden memory;

- The GRSCRUB must be disabled to configure the registers;

- The OPDONE and SCRERR signals in the Status Register (STATUS) must be cleared;

- Set the Configuration Mode Register (CONFIG) with the golden CRC OPMODE (0100);

- Set the address for the first frame of the FPGA configuration memory to be scrubbed in the Low FPGA Frame Address Register (LFAR);

- Set the FPGA Device Identifier Register (IDCODE);

- Set the number of frames and the frame length in the FCR register;

- Set the low address for the first CRC code in the LCRCAR;

- The mask data must be previously stored in the Golden memory;

- Set the low mask address in the Low Golden Mask Address Register (LMASKAR).

After setting the registers, the GRSCRUB can be enabled by writing the logical 1 in the EN bit of the configuration register. When the GRSCRUB finishes the CRC computation, the OPDONE bit goes to high, and an interrupt is generated (if interrupts are enabled).

65.4 Mask data information

In the FPGA configuration memory there are dynamic bits that change their values during design execution, such as LUTRAMs and shift registers (SRL). During the configuration bitstream generation, the synthesis tool creates a mask file that indicates all dynamic bits as '1'. These bits should not be ver-

GRIP
Apr 2024, Version 2024.1

893

Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

ified in the error detection steps. For that, the GRSCRUB applies the mask word to the readback word before the data checking, following steps below:

1) Read mask word from Golden memory;
2) All bits of the mask word are inverted: *NOT mask_word*;
3) An *AND* operation of the readback word and the inverted mask word is performed.

- *Example:*

  > *mask_word: 0x0000FFFF*
  > *readback_word: 0x0FE50400*
  > *Result: readback_word AND (NOT mask_word) = 0x0FE50000*
  > *Thus, only 0x0FE50000 is applied to the fault detection methods.*

The mask data must be saved on the Golden memory and the start address should be set in the Low Golden Mask Address Register (LMASKAR). Since the GRSCRUB accesses only the masked data from the configuration frames (i.e., configuration block 000), it is not required to store the entire file in the Golden memory. However, the mask words must exactly corresponding to the readback words. Thus, the first mask word, whose address is set in the LMASKAR register, is related to the first word of the first readback frame, whose address is set in the Low FPGA Frame Address Register (LFAR).

The mask file has the same format as the configuration bitstream file. If the user decides to store only the mask words related to the scrubbed frames, the correlation between both must be matched, misalignment would cause erroneous verification of the bits.

Since the masked bits are not verified in the readback mode, faults affecting those bits cannot be detected.

65.5   FPGA frame information

Table 1042 shows the configuration bitstream and fame length for Xilinx Virtex-5 and Kintex UltraScale FPGAs as example.

Note: Each FPGA device has different configuration bitstream length, number of frames, and frame length. See the FPGA documentation for more information.

Table 1042. Configuration bitstream information for Xilinx Virtex-5 and Kintex UltraScale FPGAs

	Virtex-5 (XC5VFX130T)	Kintex UltraScale (KU060)
Configuration bitstream length	6,154,368 bytes	24,124,908 bytes
Total number of frames	37,520 frames	49,030 frames (plus 537 overhead words)
Block configuration frames[a][b]	25,980 frames (4,260,720 bytes)	37,499 frames (18,449,508 bytes)
Frame length	41 32-bit words	123 32-bit words

a. Only the configuration frames are verified (block type 000: CLBs, DSPs, and IOBs).
b. Block RAM contents are not included (block type 001).

65.6   Golden memory

The GRSCRUB requires access to a Golden memory in which the golden data must be stored. The memory can be ROM or RAM, and the access is made through the AMBA AHB bus. The stored data is related to the golden configuration bitstream, mask file, mapped frame addresses, and golden CRC codes. Figure159 describes an example of data saved in the Golden memory and the GRSCRUB registers that must be configured, as follows:

- Golden configuration bitstream: The entire configuration bitstream must be saved on memory. The Low Golden Bitstream Address Register (LGBAR) and High Golden Bitstream Address Register (HGBAR) correspond to the addresses of the first and last configuration bitstream words, respectively. The Low Golden Start Frame Address Register (LGSFAR) is the address in the Golden memory of the first word of the first frame to be scrubbed.

GRIP
Apr 2024, Version 2024.1
894
Frontgrade Gaisler AB
Kungsgatan | SE-411 19 | Goteborg | Sweden
+46 31 7758650 | frontgrade.com/gaisler

- Mask data: The required mask data is directly related to the scrubbed frames. The Low Golden Mask Address Register (LMASKAR) is the address of the first mask word of the first frame word to be scrubbed.

- Mapped frames addresses: The mapped addresses are also directly related to the scrubbed frames. The Low Golden Frame Mapping Address Register (LFMAPAR) is the address in the Golden memory of the first mapped frame to be scrubbed.

- CRC codes: One CRC code is saved per frame. The Low Golden CRC Address Register (LCRCAR) is the address in the Golden memory of the first golden CRC code of the first frame to be scrubbed.

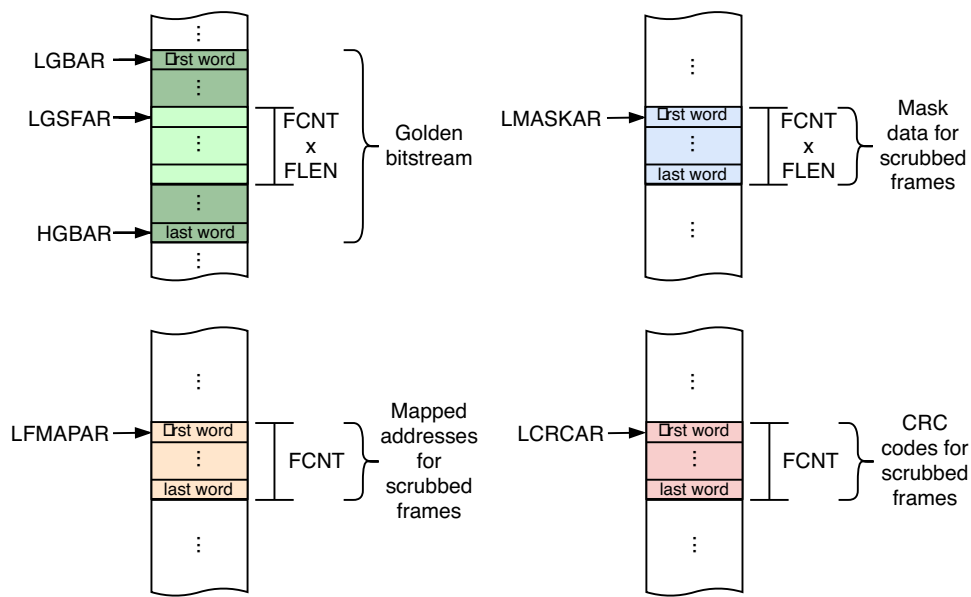
- The FCNT and FLEN bitfields of the Frame Configuration Register (FCR) are the number of scrubbed frames and length of each frame, respectively. Therefore, they represent the number of memory positions that must be sequentially accessed by the GRSCRUB in each operation.


Figure 159. Example of data storage configuration in the Golden memory and the relation with the GRSCRUB registers

As an example, Table 1043 describes the storage length required for Xilinx Virtex-5 and Kintex UltraScale FPGAs. Note that each FPGA device has different configuration bitstream length. See the FPGA documentation for more information.

Table 1043. Description of required Golden memory storage for Virtex-5 and Kintex UltraScale FPGAs

Data Memory	Virtex-5 [XC5VFX130T] (bytes)	Kintex UltraScale [KU060] (bytes)
Configuration bitstream	6,154,368	24,124,908
Mask[a]	4,260,720	18,449,508
Mapped frame addresses[b]	103,920	149,996
CRC codes	103,920	149,996
Total required storage	**10,645,661**	**42,907,220**

a. Since the GRSCRUB accesses only the mask data related to the configuration frames, it is not required to store the entire file.
b. Only configuration frames are mapped.

65.7 SelectMap configuration interface

The FPGA slave SelectMap configuration interface is used to load the configuration bitstream into the FPGA and for scrubbing operations. The GRSCRUB connects directly to the SelectMap pins, which are controlled and used as follows:

- **CCLK:** The SelectMap configuration clock is provided by the system, and it is controlled by the GRSCRUB clock enable signal (SMAPO.clk_en). By stopping the CCLK, it is possible to pause the data loading or reading from the SelectMap. The system design must provide a buffer to enable/disable the CCLK based on SMAPO.clk_en. The implementation details of the required setup are further described. See the FPGA Data Sheet to details about the maximum slave SelectMap CCLK frequency.

- **PROGRAM_B:** This signal is used to clean the FPGA configuration logic before starting the programming phase. The GRSCRUB set the PROGRAM_B to low during the number of clock cycles defined in the TPROG register. See in the FPGA documentation the minimum pulse width required. By default, TPROG is 150 clock cycles.

- **INIT_B:** It indicates when the FPGA is ready to receive configuration data. It also indicates any configuration or readback errors by low pulse.

- **DONE:** The GRSCRUB monitors the FPGA DONE signal to identify the completion the configuration sequence.

- **M[2:0]:** The configuration mode pins must be configured to logical "110" to select the slave SelectMap interface. For that, the pins can be tied directly to high or low level, or connected to the M pins of the GRSCRUB.

- **D[31:0]:** The bidirectional data bus is used for configuration and scrubbing operations. The RDWR_B signal defines the direction of the pins. SelectMap supports 8-bit (D[7:0]), 16-bit (D[15:0]), or 32-bit (D[31:0]) data bus widths. The bus width must be informed in the smap_buswide configuration option of the GRSCRUB, which has independent input and output data buses. The system is responsible for multiplexing the data signals, based on RDWR_B, and provide the connection to the SelectMap bidirectional data bus.

- **RDWR_B:** It is used to select the direction of the data bus. When RDWR_B is high (logical 1), the SelectMap data pins are outputs (reading from the FPGA). Otherwise, the bus is input (loading data to the FPGA). The GRSCRUB only changes the RDWR_B when the SelectMap interface is disabled (i.e., when CSI_B is logically 1).

- **CSI_B:** This signal enables (logical 0) and disables (logical 1) the SelectMap interface.

In order to allow the GRSCRUB to access and control the slave SelectMap interface, the generated FPGA configuration bitstream must be configured following the requirements presented in table 1044.

Table 1044. Example of configuration bitstream settings for enabling the FPGA slave SelectMap interface

Synthesis tool	- Vivado Design Suite 2018.1; or - ISE Design Suite 14.7

Configuration bitstream settings	- Enable the mask file generation
	- Do not prohibit readback in the configuration bitstream security settings
	- Do not use encryption in the configuration bitstream
	- Set the SelectMap pins to persistent in the configuration bitstream generator (bitgen)[a]:
	    -g Persist:Yes or
	    BITSTREAM.CONFIG.PERSIST YES
	- Set the constraints to allow programming and readback the FPGA through slave SelectMap interface:
	    CONFIG CONFIG_MODE=S_SELECTMAP32+READBACK

a. The ICAP interface cannot be used in the FPGA design if Persist:Yes is set.

65.8   Soft-errors affecting the FPGA configuration interface

The FPGA configuration interface might also be affected by soft-errors, which may lead to catastrophic results during the scrubbing operation. For instance, if during a blind scrubbing the FPGA frame address register is affected and its value is changed to other valid address, all the following frames would be wrongly overwritten, and the design would be compromised.

Therefore, the GRSCRUB verifies the integrity of the FPGA configuration interface before each new scrubbing run. The verification is performed by reading a specific frame and checking its address. If the returned address is precisely the expected, the interface is considered responsive, and the scrubbing run starts. Otherwise, the CI_INTEGRITY_ERROR is reported. In this case, it is recommended to power cycle the FPGA. To enabling the verification feature, the CICHECK bit in the Setup Register (SETUP) must be 1.

Additionally, a safer approach is to set up the configuration interface for each scrubbed frame, instead of configuring all frames at once. For instance, writing one frame at time during blind scrubbing avoids overwritten the entire memory in case of errors in the FPGA frame address register. The BLK-FRAME bitfield in the Setup Register (SETUP) defines the number of frames to be scrubbed sequentially during blind scrubbing or readback. If BLKFRAME is 0, all frames are scrubbed at once. The default is scrubbing only one frame at time (BLKFRAME = 1).

65.9   Interrupts

Interrupts are generated to indicate task finished (when the OPDONE bit is asserted) and internal errors in the GRSCRUB (when the SCRERR bit is asserted). Additionally, when the SCRUND bit is asserted, an interrupt can be generated.

Interrupts are disabled by default. The IRQDEN, IRQEEN and IRQSDEN bits of the Configuration Mode Register (CONFIG) should be high to allow interrupts for OPDONE, SCRERR, and SCRUND, respectively. All interrupts are connected to the interrupt controller to inform the processor of the events. The interrupts are pulse signals, being asserted for one clock cycle.

The usual procedure is that an interrupt routine handles the interrupt bits in the Status Register (STATUS). When it is finished, it clears the status bits by writing one, and the GRSCRUB can be enabled again.

65.10   GRSCRUB error codes

Table 1045 describes the GRSCRUB internal error codes. When an internal error occurs, the GRSCRUB set the ERRID bit of the Status Register (STATUS) with the error code, set the SCRERR to high, and launches an interrupt (if interrupts are enabled).

For all errors, except for UNCORRECTABLE_BIT_ERROR, the GRSCRUB safely stops the current operation, finishes the synchronization with the FPGA, waits for the end of the last memory access, and returns to the idle state. The SCRERR bit must be cleared before enabling the GRSCRUB again and starting a new operation. The UNCORRECTABLE_BIT_ERROR means that the GRSCRUB failed to correct an FPGA frame during readback operation. Then, this error is reported, and the GRSCRUB continues the scrubbing operation.

The DMA errors are related to the Golden memory and are most likely to occur due to invalid memory accesses. For the other errors, it is recommended to properly reset and reprogram the FPGA.

*Table 1045.*GRSCRUB internal error codes

Error	Code	Description
NO_ERROR	00000	GRSCRUB without errors. The GRSCRUB is working correctly. The SCRERR signal remains low, and no interrupt is launched.

GRIP

+46 31 7758650 | frontgrade.com/gaisler

*Table 1045.*GRSCRUB internal error codes

Error	Code	Description
PROGRAM_ERROR	00001	Error programming the FPGA configuration bitstream. This error is triggered when the INIT_B signal from the slave SelectMap interface pulses to low during the programming phase, which means error to configure the FPGA. Possible causes: - Frame length and number of frames wrongly set in the register; - Wrong configuration bitstream data stored in the Golden memory; - Wrong addresses set in the registers; - Wrong TPROG.
UNCORRECTABLE_BIT_ERROR	00010	Uncorrectable error(s) in the configuration memory during readback. After correcting a faulty frame, the replaced frame still presents an error. That might occur if the GRSCRUB failed to correct the frame or a new error affected the same frame in the time between correction and verification. Moreover, some upsets require two sequential scrubbing cycles to be corrected. The SRAM-based FPGAs present two types of configuration memory errors: a single point error is defined when an upset affects a function logic bit, and a burst of errors is defined when a single upset directly affects the state of multiple bits. The burst of errors may occur due to upsets in configuration bits responsible for controlling the status of other bits in the FPGA. When a control bit is flipped, all other bits under its control are also affected and may only return to the correct state after the original control bit is corrected. In the worst-case scenario, it is required two scrubbing cycles to recover all bits and return the configuration memory to a consistent state. The first scrubbing cycle will report UNCORRECTABLE_BIT_ERROR, and the second cycle will correct all remaining bits. This is the only internal error that does not lead the GRSCRUB to return to the idle state. The readback scrubbing continues the execution. In the UE_FRMID bitfield of the Error Frame Id Code Register (ERRFRMID) is informed the frame id where the last uncorrectable error occurred. The register is overwritten at each uncorrectable error.
DMA_MEM_READ_ERROR	00011	DMA error reading the Golden memory. Possible cause: - Illegal access.
DMA_MEM_WRITE_ERROR	00100	DMA error writing the Golden memory. Possible causes: - Illegal access. - PROM memory.
READBACK_ERROR	00101	Error during readback operation. This error is triggered when the INIT_B signal from the slave SelectMap interface pulses to low during the readback phase, which means error to read the FPGA frames. In the Frame Id Code Register (FRAMEID) is informed the id of the last frame scrubbed. Possible causes: - Frame length and number of frames wrongly set in the register; - Wrong addresses set in the registers; - The FPGA is not programmed; - Frames addresses are not stored in the Golden memory.

*Table 1045.*GRSCRUB internal error codes

Error	Code	Description
FRAME_MAPPING_ERROR	00110	Error during mapping operation.
		This error is triggered when the INIT_B signal from the slave SelectMap interface pulses to low during the mapping phase, which means error to read the frame content or the address.
		In the Frame Id Code Register (FRAMEID) is informed the id of the last frame mapped.
		Possible causes:
		- Frame length and number of frames wrongly set in the register;
		- Wrong addresses set in the registers.
WRITE_FRAME_ERROR	00111	Error to write an FPGA frame.
		Error due to correcting frame during readback; or error during blind scrubbing.
		In the Frame Id Code Register (FRAMEID) is informed the id of the last written frame.
		Possible causes:
		- Frame length and number of frames wrongly set in the register;
		- Wrong configuration bitstream data stored in the Golden memory;
		- Wrong addresses set in the registers;
		- The FPGA is not programmed;
		- Frames addresses are not stored in the Golden memory.
CI_INTEGRITY_ERROR	01000	Error during verification of the configuration interface
		The configuration interface is not responsive or its integrity is compromised.
		Possible causes:
		- The FPGA configuration interface is not correctly set. For instance, the bitstream does not configure the SelectMap as specified.
		- The FPGA configuration interface was affected by soft-errors.
		It is recommended to power cycle the FPGA.

65.11 Enabling and disabling the GRSCRUB

Before enabling the GRSCRUB, all the registers must be configured according the specific operation mode set. The GRSCRUB is enabled when the EN bit of the Configuration Mode Register (CONFIG) goes to high. The EN bit must stay high while the GRSCRUB is executing the operation. At the end of the execution, the GRSCRUB sets the OPDONE bit to high, sets the EN bit to low, and returns to the idle state.

After enabling the GRSCRUB, the registers should not be written. Otherwise, that can provoke a malfunction in the operation sequence. In addition, if the GRSCRUB is disabled (i.e., by setting the EN bit to low) during execution, the operation will not be finished. In that case, the GRSCRUB stops the current operation, finishes the synchronization with the FPGA, waits for the end of the last memory access, and returns to the idle state. The EN bit should only be enabled again after the GRSCRUB has returned to idle state.

The OPDONE and SCRERR bits should always be cleared before enabling the GRSCRUB and starting a new operation.

65.12 Bus master interface

65.12.1 Protocol support

The GRSCRUB features a generic bus master interface to increase its flexibility. Additionally, Frontgrade Gaisler provides wrappers for both AMBA AHB 2.0 and AXI4.

65.12.2 Bus access

The access width for both writing and reading is a 32-bit word. By default, the GRSCRUB uses a wrapper for AMBA AHB 2.0 features a bridge to convert the generic bus master into an AHB bus master interface.

The wrapper for AXI4 features a bridge to convert the generic bus master into an AXI4 bus master interface. For further information regarding the accesses, contact Frontgrade Gaisler.

65.13 Registers

The GRSCRUB is programmed through registers mapped into APB address space, which are shown in table 1046. Only 32-bit single-accesses to the registers are supported.

Table 1046. GRSCRUB registers

APB address offset	Register description
0x00	Status register (STATUS)
0x04	Configuration mode register (CONFIG)
0x08	FPGA device identifier register (IDCODE)
0x0C	Delay register (DELAY)
0x10	Frame configuration register (FCR)
0x14	Low FPGA frame address register (LFAR)
0x18	Low golden bitstream address register (LGBAR)
0x1C	High golden bitstream address register (HGBAR)
0x20	Low golden start frame address register (LGSFAR)
0x24	Low golden mask address register (LMASKAR)
0x28	Low golden frame mapping address register (LFMAPAR)
0x2C	Low golden CRC address register (LCRCAR)
0x30	Low golden readback data address register (LGRBKAR)
0x34	Number of errors detected register (ECNT)
0x38	FPGA setup register (SETUP)
0x3C	Capability register (CAP)
0x40	Frame id code register (FRAMEID)
0x44	Error frame id code register (ERRFRMID)

others = reserved
For more details, see the operational modes section.

3	CORM	Correction mode: 0 = detection and correction (default); 1 = only detection
2	SCRM	Scrubbing operational mode: 0 = blind (default); 1 = readback Blind scrubbing is set by default.
1	SCRUN	Scrubbing run: 0 = one time (default); 1 = periodic In the periodic execution is considered the delay between runs, and the OPDONE only goes to high if the GRSCRUB is disabled during the delay period (when the HOLD bit is high). The SCRUND bit goes high after each scrubbing execution in periodic run. One time scrubbing is set by default.
0	EN	GRSCRUB enable - starts operation mode: 0 = disable; 1 = enable After enabling the GRSCRUB, EN bit must be preserved high until the end of the operation (when OPDONE bit goes to high). Otherwise, the GRSCRUB is disabled, and the operation is not finished. See section 65.11 for more details.

FFCEN and CRCEN data check selection only works if enabled in the GRSCRUB generics. See Capability Register (CAP).

65.13.3 FPGA Device Identifier Register (IDCODE)

Table 1049. 0x08 - IDCODE - FPGA device identifier register

31	0
IDCODE	
0	
rw	

31: 0   IDCODE   FPGA device identifier code

The 32-bit FPGA identification code is defined in the FPGA specification and represents the specific device id based on the IEEE Std 1149.1 (JTAG).

65.13.4 Delay Register (DELAY)

Table 1050. 0x0C - DELAY - Delay register

31	0
DELAY	
0	
rw	

31: 0   DELAY   Delay, in number of ticks, between full blind or readback scrubbing cycles. The delay is set only for periodic scrubbing runs, and it is applied after all configured frames being scrubbed. Therefore, after the last scrubbed frame, the GRSCRUB waits the number of ticks set in the DELAY register, then returns to the first frame configured, and restarts the scrubbing operation. No delay is set by default.
A tick is counted for each rising edge of the tick_in input signal of the GRSCRUB. The period in which the GRSCRUB stays in hold depends on the tick_in frequency directly.

During the delay period while the GRSCRUB is waiting, the HOLD bit of the Status Register (STATUS) is set to high. When the delay is over, the HOLD bit is set to low.

If the EN bit of the Configuration Mode Register (CONFIG) is disabled while the GRSCRUB is waiting during the delay period, the GRSCRUB stops the delay, sets the OPDONE bit, and returns to idle state.

65.13.14 Number of Errors Detected Register (ECNT)

*Table 1060.*0x34 - ECNT - Number of errors detected register

31	16	15	0
UECNT		RECNT	
0		0	
rw		rw	

31: 16	UECNT	Number of uncorrectable errors. UECNT is the number of frames that still presenting an error after correction, which means that the GRSCRUB was not able to correct the previous error or a new error occurred in the same frame in the time between correction and verification. Only active in readback scrubbing mode and when correction is enabled (CORM=0).
15: 0	RECNT	Number of errors detected. Only enable in readback scrubbing mode. If the error correction is enabled (CORM=0), this counter represents the number of frames detected with error. Since the frame is corrected when the first error is detected, just one error is counted in the frame. If only detection is enabled (CORM=1) with FFC, this counter represents the total of error bits detected in the configuration memory. However, only one error is counter per frame for CRC data check.

The register is only cleared at the system reset, and the error counters accumulate over scrubbing runs. The user should clear the register to initiate a new count.

65.13.15 FPGA Setup Register (SETUP)

*Table 1061.*0x38 - SETUP - FPGA setup register

31	30	29	22	21	20	19	12	11	4	3	0
RESVD	CICHECK	BLKFRAME		BITSWPEN	CISEL	TPROG		ROWBND		RESVD	
0	1	1		1	0	150		2		0	
r	rw	rw		rw	r	rw		rw		r	

31	RESVD	RESERVED
30	CICHECK	It enables the verification of the configuration interface integrity before each scrubbing run. 0 = Disabled; 1 = Enabled.
29: 22	BLKFRAME	Maximum number of frames to be scrubbed at time (i.e., reading sequentially during readback, or writing sequentially during blind scrubbing). If BLKFRAME > 0, the frames are scrubbed by blocks, and a maximum of *BLKFRAME* frames is scrubbed each time. Thus, the number of frames defined in the FCNT bitfield of the Frame Configuration Register (FCR) is split into the *BLKFRAME* size. This feature is used to have more control of the FPGA configuration interface, and to avoid catastrophic results when the interface is affected by soft-errors. If BLKFRAME = 0, all frames set in the FCR are scrubbed sequentially at once. Default value = 1 (only one frame is scrubbed at time).
21	BITSWPEN	FPGA bit swapping enable: 0 = disable; 1 = enable. Enabled by default
20	CISEL	Configuration interface selected (read only): 0 = SelectMap; 1 = Not used.
19: 12	TPROG	Number of clock cycles to wait with PROGRAM_B signal asserted for FPGA programming (PROGRAM_B pulse width). Check the target FPGA Data Sheet for the TPROGRAM pulse width. One microsecond is safe for most Xilinx FPGAs. TPROG >= 1 us / smapclki_period Default value = 150 (wait 150 clock cycles).
11: 4	ROWBND	Row boundary alignment: number of FPGA frames in the rows boundaries. Default value = 2 (two frames in the rows boundaries). It must be zero if there is no row boundaries in the FPGA.
3: 0	RESVD	RESERVED

65.13.16 Capability Register (CAP)

Table 1062. 0x3C - CAP - Capability register

31 RESVD 23	22 DATACK 20	19 SMBUS 18	17 CINT 16	15 FAMILY 4	3 RESVD 0
0	0	0	0	0	0
r	r	r	r	r	r

31: 23	RESVD	RESERVED
22: 20	DATACK	Supported data checks (read only):
		bit#20 = FFC;
		bit#21 = CRC;
		bit#22 = Not used.
19: 18	SMBUS	SelectMap bus wide in bits (read only):
		00 = 8-bit wide;
		01 = 16-bit wide;
		10 = 32-bit wide;
		11 = Not used.
17: 16	CINT	Supported configuration interfaces (read only):
		bit#16 = SelectMap
		others = Not used.
15: 4	FAMILY	Supported FPGA families (read only):
		bit#4 = Xilinx Virtex-5;
		bit#5 = Xilinx Kintex UltraScale;
		others = Not used.
3: 0	RESVD	RESERVED

The register value reflects the configuration set in the generics.

65.13.17 Frame Id Code Register (FRAMEID)

Table 1063. 0x40 - FRAMEID - Frame id code register

31 RESVD 16	15 FRMID 0
0	0
r	rw

31: 16	RESVD	RESERVED
15: 0	FRMID	Frame id of the current scrubbed frame.
		It is updated at every new scrubbed frame.
		Frame id is also updated during mapping phase.

The frame id represents the identification of the frame, which is defined from 0 to FCNT-1. Thus, FRMID 0 means the first frame, whereas the FRMID FCNT-1 means the last one.

In case of READBACK_ERROR, FRAME_MAPPING_ERROR, or WRITE_FRAME_ERROR errors, the FRMID represents the last frame processed by the GRSCRUB. In these cases, the reported FRMID might not be precise. The GRSCRUB has an internal FIFO to receive the amount of data from the FPGA, and the current frame id takes into account only the processed data.

The register is only cleared at the system reset.

65.13.18Error Frame Id Code Register (ERRFRMID)

*Table 1064.*0x44 - ERRFRMID - Error frame id code register

31	16	15	0
UE_FRMID		ERR_FRMID	
0		0	
rw		rw	

31: 16	UE_FRMID	Frame id of the last frame with uncorrectable error.
		It is only updated if a new uncorrectable error occur.
		This bitfield is only valid if the UECNT from the Number of Errors Detected Register (ECNT) is higher then 0.
15: 0	ERR_FRMID	Frame id of the last frame detected with error during readback.
		It is only updated if a new frame with error is detected.

The frame id represents the identification of the frame, which is defined from 0 to FCNT-1. Thus, FRMID 0 means the first frame, whereas the FRMID FCNT-1 means the last one.

The register is only cleared at the system reset.

65.14   Vendor and device identifiers

The core has vendor identifier 0x01 (Frontgrade Gaisler) and device identifier 0x0C1. For a description of vendor and device identifiers see GRLIB IP Library User's Manual.

65.15   Implementation

65.15.1 Reset

The GRSCRUB changes its reset behavior depending on settings in the GRLIB configuration package (see GRLIB User's Manual). GRSCRUB features an asynchronous reset for the registers if the parameter grlib_async_reset_enable is set. Otherwise, the GRSCRUB implements a synchronous reset. The reset is applied to all registers in GRSCRUB.

The asynchronous reset of the SelectMap IO registers is controlled by ioreg_arst in the GRSCRUB configuration options (section 65.17). If the ioreg_arst is defined as 0, the asynchronous reset is disabled. To enable the asynchronous reset of the SelectMap IO registers, both ioreg_arst and grlib_async_reset_enable must be set. If the asynchronous reset of the SelectMap IO registers is enabled, logic might be inferred between the IOs and flip-flops during implementation in an FPGA tool.

Two reset signals are defined in the GRSCRUB, one for each clock domain. The RSTN is the reset signal considering the CLK clock domain, which is the system clock. The SMAPRSTN is used to reset the internal SelectMap control module and IO registers, and it is related to the SMAPCLKI clock domain.

The reset values of the GRSCRUB signals are defined in section 65.19.

65.15.2 Endianness

The core support both big-endian and little-endian systems. The core does not change endianness behaviour depending on the settings in the GRLIB configuration package (see GRLIB User's Manual). The endianness is configured through the AMBA AHB bus, which is used to set the generic bus master interface to access the external memory.

65.15.3 SelectMap timing parameters

All pins of the slave SelectMap interface on the FPGA are synchronous with the input clock (CCLK), except PROGRAM_B that is an asynchronous reset. Refer to the Xilinx FPGA Configuration Guide to a description of the SelectMap pins and their functionalities.

The CCLK frequency (Fcclk) is not necessarily the same as the system (microcontroller or FPGA design) clock (Fsys_clk). System and SelectMap interface can run in different frequency domains, following the relation Fsys_clk >= Fcclk. See the FPGA Data Sheet to details about the maximum slave SelectMap CCLK frequency. Also, the timing limitation due to the interface connection between the SelectMap and GRSCRUB should be considered to define Fcclk.

Figures 160 and 161 present the timing characteristics of the SelectMap pins related to CCLK for data loading and reading, and table 1065 describes the timing parameters. For timing information of the FPGA SelectMap interface, refer to the FPGA Data Sheet.

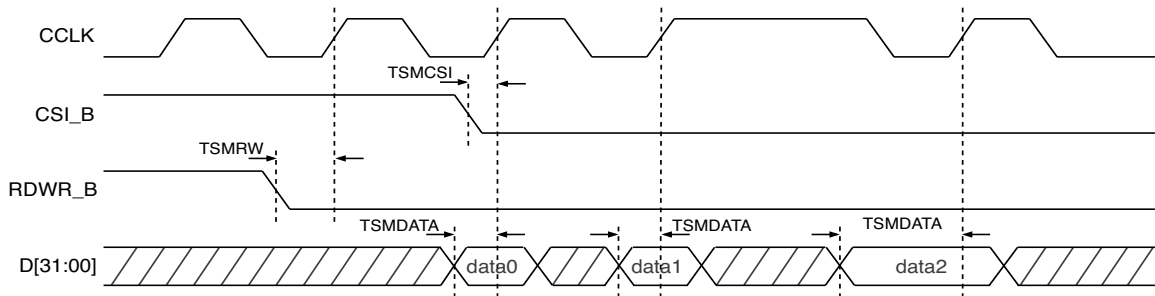
Note: The timing parameters are technology dependent.


Figure 160. SelectMap timing characteristics for data loading to FPGA
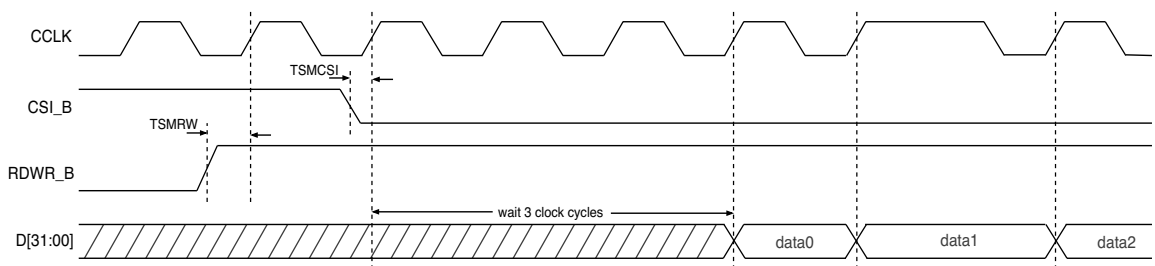

Figure 161. SelectMap timing characteristics for data reading from FPGA

Table 1065. SelectMap timing parameters

Name	Parameter	Reference edge	Min	Max	Unit
TSMDATA	D[31:00] setup/hold	Rising clock edge	TBD	-	ns
TSMCSI	CSI_B setup/hold	Rising clock edge	TBD	-	ns
TSMRW	RDWR_B setup/hold	Rising clock edge	TBD		ns
TSMCO	D[31:00] clock to out in readback	Rising clock edge	-	TBD	ns

65.15.4 SelectMap clock enable

The SelectMap clock CCLK is controlled (enabled/disabled) by the SMAPO.clk_en signal from the GRSCRUB. The GRSCRUB main clock (CLK signal) is the system clock. The system must also provide the SelectMap clock to the GRSCRUB (SMAPCLKI signal) and the CCLK to the FPGA. In addition, the system design must contain a dedicated register buffer to allow enabling/disabling the CCLK based on SMAPO.clk_en.

65.15.5 Scrubbing run period

The period to execute one scrubbing run, which means the time to scrub all frames configured in the registers once, depends on the characteristics of the system presented below. Blind and readback scrubbing modes are affected by the following factors:

GRIP

+46 31 7758650 | frontgrade.com/gaisler

- Number of frames to be scrubbed, which is defined in the FCNT bitfield of Frame Configuration Register (FCR);

- Number of words in each frame, which is defined in the FLEN bitfield of Frame Configuration Register (FCR);

- The data bus width (8, 16, or 32-bit wide) for the SelectMap interface defined in the smap_buswide of the GRSCRUB configuration options (section 65.17).

- The target Xilinx FPGA family;

- The GRSCRUB clock frequencies: CLK and SMAPCLKI signals;

- The required time to access the Golden memory.

Additional factors affect the readback scrubbing, as following:
